SUPERHEATING COMPOUND EXPRESS LOCOMOTIVE, BAVARIAN STATE RAILWAYS.

CHARLES R. KING.

Progress in locomotive design in Bavaria is so rapid and continuous that the builders there take the lead of all Europe, including even Austria—France now being the last of the stragglers. The latest development in the four-cylinder balanced compound locomotive is illustrated in the subjoined photographic reproduction. It has been specially designed for high speeds, to average about 95 miles per hour between stops, on the Muenchen to Nürnberg section of the Bavarian State Railways. The engine, of which several others are in construction, has not yet undergone its official trials, but the chief engineers of the celebrated J. A. Maffei Locomotive Works have shown in many previous examples that their locomotives can always exceed the stipulated output for power and speed. To attain this object a very large boiler with a great heating surface and flues with superheating pipes in the upper rows has been provided; and to carry this generator without exceeding the maximum limits of load in the driving wheels (35,200 pounds) an extra pair of wheels had to be introduced under the footplate, so making a four-connected engine with two bearing trucks which, with certain modifications, would permit the locomotive to run with either the smokebox or the firebox in front. The engine proper is a four-cylinder balanced compound of that Central European type which is rapidly displacing all other engine arrangements. All main rods drive the leading connected axle which is of the oblique-arm type with hollow crank seats. One valve gear actuates two out of the four valves. The valves are of the type described in the issue of May, 1906, page 437. The valves by which the live steam is introduced into the low-pressure cylinders, when starting, are, here, quite different. At each end of the low-pressure valve chests there are, at right angles to the diameter of the chambers, two cylindri-

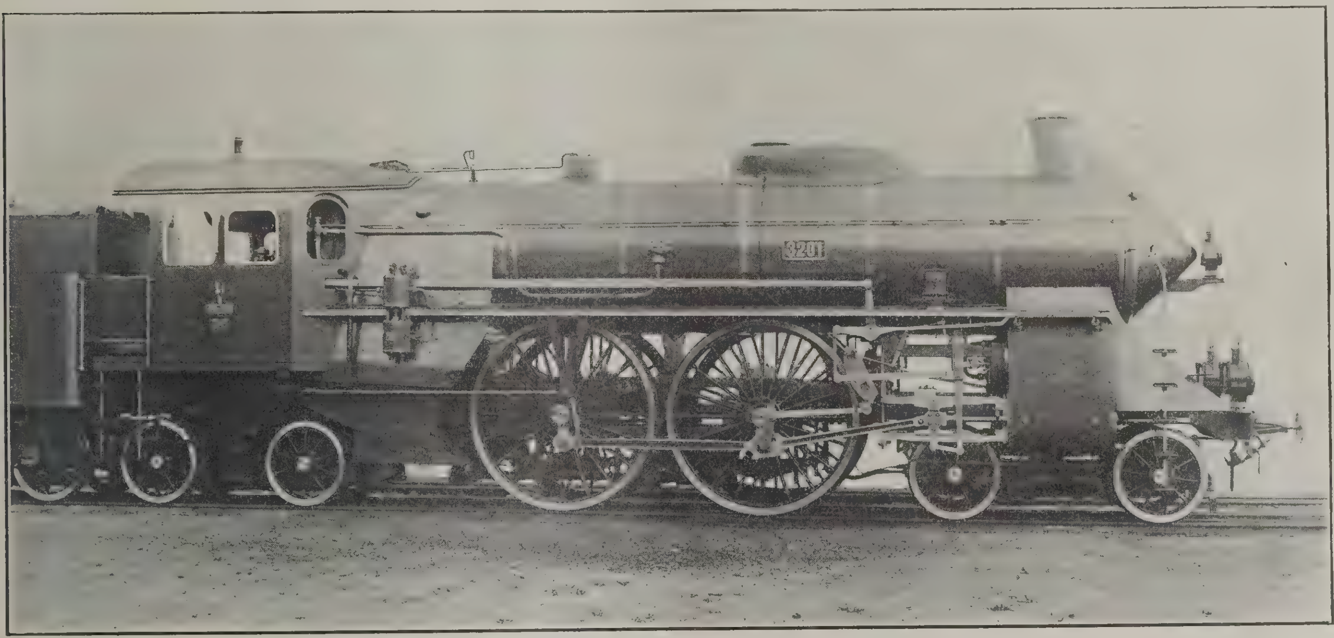

Fig. 1. Superheating Compound Express Locomotive, 4—4—4 Type, Bavarian State Railways.

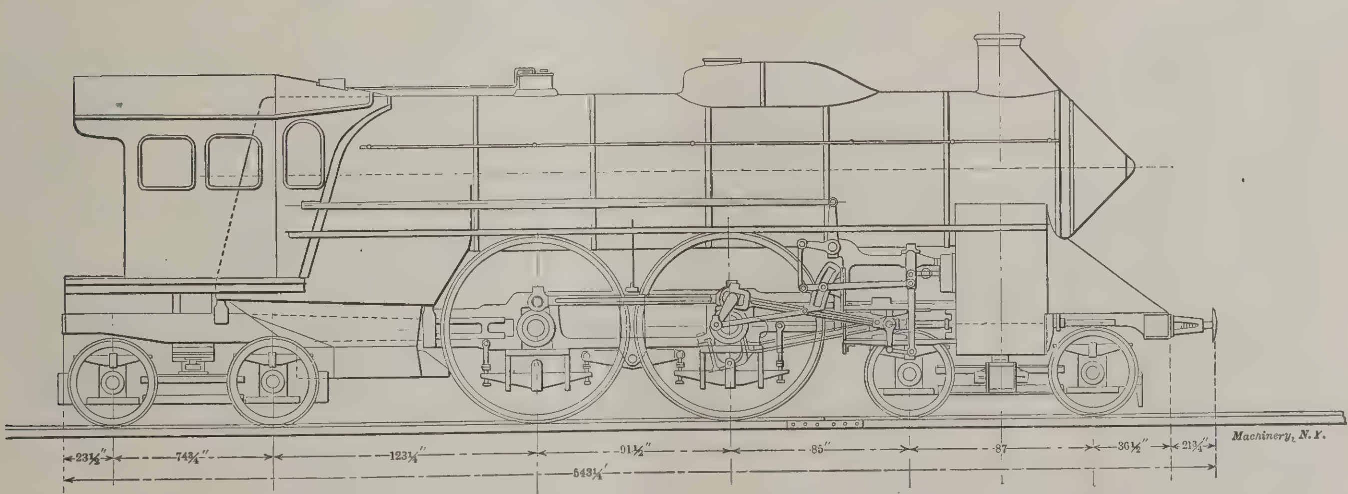

Fig. 2. Diagram showing Wheel Center Distances, Etc., 4—4—4 Superheating Compound Express Locomotive.

cal valves which when raised give entrance to the live steam whenever the valve travel exceeds a cut-off of 70 per cent of piston stroke. This movement is derived from a long rod connecting the valve stems with the reach-rod shaft and is therefore automatic in operation and independent of the locomotive engineer. There is also an attachment on the expansion link for working the oil pump, also visible in the engraving. The frames are of the bar type. All projections in the locomotive are cased in with plates shaped so as to cut or divide the air when the machine is traveling at high velocities. The cylinders, smokebox, chimney, the dome and sand box (ranged together) and the entire cab front, have been curved up or shaped with this object, the saving of power thereby effected meaning increased speed. The proportions of the main rods and side rods have been calculated for the maximum of tractive effort, which is 5 tons, while the total adhesive weight is 32 tons with engine loaded, a coefficient of 1:6.4. The engine is not designed for great tractive power, but to make a speed of 94 miles per hour with a trainload of 180 metric tons. The metric ton is about 10 per cent more than the U. S. ton and the traction effort is calculated according to Continental formula which gives very much lower values than the American formulas. The weights of the engine in the following list are the correct ones; those published by some Continental journals relate, presumably, to the estimated weights in the original project for the new engines.

SUPERHEATING COMPOUND BALANCED LOCOMOTIVE.

Type C 2/6 Bavarian State Railways.

H. P. cylinders	16⅛ inches.
L. P. cylinders	24 inches.
Stroke	25¼ inches.
Boiler pressure	205.8 pounds.
Driving wheels diameter	7 feet 2⅝ inches.
Tractive effort (effective)	10,400 pounds.
Diameter of front and back truck wheels	3 feet 3½ inches.
Boiler (inside diameter)	5 feet 7 inches.
No. of tubes	208
Tubes, diameter (inside)	0 feet 2 inches.
No. of flues enveloping superheat pipes	18
Flues, diameter (inside)	0 feet 5 inches.
Total free length of tubes	16 feet 1 inch.
Heating surfaces (inside measurement):	
Small tubes	2,130.5 square feet.
Large flues	409 square feet.
Firebox	177.5 square feet.
Total	2717.0 square feet.
Grate area	50.0 square feet.
Weights:	
Engine, empty	167,200 pounds.
Engine, fully loaded	184,800 pounds.
Weight distribution:	
Drivers	70,400
Front truck	62,700
Rear truck	51,700
Total	184,800
Gage	4 feet 8½ inches.
Minimum radius of curves	600 feet.
Rigid wheel base of engine	7 feet 7⅜ inches.
Total wheel base of engine	38 feet 4½ inches.
Total length of engine	45 feet 2 inches.
Greatest breadth of engine	10 feet 2 inches.
Greatest height of engine	15 feet.
Height of boiler center	9 feet 10 inches.

Tender.

Rigid wheel base	5 feet 8⅞ inches.
Total wheel base	17 feet 4⅝ inches.
Total length of tender	24 feet 2 inches.
Greatest width	10 feet
Wheels, diameter	3 feet 3½ inches.
Water capacity	5,730 gallons.
Coal capacity	8.8 U. S. tons.
Weight, empty	41,800 pounds.
Weight, loaded	114,400 pounds.
Total wheel base of engine and tender,	60 feet 7½ inches.
Total length of engine or tender	69 feet 4 inches.
Weights:	
Engine and tender empty	104 U. S. tons.
Engine and tender fully loaded	149 U. S. tons.

* * *

It is claimed that the Baldwin Locomotive Works would, by itself, support a city of 100,000 inhabitants.

NEW NORTHERN PACIFIC RAILWAY LOCOMOTIVES.

The American Locomotive Company has recently completed twenty Pacific type locomotives for the Northern Pacific Railroad. They are identical in design with the Class Q—1 engines built by this company for that road, except in the design of the boilers.

The boilers of both classes are radial-stayed, extended wagon-top type with the same size firebox and the same outside diameter at the front and back and the same length over all. Both boilers have 2-inch tubes spaced 2⅞ inches centers, at the front end in the boiler shown, and 2 29-32 inches centers at the front end in the boiler of Class Q—1. The boilers of the engines illustrated, however, are designed with a combustion chamber. The combustion chamber is 3 feet long and the tubes are 16 feet 9 inches long. In the Class Q—1 engines without combustion chambers the tubes are 18 feet 6 inches long; or, in other words, the combustion chamber cuts off 1 foot 9 inches in the length of the tubes. In addition to being shorter, the number of tubes in this boiler is also less than in the boiler of the Class Q—1, there being 306 tubes in the one as against 347 in the other.

The tube heating surface and total heating surface are, accordingly, much less in these later engines than in those without combustion chamber, while the firebox heating surface is much greater. The comparative heating surfaces are as follows:

	With Combustion Chamber.	Without Combustion Chamber.
Tube heating surface	2,737 sq. ft.	3,339 sq. ft.
Firebox heating surface	233 sq. ft.	182 sq. ft.
Arch-tube heating surface	9 sq. ft.	7 sq. ft.
Total heating surface	2,979 sq. ft.	3,528 sq. ft.

From this comparison it will be seen that the tube-heating surface has been reduced 602 square feet, or 18 per cent, and the total heating surface 550 square feet, or about 15.6 per cent, while the firebox heating surface has been increased 51 square feet, or about 28 per cent.

It will be interesting, also, to compare the ratios of tube heating surface and total heating surface to the volume of one cylinder in the two classes of engines, both having the same size cylinders:

Tube heating surface divided by volume of one cylinder: With combustion chamber = 478; without combustion chamber = 583.

Total heating surface divided by volume of one cylinder: With combustion chamber = 520; without combustion chamber = 616.

These ratios are lower in the engine with the combustion chamber and higher in the engine without than are generally found in the Pacific type locomotive, the average ratio of tube-heating surface to cylinder volume in this type being about 525, and of total heating surface to cylinder volume 550.

Whereas it might at first appear that this great reduction in heating surface was rather a venturesome experiment, particularly in this type of engine in which large boiler capacity is so essential, this design of boiler is no new experiment on the Northern Pacific. Mr. D. Van Alstyne, mechanical superintendent of the Northern Pacific, has made a very careful study of locomotive boiler design, and, as a result, in 1904 one of twenty tandem compounds built by this company for the Northern Pacific at that time was fitted with a combustion chamber and its record, under the severest tests in service on divisions where the water conditions were the worst, has been most satisfactory. The application of a boiler with combustion chamber to the Pacific type, therefore, is only a further development along the same lines.

The combustion chamber in the Pacific type is supported by expansion stays, radial stays, staybolts and bottom braces. The water space at the bottom is 7½ inches, and 7 inches at the side, giving good water circulation with no danger of the combustion chamber being overheated. In these engines the front tube sheet was moved 15 inches further ahead than it is in the Pacific engines without combustion chambers. This was done to avoid reducing the length of the flues by the full

length of the combustion chamber as the number of tubes had also been reduced.

Though the tube heating surface is greatly reduced by the combustion chamber, the firebox heating surface is greatly increased, and, in the case of the Mikado type (described below) this increase in the firebox heating surface seems to more than offset the loss of the tube heating surface and to give an engine with just as good steaming qualities.

The advantages and disadvantages of the boiler with combustion chamber have already been thoroughly discussed in various papers on the subject and the merits of this design ably presented so that it is useless for us to elaborate on them in this description.

These engines, however, afford a good opportunity for judging of the comparative merits of the two designs of boiler and the record of these engines with combustion chambers as compared with those of the same design running on the same road and under the same conditions, but with boilers without combustion chambers will be of great interest to railroad officials and the technical world.

What will add further interest to the Pacific type locomotives is that the twentieth engine of this lot is equipped with the latest design of the Schenectady superheater which is attracting a great deal of attention among railroad men in this country at the present time.

The combustion chamber and superheater are among the most recent developments in locomotive design and the Northern Pacific officials, and the whole railroad world as well, will have an opportunity such as they do not often enjoy to watch the performance of the three different exponents of recent locomotive construction—the simple engine with long flues, the simple engine with short flues and combustion chamber, and the simple engine with combustion chamber and superheater, all three engines being identical in design except for the special features of combustion chamber and superheater.

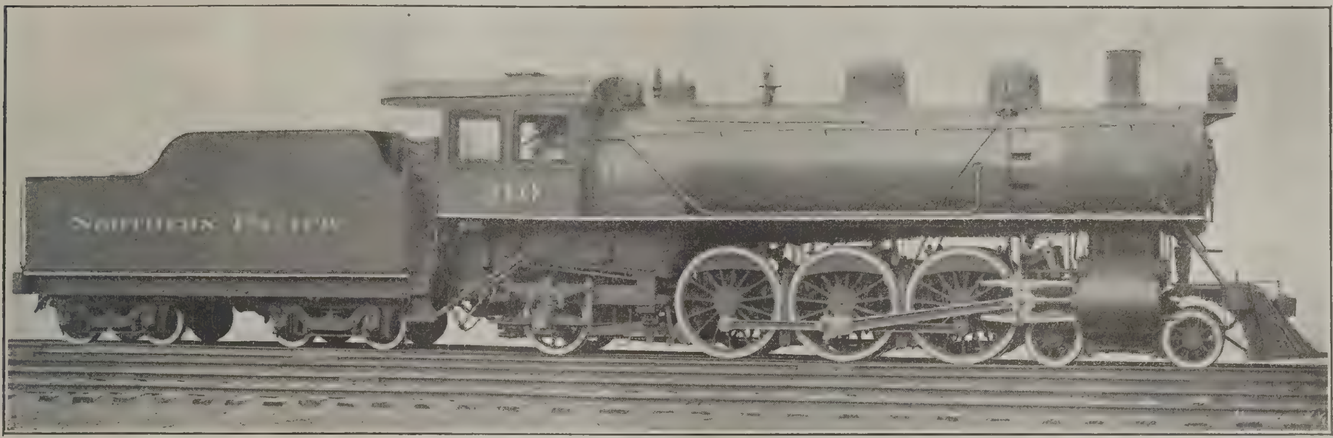

Fig 1. Northern Pacific Railroad Pacific or 4—6—2 Type Locomotive. Cylinders 22x26.

Fig. 2. Northern Pacific Railroad Mikado or 2—8—2 Type Locomotive. Cylinders 24x30.

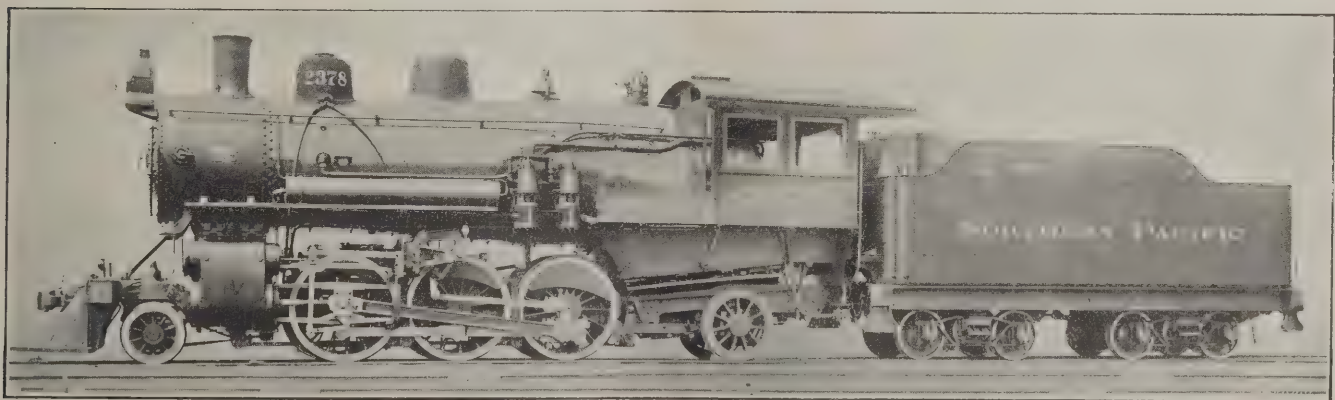

Fig. 3. Northern Pacific Railroad Prairie or 2—6—2 Type Locomotive. Cylinders 21x28.

Mikado Type.

The same course as in the case of the Pacific type has been followed in the thirty Mikado type engines, a halftone of which is here given. These engines are identical in design with the Class W simple engines built by this company for the Northern Pacific in 1904 and 1905, except for the special feature of the combustion chamber. In the Mikado type, however (as was not the case in the Pacific type locomotives), the boiler with combustion chamber contains the same number of tubes as that without combustion chamber, while the

length of the tubes has been shortened by the full length of the combustion chamber. This reduces the total heating surface by 14.2 per cent. The comparative heating surfaces of the two classes of the Mikado type are as follows:

	Without Combustion Chamber.	Without Combustion Chamber.
Tube heating surface........	3,192 sq. ft.	3,798 sq. ft.
Firebox heating surface......	234 sq. ft.	200 sq. ft.
Arch-tube heating surface.....	11 sq. ft.	9 sq. ft.
Total heating surface.....	3,437 sq. ft.	4,007 sq. ft.

The combustion chamber has already been tried with great success in this design—the tandem compound Mikado type engines, to which we have already referred as having had this type of boiler, being of the same design as Class W except with compound cylinders. Though, as we have before stated, we do not care to discuss at length the merits of the combustion chamber, it will not be out of place right here to give a few extracts from Mr. Van Alstyne's paper, "Some of the Essentials in Locomotive Boiler Design," presented before the North-West Railway Club. He says: "What seems to me an especially good feature of the combustion chamber, if it is practical, is the fact that it very materially increases the heating surface of the firebox"; again: "The beauty of the combustion chamber is in getting the flues away from the fire," and later, "The great convenience and economy that is derived from this combustion chamber" (referring to the Mikado engine which we have already mentioned) "is due to the fact that the flues can be worked without disturbing the brick arch.

A report of the condition of the boiler of this engine after an inspection made by Mr. Van Alstyne immediately after the engine had been cooled off seems to justify his claims as to the advantages of the combustion chamber.

The brick arch was in place, the flues showed very little indication of leaking or having had any work done on them, the combustion chamber showed no signs of overheating and was free from ashes, and the bottom flues were open and not choked.

Only one engine failure from leaky tubes was reported against this engine during its years service on the Yellowstone Division, and this, where the water conditions are notoriously bad and Mr. Van Alstyne says that he believes that they were doing only about 25 per cent as much flue expanding on her as on the other engines on the same division.

This engine has since been sent to the Montana Division.

Prairie Type.

The Prairie type illustrated and described here is the first of this type of locomotive to be built for the Northern Pacific. This type has proven so satisfactory on other roads that they ordered twenty of this company, which were completed last May.

These engines are also equipped with boilers having combustion chambers. The combustion chamber of this type is 4 inches shorter than the other two types described, and the tubes are some 3 feet shorter. These differences, however, are due solely to differences in the types of the engines.

One of each lot of both the Mikado and Prairie types is equipped with Walschaert valve gear, and the halftones of these types show the engines having this valve gear.

How much faith the Northern Pacific has in the locomotive boiler with combustion chamber, and what a satisfactory type of boiler they consider it, is shown by the number of engines—70 in all—that they have ordered with boilers of this design.

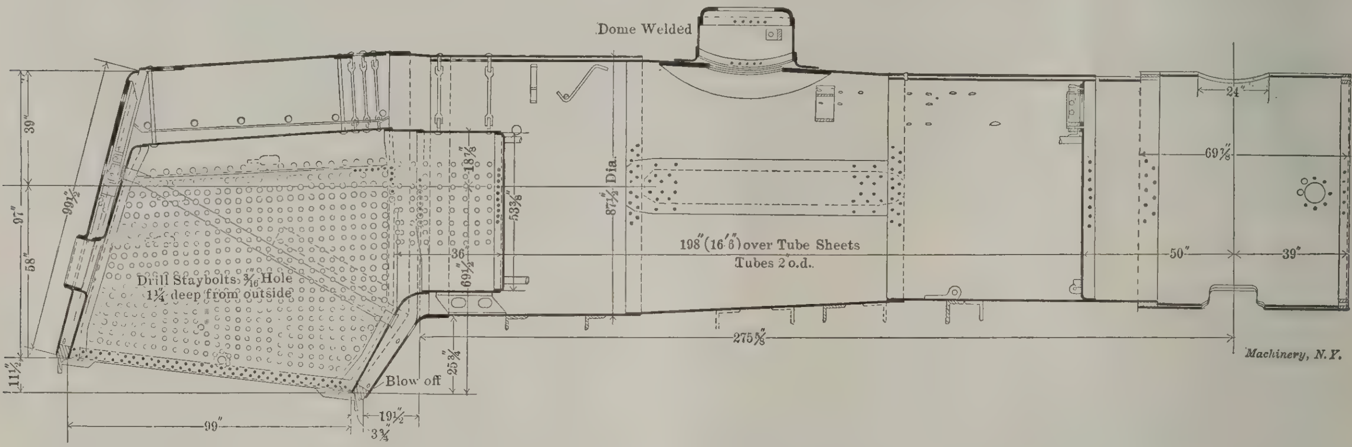

Fig. 4. Longitudinal Section of Boiler for Mikado or 2—8—2 Type Northern Pacific Railroad Locomotive.

NOMENCLATURE OF WALSCHAERTS VALVE GEAR.

CHARLES R. KING.

The terms used to denominate the component parts of the Walschaerts valve gear have, in the United States, since its introduction here, undergone changes which, though they may be handy in shop routine, are not very exact, while they might eventually prove to be untranslatable in technical dictionaries.

In the Walschaerts valve gear the mechanism is so simple that, after a lapse of fifty years, there is no necessity now to complicate matters by the introduction of wonderful terms for describing the parts, as "kicker," etc. We have, first, a simple crank describing a true circle: 1, "valve crank," and a rod connecting it with the radius link; 2, "valve-crank rod." This arrangement gives only a valve motion corresponding with the driving crank periods. Hence, "lead" is given by means of a lever; 3, "lead lever," which pivots on the radius rod (below the valve stem for outside admission and above the valve stem for inside admission with ordinary piston valves). The tip end of the lead lever is connected, as the case may require, with the valve stem or otherwise with the radius rod, and its lowest extremity is connected, as closely

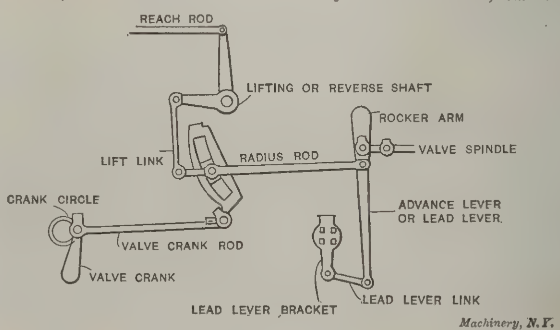

Diagram Illustrating Parts of the Walschaerts Valve Gear.

as can be done, to the piston crosshead. This involves a link: 4, "lead-lever link" and a bracket: 5, "lead-lever bracket" for attachment to the crosshead. This latter should be made as short as possible consistent with the length required for the lead lever. In the ideal arrangement the center of the crosshead should be the center also of the rear pin of the lead-lever link in order to increase the rigidity of the lead-lever drive. All the foregoing terms are perfectly accurate in their descriptiveness, and, if translated literally, have the same significance in all Latin languages, and without ambiguity. The terms originally employed for the Walschaerts valve gear were French, for, although this name is Flemish, French is the scientific language of the Belgians. The object of these remarks is, it will be evident, to favor a classic and universal

engineering language, in place of shop jargon which, only too often, is the basis for our industrial vocabulary, and to show that the Walschaerts valve gear parts, at least, are not in need of being christened anew after half a century of regular use.

SIDE PLAY OF TRUCKS ON CURVES, AND METHOD OF CALCULATION.

In the July issue of Railway Machinery the writer noted an article on "Side Play of Trucks on Curves, and Method of Calculation." The article in question gives formulas and indicates the derivation of the same, together with a table showing side play required for rigid wheel bases up to 15 feet for various curve radii.

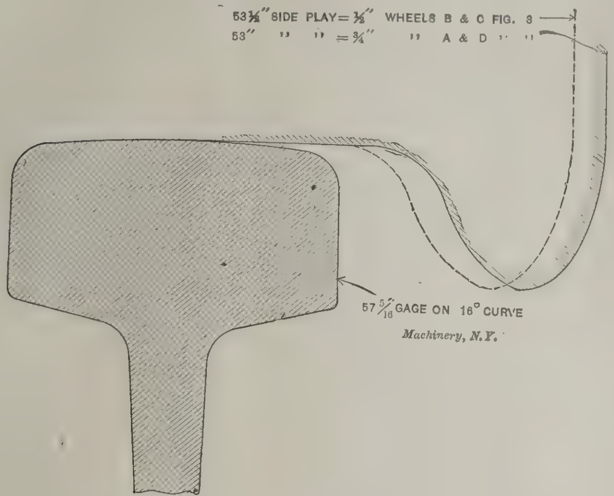

Fig. 1. Showing Side Play of Wheel Flange and Rail Head.

The writer quotes from the findings of Mr. A. M. Wellington, to the effect that "a rigid truck, in passing a curve, whether alone, or coupled with another, takes the position with the rear axle, approximately radial, as indicated in Fig. 2"; said Fig. 2 showing the front wheel pressing against the outer rail, and the rear wheel pressing against the inner rail. The figures given for side play for the different curves and wheel bases, are evidently based upon the assumption that the rear axle of any rigid wheel base is literally radial to the curve with the result that requirements for side play are obtained which are impossible to provide for in most cases.

From an extended experience in locomotive design, with both railroads and locomotive building plants, the writer of the present article takes exception to the article in July issue, not in a spirit of carping criticism, but rather to bring out more fully for the benefit of readers of Railway Machinery, a subject about which but little has so far apparently been published.

That the rear wheel of a rigid truck will press against the inside rail of a curve, and the forward wheel will press against the outer rail, is a correct statement, but that the rear axle assumes a position approximately radial to the curve, is a statement which actual practice does not seem to warrant.

As an example of actual practice on the P. & R. Ry, Fig. 5 shows the wheel-base of a four-wheel switching engine. The wheel-base W is 69 inches, and the engine passes around a curve of 60-foot radius. The tires on this engine are set 53¼ inches between flanges and a box play of $\frac{1}{16}$ inch on each side is allowed. The gage of track on this curve is 57¼ inches, or ¾ inch wider than standard; but if the rear axle is assumed to be radial to curve, as shown in Fig. 4, a side play of 3.3 inches would have to be provided for, which is the measure of P, or versed sine of an arc of 60 feet radius and 69 inches taken as half the chord of arc.

However, the actual side play of this engine on 57¼ inch gage is only a total of 1 5-16 inch made up as follows: (See Fig. 5.) Front wheel $A = 19\text{-}32$ inch play between the flange of wheel and rail head, plus 1-16 inch box play, all in direction of the outer rail. Rear wheel $B = 19\text{-}32$ inch play between the flange and rail head, plus 1-16 inch box play, all in direction of the inside rail. The total possible side movement being $(19\text{-}32 + 1\text{-}16) \times 2 = 1\ 5\text{-}16$ inch.

Placing the engine on a curve of 60-foot radius with the center of the curve falling on the center of the wheel-base, as in Fig. 5, the actual side play, or versed sine of arc $P = 1.2$

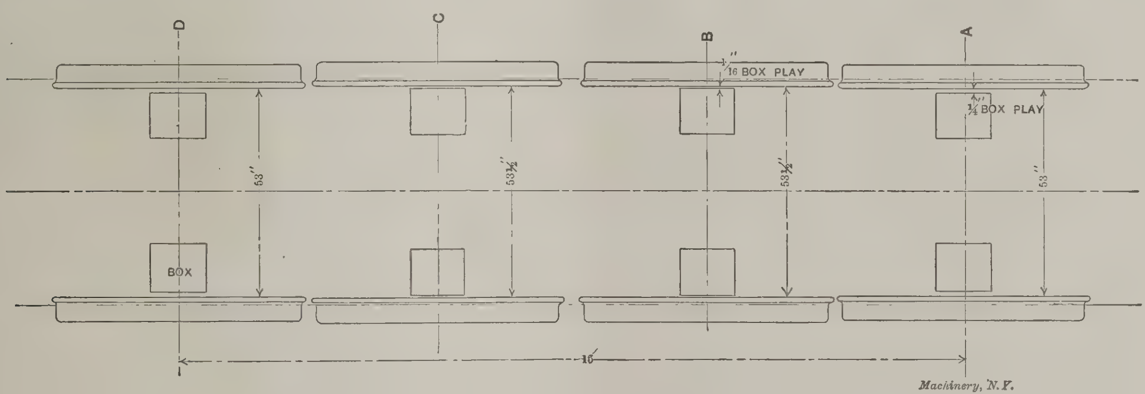

Fig. 2. Box Arrangement of P. & R. Railway Eight-driver Locomotive.

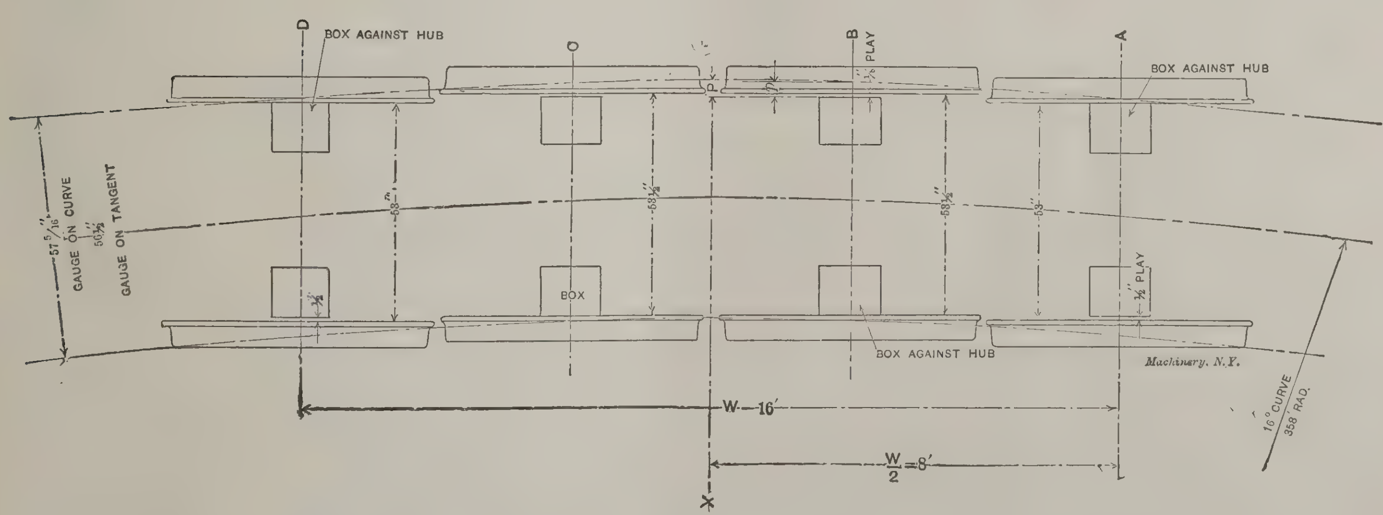

Fig. 3. Showing Position Assumed on Curve by P. & R. Railway Eight-driver Locomotive.

inches, thus showing that the engine will just pass the curve without any side play to spare.

This latter method is followed, I believe, by all builders in determining the curve an engine will pass.

On many of the standard railroads of the country the gage is widened ¼ inch for each 5 degrees of curvature with a maximum increase in gage width of ¾ inch for any curves on main line.

A considerable number of roads have consolidation locomotives (2-8-0) with 16-foot rigid wheel-bases, the wheel and box arrangement being as shown in Fig. 2. These engines

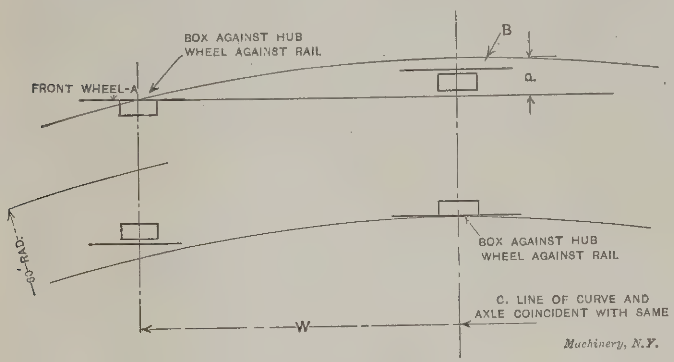

Fig. 4. Position Assumed by Four-wheel Locomotive if Rear Drivers remained Radial to the Curve.

pass 16-degree curves in daily service, without showing any track distress, or in other words, without moving the track out of its original alignment.

On the basis of ¼ inch increase in gage of track for each 5 degrees of curvature, the gage on a 16-degree curve would be $56\frac{1}{2} + (16/5 \times \frac{1}{4}) = 57.3$ inches, say $57\frac{5}{16}$ inches. Taking into account the side play of the wheel flange to rail head, as indicated in Fig. 1, and the side play between the axle boxes and wheel hubs, the total movement of the engine or side play would be only 1⅜ inch, as follows: (See Fig. 2.) For wheels *A* and *D*, the side play between the wheel flange and rail head = ¾ inch. The box play for the same wheels = ¼ inch; hence the total = ¾ + ¼ = 1 inch. For wheels *B* and *C* the play between wheel flange and rail head = ½ inch, and the box play = 1/16 inch, or a total of 9/16 inch.

The total engine side play on $57\frac{5}{16}$ inch gage track would, therefore, be 1 inch $+ \frac{9}{16} = 1\frac{9}{16}$ inch.

Taking the assumption that the forward wheel hugs the outer rail, and the rear wheel hugs the inside rail, and further that the rear axle is *radial* to the curve, as stated and

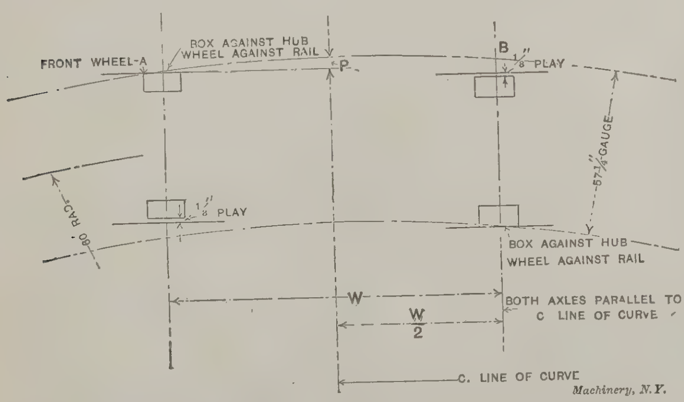

Fig. 5. Box Arrangement of P. & R. Railway Four-wheel Switching Locomotive.

assumed in the article in the July issue, the versed sine of the arc of a 16-degree curve, or 358 feet radius, with a 16-foot rigid wheel-base would be $R = \frac{W^2}{2P}$ or $358 = \frac{(16)^2}{2P}$; hence $2P = 256/358$ or $2P = 0.71$ foot. $P = 0.355$ foot, or 4.26 inches, which side play would have to be provided in wheel arrangement of engine and widening of gage.

That this amount of side play is not needed and that it cannot be found on any railroad operating 2-8-0 engines over 16-degree curves is a fact which is evidenced from sketches Figs. 2 and 3 herewith, Fig. 3 showing the method used to find whether engine will pass a curve or not. The following analysis of Fig. 3 will aid in illustrating what really takes place when a 2-8-0 engine is passing a curve:

When on a curve the flange of the front wheel *A* presses against the outer rail, and the hub of the driving wheel is brought against the box on the same side of the engine as the outer rail, tending to force the engine around into conformity with the center line of curve. The flanges of wheels *B* and *C* bear against the inside rail, and the hub of the wheel is brought against the box on the same side as the inside rail. Wheel *D*, or rear wheel, is forced against outer rail by the swing of the engine frame toward the outer rail, this action being caused by the curvature of the track forcing the wheel hubs *B* and *C* against the driving boxes, and thus forcing the wheels and engine bodily toward the outer rail, an amount equal to the total side play of wheels *B* and *C*.

Taking the engine shown by Figs. 2 and 3, and letting the center line of curve fall midway between wheels *B* and *C* and further (see Fig. 6), letting *P* equal height of arc for the total wheel-base, and *p* equal height of arc for wheel-base from *B* and *C* we have the following:

Radius = 358 feet (16 degrees).
Chord of arcs = 16 feet, and 5½ feet.
Then, letting R = radius
C and c = ½ chord of arcs.
P = height of arc for total wheel-base.
p = height of arc for wheel-base B to C.

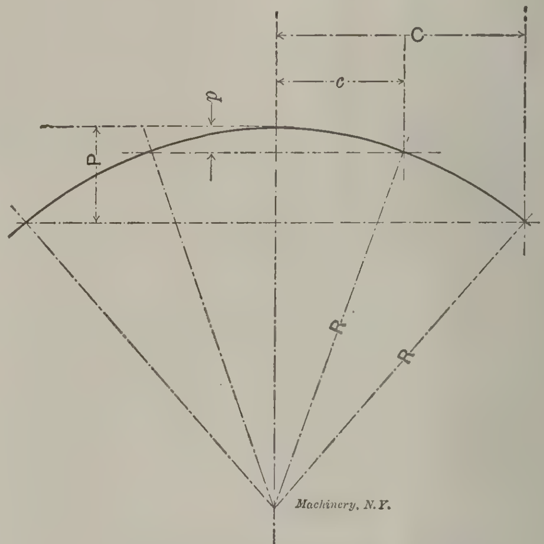

Fig. 6. Diagram Illustrating Geometrical Calculation.

We have by geometry the equation

$$R^2 - C^2 = (R - P)^2.$$

Or taking C as 8 feet (½ chord of arc for total wheel-base) we have

$$(358)^2 - (8)^2 = (358 - P)^2 \text{ or}$$
$$128164 - 64 = (358 - P)^2$$
$$\sqrt{128100} = 358 - P$$
$$P = 0.1 \text{ foot, or } 1.2 \text{ inches.}$$

Again taking same equation, and using for c the half-chord of arc for wheels *B* and *C*, or 2¾ feet, we have $(358)^2 - (2.75)^2 = (358 - P)^2$ or $128164 - 7.56 = (358 - P)^2$.

Hence $P = 0.02$ foot $= 0.24$ inch.

The actual height of arc which must be considered, therefore, is the measurement taken from points of contact of wheels *B* and *C*, and *A* and *D* and is equal to $P - p = 1.2$ inch $- 0.24$ inch $= 0.96$ inch, the latter figure being the actual side play required for passage of engine on curve.

Since the actual possible side play of the engine is $1\frac{9}{16}$ inch, as found previously, it may be seen that engine will readily pass the curve.

With regard to industrial plants, mines, etc., where extremely sharp curves are often necessary, it is the practice to widen the gage of track as much as the limit of car, or engine construction will permit, but this increase in gage will in no case ever approach the limits laid down in the article as it appeared in the July issue.

On narrow gage roads, the gage is usually widened 1/16 inch for each 2½ degrees of curvature, so that on a curve of

say 40 degrees, the gage would be widened $40/2\frac{1}{2} \times 1/16 =$ 1 inch.

As another illustration of the correctness of statements given herein, a 6-wheel switching engine with a 10-foot rigid wheel-base (middle tire without flange) will pass a 40-degree curve, or 143-foot radius, with a total side play consisting of ¼ inch box play, plus the play due to widening of gage, which is not more than 1¾ inch total at most, on standard gage roads, making a total of 2 inches side play. Gage is here taken as 1 inch wider than on tangent; and tires 53¼ inches apart, inside face to inside face of tire.

Consulting the table in the article as given in the July issue, 4 inches side play is required for a 150-foot radius curve, and 10-foot wheel-base.

For curves of from 35 feet to 50 feet radius, which cannot be stated in degrees, the gage must be widened accordingly, but it will be found that a rigid wheel-base in such cases is limited to from 4 feet to 5 feet 3 inches. In no case, however, is a side play of as much as 4 inches provided for.

In the calculations given herein, no regard has been paid to the fact that depth of flange below the rail has the effect of lengthening the wheel-base, since, with flanges 1⅛ inches deep, and small wheels, as usually found on engines with long, rigid wheel-bases, the addition to actual wheel-base from this cause is trifling, and need not be considered, particularly since an extra amount of side play over and above the actual requirements of the case, is always provided, to minimize wear and tear on flanges and rails. Besides this, it is open to question as to whether an allowance need actually be made for extension of wheel-base due to flange depth, since an inspection of standard flange in Fig. 1 will show that it is eased off, so as to clear the rail, and that the point of the flange cannot come into contact with the rail, unless the flange is worn in such manner as to make its wearing face a line at right angles to the wheel tread face. When sufficient wear has taken place to produce this result, it would then have the effect of lengthening the wheel base, as described in the article in the July issue, but since, at the same time, it would also have the effect of increasing the side play of the engine, due to wear, it may be seen that no allowance need be made for extra side play, on account of depth of flange on standard equipment.

Attention should be called to one fact, however, which is that on very heavy modern engines with maximum wheel loads, the rear wheels of a 2-8-0 engine, or even of 4-6-0 type, will have a tendency to ride against the inside rail, due to the fact that the friction between the wheel tread and rail face will be greater than the effect of the side swing of engine toward the outer rail, produced by the middle wheels pressing against the inside rail and bearing against the driving boxes at same time.

In such cases greater side play must be provided to pass a given curve than for a light engine of the same wheel-base in order to avoid distortion of the track or danger of derailment. The exact amount of extra allowance in such cases can best be determined by actual trial of the engines over the curves in question.

Finally, it should be remembered that no fixed rule or table can be given, providing for the exact amount of side play required for all styles of rigid wheel-bases, but each case must be considered individually, to determine the increased width of gage and side play between wheel hubs and boxes for passage over any given curve.

CHAS. A. BINGAMAN,
Asst. Chief Draftsman P. & R. Ry. Co.

Reading, Pa.

[For the benefit of readers unfamiliar with the method followed by civil engineers to express curvature in railway location it may be well to explain that the "degree of a curve" is determined by the central angle subtended by a chord of 100 feet. Hence the radius may be found by the formula $R = \frac{50}{\sin \frac{1}{2}\alpha}$, in which $\alpha =$ the degree of the curve, but for curves up to 10 degrees and even greater the common practice is simply to divide 5,730 (the radius of a 1-degree curve) by the number of degrees; this gives the radius with sufficient accuracy for most purposes.—EDITOR.]

BROWN SANITARY CLOSET SHIELD.

This sanitary appliance for a water closet is an entirely new construction, patented by Alex E. Brown, and manufactured by the Brown Hoisting Machinery Company, Cleveland, Ohio. Its construction has already attracted considerable notice and it is believed that a description will be of considerable interest to our readers in view of the peculiar difficulties attending the making of satisfactory shop arrangements of this sort.

It consists of a series of stalls, or compartments, as shown in Fig. 1, separated by concrete steel partitions (of the "ferroinclave" construction), attached to light angle supports, and covered by one concrete steel hood (also of the "ferroinclave"

Fig. 1. Row of Brown Sanitary Closet Shields.

construction), which runs to an apex at about an equi-distance from either end partition. At this apex is a ventilating pipe. With the exception of the two ends, the partitions do not extend up to the hood, thus giving sufficient air circulation. As will be seen in the cross section, Fig. 2, the hood extends out over the doors.

The doors are steel plates rolled in the form of semi-cylindrical shells. They are hung from the top on light angles, which extend across the partitions, and are so adjusted that in rotating on rollers they describe the path of a cylindrical shell about its vertical axis.

Some of the advantages of this appliance are:

1. A saving of space, practically three feet being saved by this door, over the ordinary side-hinged style.

2. Sanitary, the excellent hood or ventilating system taking away all odors, and the concrete walls allowing easy cleaning with a hose.

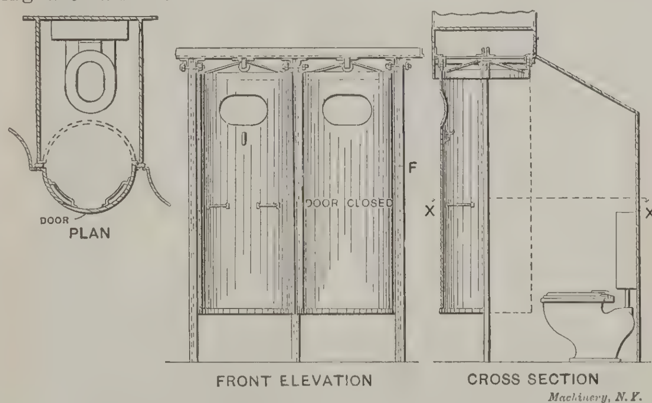

Fig. 2. Showing Construction of Brown Sanitary Closet Shield.

3. The interior is at all times closed to the outside view, thereby making it practicable to erect the same at points in a building that would be too exposed for the types of closet in ordinary use.

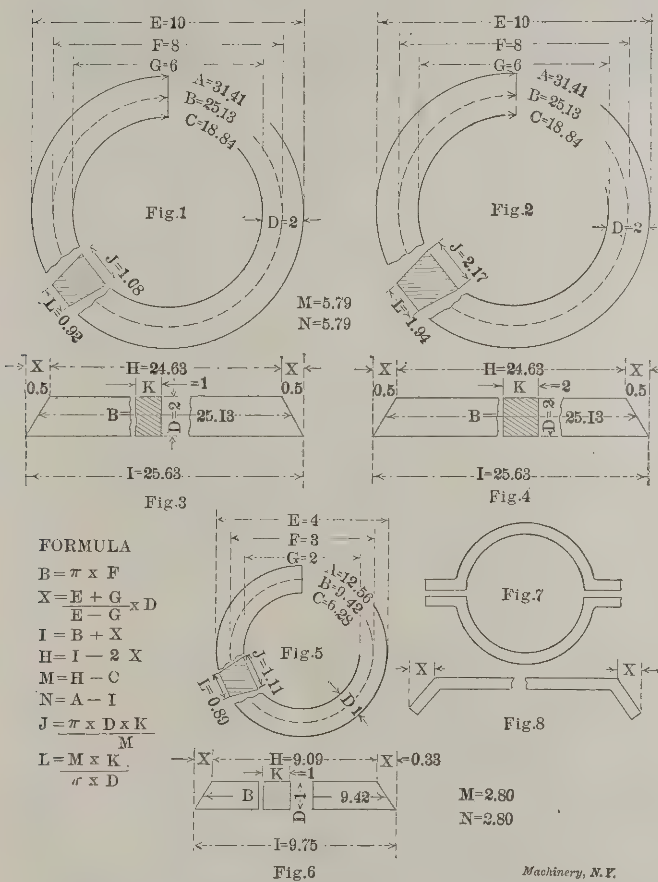
4. It can readily be seen by the door whether a closet is or is not occupied. A closet cannot be occupied without the door being out. This fact, together with the lack of light and the partitions, is the means of a great saving in time, in that it eliminates the usual causes for the men loafing.

FORMULAS FOR CONSTRUCTING RINGS MADE FROM SQUARE OR FLAT IRON BENT EDGEWISE.*

S. Uren.

In 1904 I was chairman of the committee on reducing railroad forgings to an exact science. At that time I was not prepared to give mathematical formulas for constructing rings made from square iron or flat iron bent edgewise; however, I have since produced formulas that will give the exact dimensions of a ring bent from square or flat iron, in its original shape before bending; also the exact dimensions of the ring after being bent.

Many different methods are employed by practical smiths to determine the proper length to cut the straight bar. The carriage smith will either roll the wheel over a long bar of iron or will use a small wheel and roll the outside of the wheel and the inside of the tire, making the allowance for the openings between the felloes, which method is correct. In a locomotive or manufacturing shop conditions are differ-



Formulas for Constructing Rings made from Square or Flat Iron.

ent as the smith works from drawings and in many cases has no means of measuring the circumference the ring is to fit over. Oftentimes the ring has to be finished on all sides in the machine shops and the proper allowance has to be made for finishing. Many smiths have different methods of calculating the straight length of the bar. Many use the old rule: "as 7 is to 22 so is the diameter to the circumference." Others, simply: "3 times the diameter plus 1/7 the diameter." Then again others use the simple method: "3 times the inside diameter plus 3 widths of the iron." The writer's method is to use the formula: "3.1416 multiplied by the diameter of the ring at the neutral axis of the bar."

The above methods are practically correct, measuring from the center of the metal but do not give the short and long side of the straight bar, as shown in Figs. 3, 4 and 6. I, as well as others, have searched mathematical and mechanical books for formulas that would give the different functions of a ring that has been bent from a heated bar of iron of given dimensions. I could not find anything bearing on the subject, consequently Mr. Harkins, my assistant foreman, who is an expert mathematician, and myself undertook to solve the problems and we have fully demonstrated and proved by experiments in actual practice of the formula.

Fig. 1 represents a ring bent from a bar of iron 2 inches wide by 1 inch thick. The usual custom of the practical blacksmith is to cut the bar to the length given by the formula: "3.1416 multiplied by the diameter of the ring," and to guess at the angle to which the end of the bar is cut. Oftentimes after the ring is bent, the inside will meet, leaving an opening on the outside, and if cut in excess, a similar condition occurs on the inside. In nearly all cases the smith will cut his iron long and trim to the proper shape after being bent. The formula of Fig. 2 is simple, and will give the angle; the end of the bar should be cut before bending. The difference between the long and short diameter, divided by the sum of the long and short diameter, multiplied by the width of the iron will give the required angle. The result in all cases should be added to the length produced by the above formula and the angle should be cut as shown at *X*, Fig. 2. If the ring is not to be welded, the ends will come together, forming a perfect joint.

It will be observed from Figs. 1 and 2 that the metal changes its shape in bending. The inside circumference of Fig. 1 is 18.84 inches. The length as shown in Fig. 2 to produce the circumference is 24.63 inches, or 5.79 inches in excess of the inside circumference of the finished ring. The reverse conditions exist in the outside of the ring. The actual length of the straight bar is 5.79 inches shorter than the actual outside circumference of the ring; consequently the surplus metal has to be accounted for on the inside of the ring and to be diminished on the outside. The extra metal increases the thickness of the inside of the ring, as shown in section at *J*, and decreases the thickness, as shown at *L*.

Oftentimes the smith has to make rings in sections, as shown at Fig. 4. The same formula will apply to produce the angle projections in the straight bar. The usual custom of the smith is to guess at the angle when forging the projections in the straight bar and set the ends properly after the section of ring is bent. The formulas are correct if the rings are bent at an even temperature and the metal has the same tensile and compression strength. Practically the metal has about equal tensile and compression strength at a bright red heat. When making rings from uneven shaped iron such as T-shapes or channel, the formula "3.1416 multiplied by the diameter" must be figured from the neutral axis of the bar.

Fig. 1 shows a 6-inch inside diameter ring produced from 1 × 2-inch bar; and Fig. 2 the same inside diameter ring produced from a 2-inch square bar. The figures obtained by using the formula correspond to the dimensions of similar rings produced in actual practice. Very few smiths realize that the length of the short side of the straight bar in a 6-inch ring 2 inches wide is 5.79 inches longer than the inside circumference of the ring and the long side as much shorter than the outside circumference. The formula to produce *J* is all that is required for whatever *J* exceeds *K* is the amount that *L* is less than *K*. The foregoing formula applies to diameters between 1 inch and 10 feet for large radii or railroad curves, the functions would be almost infinity.

* * *

The railway rate bill affecting all common carriers went into effect August 28. It gives the Interstate Commerce Commission authority to examine into all charges of unjust railroad rates and to fix the maximum rate in such cases. A failure to publish tariffs causes a carrier to be liable to a fine of from $1,000 to $20,000 in each case. No tariff may be changed without giving thirty days notice.

* Paper read by Mr. S. Uren (Southern Pacific Co.) before the International Railroad Master Blacksmiths' Association Convention, Chicago, Ill., August 21-23, 1906.

PLANING A SMALL MACHINE PART.

H. P. FAIRFIELD.

H. P. Fairfield.

The planer is in some respects one of the most interesting of machine tools. To quickly secure the pieces to be machined in such a manner as avoids springing them, and at the same time hold them fixed and firm against the thrust of the cutting tool, is seldom as simple a proposition as it might seem to be. The tool, while the cut is being made, tends to slide the work along the planer table in two directions for the horizontal plane, and beside this there is a tendency for the tool to tilt or tip the work. Any holding of the work must, therefore, provide against it moving, first, along the direction of the cut; second, across the planer table due to the pressure of the cut or feed, and third, to prevent any tilting. To furnish a method of fastening the work that provides for all these, and yet admits of quick handling, is that which in a manner differentiates one planer hand from an-

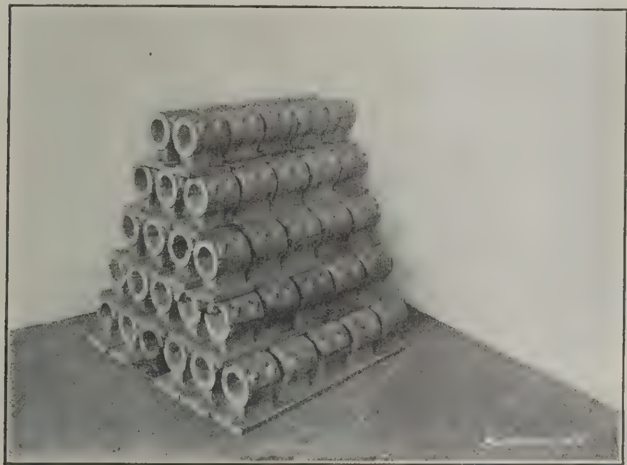


Fig. 1. A Pile of the Finished Parts.

other. Where the number of like pieces is large, it usually pays to design special jigs and fixtures with which to hold the work. This is especially true of small machine parts, and the fixtures are usually designed to hold a considerable number of pieces at one setting. Held in this way, setting the tool accurately for one piece sets it for the whole string of pieces, as it is termed. On the other hand, spoiling one piece

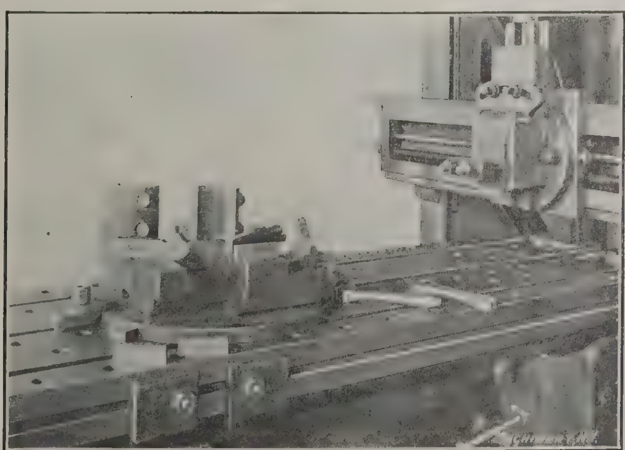

Fig. 2. Planer Chuck Used for Holding the Caps.

HOWARD P. FAIRFIELD was born at Patten, Me., in 1868. He served an apprenticeship with the S. A. Woods Machine Co., Boston, Mass., and has worked for the Boston & Albany Railroad, and the Goodyear Shoe Machine Co. Some years ago Mr. Fairfield left the commercial machine shop and became a teacher in the Case School of Applied Science, Cleveland, O., where he remained for eight years teaching wood-working, pattern-making, machine design, drawing, and machine construction. He left the Case School in 1899, and has since been connected in a similar capacity with the Worcester Polytechnic Institute, Worcester, Mass.

of the string usually spoils all. In so far as the cutting operations on the planer go, they are usually simple in their character, and should be easily mastered. As already hinted at, it is the ability of the workman as regards fastening, or holding his work, that counts.

In the half-tones herewith are shown the planer operations as performed upon a simple machine part—a cap box. No special methods for holding are shown, as all the fastenings used for holding this piece are those in common use for many other pieces, distinctly different in their outlines. Fig.

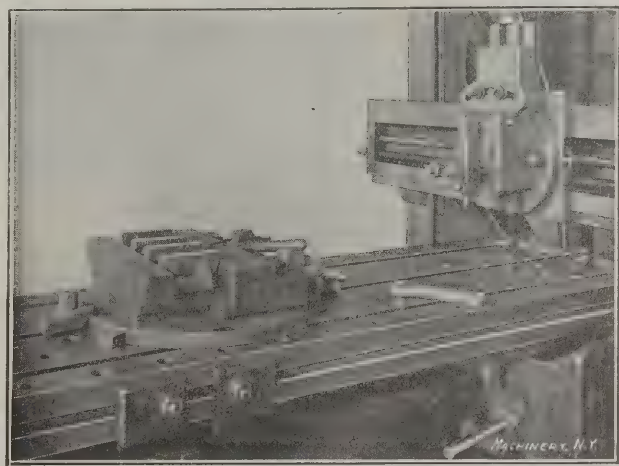

Fig. 3. Two Caps in Place in the Chuck.

1 shows a group of the pieces, planed, drilled, tapped, counterbored and fastened together with four filister head machine screws each, but only the planing operations are shown here.

An essential part of any planer outfit is a chuck for holding small pieces, and this is shown in Fig. 2. This figure shows also the tools used to rough cut and smooth plane the caps, seen standing at the top of the planer jaws. In Fig. 3 it will be noted that the chuck is held to prevent sliding along the length of the planer by two pins which fit holes in the table.

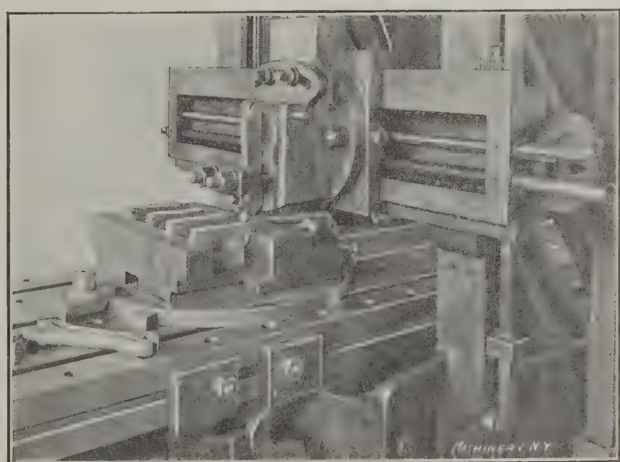

Fig. 4. The Tool in Position Ready for the Roughing Cut.

These are termed planer stops, and are used ahead of all work to prevent slipping due to the thrust of cutting. The work in this case is leveled by using short parallel pieces under the projecting ears on the cap. One jaw of the chuck is a fixed part of the base, while the other is made adjustable upon slides, and can be forced against the work by means of the screws shown at the right of the chuck base. If the pieces tend to elevate when the adjustable jaw is forced against them, light blows with a hammer will seat them again. Fig. 4 shows the tool in position, and the trips set ready to start the roughing cut, and Figs. 5 and 6 show the feed gear in place and the cut being made. The finishing tool used and its method of use is shown in Fig. 7. The tool is about one inch wide, and is fed a distance equal to two-thirds its width each stroke. In this case the feeding is by hand, the feed gear showing slipped out of mesh.

The base portion of the brackets lends itself very handily

to stringing, and Figs. 8 and 9 show the straps and bolts used to bind them to the planer table. In Figs. 10 and 11 the pieces are shown mounted in position, and strapped to the table. Fig. 12 shows tool set to take the roughing cut, and Fig. 13 the cut being taken. Note the stop against which the foremost piece butts to prevent slipping under the thrust of the cutting tools. The final cut is taken with the finishing tool, as in the case of the caps, and is shown in Fig. 14. Fig. 15 illustrates the finishing tool and its use, also the fact that it is *not* a scraping tool. In planing the reverse surfaces of the brackets, use is made of two back stops. Fig. 16 shows their form, and Fig. 17 their position on the planer table. The pieces are strung as shown in Fig. 18 butted against the pin stop. To hold them down the back stop is beveled back at its base (see Fig. 24), and the pieces are forced against it and down to the planer table by hook stops as shown in Figs. 19 and 20. The roughing tool is set as in Fig. 21, and does its work as shown in Fig. 22.

Use is again made of the finishing tool, as shown in Fig. 23. Fig. 24 is an end view to illustrate the surface as left by the finishing tool. Fig. 25 shows its use at close range and Fig. 26 the under surface of a bracket as it comes from this tool.

* * *

The 12-inch guns on board the *Dreadnaught* will be the most powerful ever carried by a warship. Altogether they will cost something like £113,200 ($550,152). The salient features of these guns are: Weight of gun, 58 tons; weight of shot, 850 pounds; weight of cordite charge, 325 pounds; shots leave muzzle at 2,900 feet per second; able to pierce at muzzle 51 inches of wrought iron. There are to be 10 of these, and each can fire two rounds a minute.—*Mechanical Engineer.*

[The muzzle striking energy, calculated by the formula $E = \frac{1}{2} Mv^2$, is over 110,000,000 foot-pounds, or enough to lift the whole battleship nearly three feet.—Editor.]

TRACING, LETTERING AND MOUNTING.—1.

I. G. BAYLEY.

Tracing.

I. G. Bayley.

At the commencement of a drawing-office career only a few tools may be purchased, adding others as they are needed. Be careful to select the best; it will pay in the end.

A straight pen or two—one for black and one for red ink—a spring-bow pen, bow pencil, and dividers, and a half set of instruments comprising six-inch compass with fixed needle-points and interchangeable pen, pencil, and lengthening bar, will suffice. T-squares, triangles, pencils, rubbers, erasers, and pens are usually provided by the office. Keep to your own instruments, and have a private mark on your triangles, scales and T-square for identification in case they become exchanged.

Small instruments should be put away each night, as in cleaning up the office they are easily lost. A drawer or cupboard with trays or boxes for the various tools is very necessary for the draftsman.

Have a large clean rag duster or brush to wipe the board and T-square occasionally, as the least particle of dust getting into the pen will clog the ink, causing you to make a poor line.

In case the eraser must be used (a thing to avoid as much as possible) rub a little French chalk or soapstone well into the part erased. Keep a little of this prepared chalk by you; it can be procured from any artists' material store.

A piece of rag, cheesecloth or chamois skin hung by a thumb-tack or drawing pin at your side comes in handy for wiping the pens.

A sand-paper pencil sharpener and an oil stone completes the list.

Inks.—Too much cannot be said about the inks used, as I believe to a certain extent a great many bad tracings can be laid to the bad quality of ink used in the various drawing offices visited by the author, in this country and abroad.

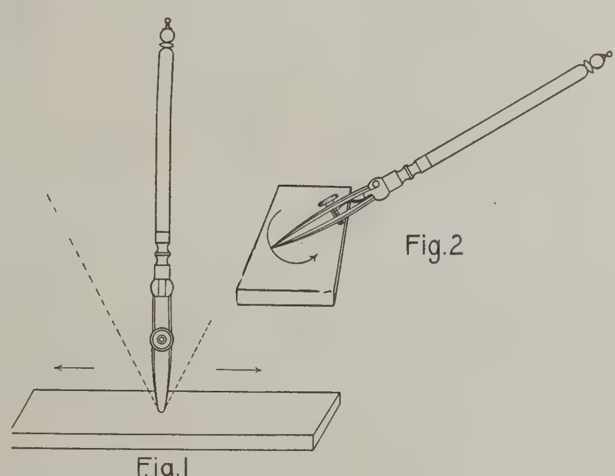
Good ink is indispensable, and no one should attempt to make a tracing until he has it. Some offices, to save (?) expense, resort to many ingenious ways of making ink by wholesale. A large bottle with a ground-glass stopper is provided. A quantity of broken ink (which can be purchased by the pound and much cheaper than buying by the stick or cake) is put into the bottle; a quart or so of ammonia is then poured over the ink. The bottle is then put in a warm place, shaken every now and then until the ink is dissolved, or partly so (the latter usually being the case) when it is supposed to be ready for use. This is the cheapest and worst way of making ink. Some drawing offices buy the ink ready mixed, put up in pint or quart bottles. For shop tracings, either of these methods may be resorted to. But for *neat* work it is almost impossible to get along with either; the only way is to mix the ink fresh each morning, washing out the pallet every day. When purchasing the ink sticks, the very best should be bought; it can be recognized by a pleasant odor which cannot be mistaken and is perceptible when grinding it in the saucer. The saucer, or pallet, should be spotlessly clean, and the water clear. Do not use too much water at first; more can be added as the ink is mixed. A little vinegar in the ink will keep away the flies. In many offices in warm climates they are a great nuisance; the writer has seen whole views completely eaten away by these pests in a very short time. Commence by rubbing a little Prussian blue in the saucer; this is not absolutely necessary, but it improves the ink somewhat and helps to thicken it quicker. Saucers made of slate with ground-glass covers are the best. The ink stick should be held firmly, but do not bear too hard upon it while grinding, or else when mixed the ink will be gritty. Grind until you cannot see the bottom of the saucer when blowing down upon the ink; this is a good test, and you can also see if the ink looks gritty. Try it on the edge of the tracing cloth or paper to see if it gives a clear black line. The cover should always be kept over the ink to keep it from evaporating and free from dust. In cold weather if the ink should thicken hold it before the fire or heater, when it will run easily and will not clog the pen.

Ordinary scarlet ink is used by some draftsmen for making red lines, although it is much better to use a mixed ink of crimson lake color, adding a little ox-gall to make it run. The prepared ox-gall in tiny jars can be procured from artists' material stores. In the absence of this a little soap rubbed into the color will answer the purpose. Bichromate of potash dissolved in the water before mixing the ink will help to keep away flies if you find they trouble you much.

It sometimes happens that boys are troubled with sweaty hands which mark the tracing as the work proceeds. This can be avoided by putting half a teaspoonful of ammonia in the water they wash their hands in.

Truing Up the Instruments.—As the pens are constantly used they will become blunt, which can be seen by holding them to a strong light and looking down upon the nibs. Every draftsman should be able to set his own instruments. There should be an oil-stone in every office for this purpose. Let it lie flat on the window sill or a table near to the light. Screw up the nibs tight, and holding the pen in an upright position between the finger and thumb, as shown in Fig. 1, move it backward and forward along the stone as indicated by the arrows, tilting it from side to side as shown by the dotted lines.

In this way a round and even surface is given to the nibs. They will be of the same length and true with each other. Now, holding the pen in a slanting position of about 30 degrees, rub the nibs upon the stone in a circular direction, as



Truing the Point of the Pen.

indicated in Fig. 2, rolling the pen as it were between the thumb and finger, turning it over and grinding both nibs alike. Hold the pen to the light occasionally to see if the nibs are level, and look down upon the points to see if the flat surfaces have been taken out. If sharpened correctly you will be able to see nothing, as when looking down upon the edge of a razor.

The thumbscrew must now be taken out and the inside edge of the pen be rubbed across the oil stone several times. Thoroughly clean the pen from any grit or oil and try it upon the edge of the tracing. If too sharp, it will have a tendency to run away from the T-square or straightedge, in which case it should be rubbed on the stone again, as in Fig. 1, though with care, as all pens should be fairly sharp.

The bow pen is trued up in the same way, with the exception that a thin slip of stone is passed between the nibs to take off any rough parts, as the nibs of the bow pen do not

I. G. Bayley was born in Ocker Hill, Tipton, Staffordshire, England, 1866. His education, outside of the common school, has been derived from home study and reading and courses with correspondence schools. He was apprenticed in the drawing rooms of the Old Park Iron Works, Wednesbury, Staffordshire, England. In addition to this company, he has worked for the King Bridge Co. and Globe Iron Works, Cleveland, Ohio, and Frank C. Roberts & Co., Philadelphia, Pa., in the positions of tracer, draftsman, checker, assistant head draftsman and designer. His specialty is mechanical drafting and designing.

hinge and some straight pens, too, for that matter, when they should also be treated in the same manner.

All instruments should have the best of care. When not in use for some time they should be kept clean and free from rust by wiping them on a piece of chamois leather greased with vaseline.

Tracing Paper.—Tracing paper is much used in architects' offices and occasionally by engineers for pencil sketching. When it is used for permanent work, the best quality should be had. But although it is possible to purchase paper capable of standing fairly rough usage, it is by no means as good as cloth.

A narrow strip of tracing cloth tacked along the lower edge protects it from being torn or soiled while leaning over the board. Either thumb tacks (drawing pins) or very small tacks may be used to hold down the paper; a small magnetized hammer can be used for the latter, picking the tacks up very quickly, so that which ever plan is adopted it takes about the same time.

In case the tracing will last for some time, or if there is any coloring to be done, the paper must be mounted on the board as described elsewhere.

Tracing Cloth.—For permanent work tracing cloth should by all means be used. Cloth is either glazed or unglazed, the foreign make being by far the best. With proper care a tracing may be taken up when complete, as clean as when cut from the roll. All shop or working tracings should be made on the unglazed or dull side of the cloth, as this side will take

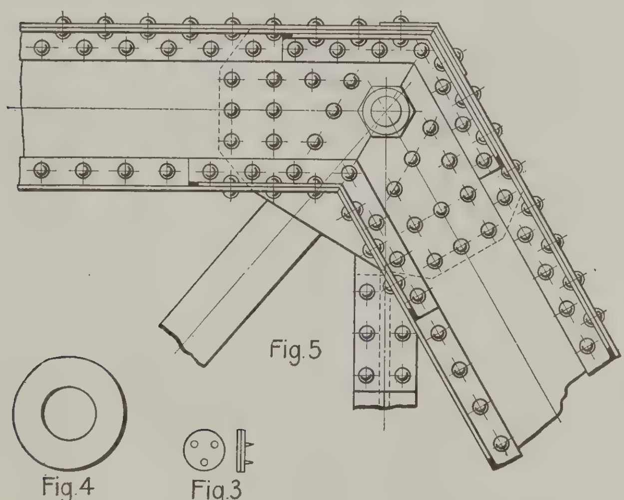


Fig. 3. Horn Center, Figs. 4 and 5, Examples of Shading.

pencil lines nicely, and when erasing has to be done it will not mar the surface so perceptibly. But for show or estimate tracings where much finer and neater work is required, the glazed side must be used. The lines will be sharper and the work will stand out much better. In either case the cloth should be laid down in the same manner as the paper. It should then be rubbed down with pulverized chalk.

Laying Down the Tracing.—The drawing to be traced is squared up with the board and wiped down with a dry cloth or duster. The roll of tracing cloth is run down the board and cut off to correct size. The edges at either side are then torn off quickly and the cloth laid down correct side up. A tack is put in the center of the top edge; the flat of the hand is drawn firmly but gently down to an opposite point at the lower edge, the fingers spread apart, while another tack driven between them holds that edge. Run the flat of the hand gently to the one side, driving in a tack; then to the opposite, stretching it well and securing it by another tack. The four corners and all intermediate spaces are then held down in the same manner.

With a dry rag or piece of chamois skin rub some pulverized chalk (or chalk scraped from the stick) all over the tracing cloth, dusting it off with a dry rag or brush. This will cause the pen to bite much better, especially in the case of show tracings where the glazed side is used. Some draftsmen use a little ox-gall in their ink for this purpose, but unless the exact quantity is used the ink will be very sensitive.

Tracing.—Everything is now ready for tracing. Try to understand the work as you proceed. If the job is likely to last long, work on one view and complete it, as sometimes the temperature of a room will change over night, causing the cloth to become quite flabby, and although it may be stretched again by holding it near the radiator or in the sun, yet it very seldom goes back to its correct position. But when making a smaller tracing which can be completed in a day, put in all the black lines first, the red or blue lines next (when making show tracings), the printing or lettering next, and finally the border and cutting-off lines.

Although as a rule red and blue lines are put in last, yet there are a few exceptions, as, for instance, when tracing a number of bolt or rivet heads in bridge or girder work; if a red line is run right through the heads, it will be easier to get them all exactly true and in line; otherwise they are apt to be put in in a very zig-zag way.

If the drawing is crowded the best plan is to stick to the rule and put red lines in last, as otherwise they will make the drawing hard to read by covering up work not yet traced. As a general rule, commence with the circles and curves first, joining the straight lines onto the curves, and not *vice versa.* When a number of circles and curves are struck from the same center, always commence with the smallest or inner one first while the center is good.

Sometimes a horn center, shown in Fig. 3, is used to protect centers from which a number of curves or circles are struck, as gear wheels, for instance. These horn centers are circular pieces of horn with three needle points. Some draftsmen glue a small piece of hard wood or horn over the centers. The pens should be tried upon the edge of the tracing to see what thickness of line they make, and when once set they should not be moved; for this reason some pens have small lock nuts on the thumbscrews. They should be wiped and the ink put in without again adjusting the screw. This particularly applies when making heavy lines. In this way all lines will be of the proper thickness. The pens can be filled with an ordinary writing pen or dipped in the ink sideways.

Working Tracings.—Working tracings or shop tracings are usually made a little heavier than others. The lines should be all the same thickness. No red or blue lines need be used, but all black, and although the tracings should be neat, especial care being given to the figures and dimension lines, yet such care need not be taken as when making a show or estimate tracing. The figures should be plain and simple and might be made a little large. The arrow points should be true and go exactly to their intended position. The figures should be checked before handing in the tracing so that as few mistakes as possible will come back to the tracer.

Show Tracings.—Estimate or show tracings should have a little more time expended upon them. The lines need not be so heavy and as a general rule are shaded, *i.e.,* the lines furthest from the light, which is supposed to come from the top left-hand corner, should be heavier than the others; this is clearly shown in Fig. 5. Shade lines can be made by going over the lines again or adjusting the screw of the pen, causing the ink to make a heavier line. When dark-lining a circle the radius is kept, but the center changed slightly, as shown in Fig. 4; or the same center and radius may be kept, going over the dark or shaded side several times with the pen.

The letters, figures and dimension lines should be made neatly, the arrow points evenly made. Some draftsmen put in the arrow heads with their spring bow pen, and since they can be put in just as quickly this way and look much neater it would be well to practice this method.

Dotted lines should be finer than full ones. The dots and spaces should be the same length—about one-thirty-second to one-sixteenth inch in length.

In shading rivet heads sometimes a small half circle is made inside the first, as shown in Fig. 5. It should be heavier than the outline of the rivet head.

The heading or title should be neat and attractive and a fancy border line might be made. All notes or stray words should have a neat red line drawn under them. Bolt heads should be neatly made and all small work neatly executed. Threads of bolts should be parallel and equally spaced, and

may be accurately drawn or indicated, as shown in Fig. 6, *c*, *d* and *e*. Dotted work can be shown to advantage if the dots forming the apex and root of the threads are united, as shown at *e*. These may seem trifles, but they all tend to make a neat tracing.

Holding the Instruments.—The author has been more than surprised at the rough and unsteady way which some drafts-

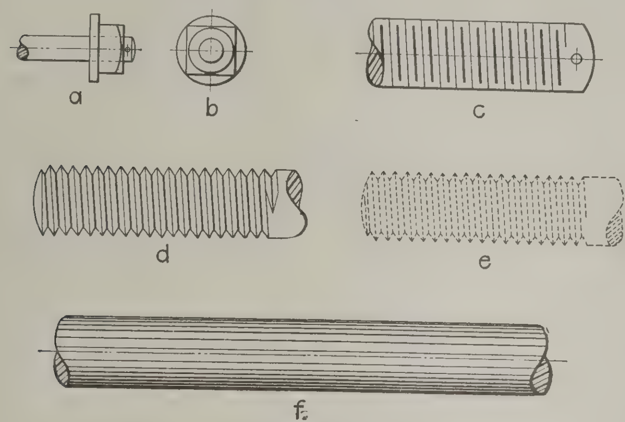

Fig. 6. Screw Threads and Shading.

men have of holding their instruments. The bow pen should be held lightly at the top between the thumb and first two fingers, resting the little finger upon the tracings to steady the instrument while finding the position for the point. This being found, the little finger should be lifted and the bow pen cleverly spun between the thumb and first finger. It is good practice at your leisure to see how quickly you can make a number of small circles; in this way you will get into the knack of cleverly spinning the bow pen as described, instead of holding it in an awkward manner.

The straight pen should be held in a slightly inclined position, the thumb-screw on that side away from the T-square or straightedge and with the second finger resting upon the screw to adjust if necessary.

* * *

The steps which have been taken by the Japanese government for the nationalization of its railways, and the recent developments in the industrial and commercial situation in Manchuria, indicate that that nation has determined on a definite policy of government control of commerce and manufacturing. Consul-General Miller in a recent report from Yokohama says:

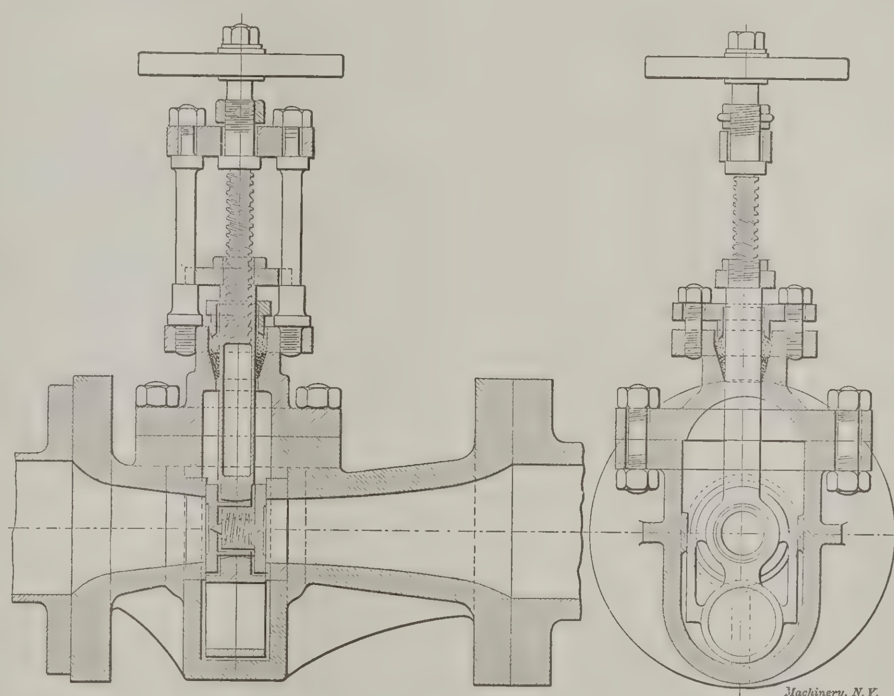
"She is undertaking one of the greatest experiments in the world's history in the relations between government and industry. If successful along the lines she is now working on, the individuals and corporations of America that are striving for the trade of the Orient will discover that they are not competing for this trade against individuals and corporations of Japan, but that they are in commercial conflict with the Japanese nation. I am convinced that this is the condition to which American manufacturers and merchants must look forward and be prepared to meet.

"The financial world seems now to be in keen competition to provide Japan with money for almost every purpose, and the lack of wealth is not likely to retard her industrial and commercial expansion. In viewing this great Japanese experiment of nationalization of industries it is not wise to prejudge it, and assume it will be a failure because it would fail in European or American countries. A thorough knowledge of Japanese history and character will cause any thoughtful person to hesitate before pronouncing it impracticable."

THE HOPKINSON-FERRANTI STEAM VALVE.*

The manufacture of stop-valves has now been carried on for so many years that one might well have thought that finality had been reached. We are, however, indebted to Mr. Ferranti for a radical departure in valve construction, which promises to considerably modify existing practice. The valve works upon the principle of converting the pressure of the fluid to be controlled into velocity, passing it through a comparatively small orifice, in which the working parts of the valve are placed, at a high velocity, and then reconverting the velocity into pressure again by means of a suitably formed nozzle. We give an illustration of the valve, which is being manufactured by the well-known firm of Messrs. J. Hopkinson & Co., Limited, of Huddersfield. From the engraving its construction will be readily understood. The new idea is so simple, and the advantages of the valve are so obvious, that it seems strange that it has not been invented long ago. It must be remembered, however, that accurate knowledge on velocity and pressure conversions of elastic fluids is of quite recent date; and it has only been by a combination of circumstances that the present development has been brought about. As the result of very careful design and a large number of experiments, Mr. Ferranti has produced a valve with very much smaller working parts, through which the drop of pressure, under normal circumstances, is negligible, and which is capable of carrying the heaviest overloads. This valve can therefore advantageously take the place of an ordinary full-bore straight through valve.

As will be seen from the illustration, the steam entry to



The Hopkinson-Ferranti Steam Valve.

the valve is formed of a conical nozzle. It has been found advisable in practice to make the throat of this nozzle half the diameter of the pipe in which the valve is placed, and it therefore has one-quarter the area. In this throat the operative parts of the valve are placed. These are made according to Messrs. Hopkinson's well-known construction, the discs and seats being of their "Platnam" metal, which has been found very durable under the most severe conditions. As, however, it is of the utmost importance that the path should be perfectly smooth, so as to avoid as much as possible loss from eddying, the moving part of the valve is of special construction. This will also be seen from the illustration, which shows that the moving parts are so constructed that when the valve is closed the ordinary discs are in position against the faces; and when the valve is opened a smooth tubular passage is brought accurately into line between the cones forming the path through the valve.

**London Engineering*, June 29, 1906.

The steam, on leaving the throat, passes through a diverging nozzle and converts its velocity into pressure; and it is the smoothness of the throat and correctness of the whole path which are of such great importance in giving the valve a high efficiency. The nozzles, both leading to and from the throat, have been designed on the basis of equal conversion of energy per unit length of the path, so as to obtain the minimum loss by eddying. Every precaution is taken in the design and manufacture of the valve to ensure the tube which forms the path through the throat being in accurate alignment with the nozzles when the valve is full open. To give an idea of the importance of the smoothness of path in the throat it may be stated that when this special construction is replaced by the parts ordinarily found in a straight-through valve, the drop of pressure at once becomes serious.

The advantages to be obtained by the use of this valve are very important. The new valve, for the same capacity as that of an ordinary straight-through valve, is very much smaller in size, and is of about half its weight. This matter, though not so important on land, is one of very great importance on board ship, where everything possible is done to reduce weight. One of the most serious troubles in large steam installations is that of valve leakage, and in the valve in question it will be seen that with equally good manufacture the leakage must be at most one-half, owing to the periphery over which leakage can occur being half that in the ordinary valve. But, as is well known, the smaller the structure the stiffer it is possible to make it, and it is therefore probable that the leakage will be reduced by a good deal more than half.

Another advantage is that the valve does not require a by-pass; as it is found that partly owing to the reduced area of the opening and partly to the conical approach to the opening, the flow of steam is almost directly proportional to the number of turns given to the controlling wheel. There is, therefore, no rush of steam on opening, such as one gets with ordinary valves, and there is a continually increasing and nearly proportional flow right up to the last movement of the handle. This is a matter of considerable importance, as by careless opening of valves a good deal of damage has resulted at different times, from the sudden rush which takes place. Owing to the progressive flow through the present valve this danger is done away with. Moreover, in valves of fair dimensions, such as are now being very generally used, the work of opening and closing is very considerable. The present valve has to be moved against a quarter of the load on account of the reduced area of its working parts, and for only half the stroke of a normal valve, and the work of opening and closing may therefore be put down as approximately one-eighth of that at present required.

The lagging of steam-pipes for the purpose of saving heat losses is now generally done with very great care; and in steam installations where the engineers are concerned with the good appearance of their pipe-work it is always a very serious difficulty to so lag the valves as not to lose heat, and yet, at the same time, to prevent their spoiling the general appearance of the plant. The new valve, as will be seen from the illustration, lends itself very specially to being well lagged; in fact, the diameter of the lagging required for the pipes is about that which is required for entirely enclosing the hot part of the valves, and thus a neat and workmanlike job can now be made of the covering of a pipe system.

Many engineers will, no doubt, have come across the difficulty and annoyance arising from the fact of their having to provide different flanges upon their steam-pipes where these are jointed to stop-valves, owing to the welded-on flanges suitable for pipe-lines being too small in diameter, and having bolts at too small a radius for connecting to the cast-iron or cast-steel valve-bodies. This difficulty is entirely overcome in the new valve. It will be seen from the figure that the cones of which the valve is formed enable the bolts to be put close enough in to the center to allow of standard pipe-line welded-on flange being used. The importance with the new valve of being able to keep standard pipe-line flanges throughout the pipe system is very great, and will be much appreciated by engineers.

APPLIED SCIENCE REFERENCE ROOM OF THE PRATT INSTITUTE LIBRARY.

Most of us have been discouraged at one time or another in hunting for information on scientific subjects in the public libraries with which our country abounds. It is often exceedingly difficult to make practical use of them in obtaining information on mechanical engineering, for instance. This is due in many cases to the poor selection of books on this and kindred subjects. Many of the works are old and out of date, while the newer ones will very likely be found to belong to that large class which either gives no useful information, or else has it arranged in such form that it is unavailable for practical use. In contrast with this common condition it is with pleasure that we call attention to the efforts that are being made by those in charge of the Pratt Institute Free Library of Brooklyn, to make their applied science reference room of the greatest possible value to the community in which it is located.

Unlike most other large cities Brooklyn is not served by a large central library with sub-stations in outlying districts, but is instead supplied with a number of smaller and practically independent ones located in different sections of the city. Among these the Pratt Institute Library, although in reality a private institution, supplies the needs of a large residential and manufacturing district. It is therefore provided with a full collection of works on history, art, criticism,

A Corner of the Applied Science Reference Room.

poetry, biography, fiction, etc., as well as with such special books as are needed for the scholars and teachers of the school of which it is a part. It is only with the equipment of the applied science room, however, that we are concerned. This is located on the main floor of the building and is open every day, except Sunday, from 12:30 to 9:30 P. M. and can be used between 9 A. M. and 12:30 through the library office. Over one hundred trade and scientific papers are subscribed to, besides about fifty labor union papers, the most important of the trade journals being bound and preserved for reference. The transactions of all leading scientific societies of England and America are also to be found on the shelves, and a full set of patent office reports is available. The cases on the side walls contain classified selections of books dealing with applied chemistry, metallurgy, mechanical and electrical engineering, building trades, and allied subjects. The half-tone will give an idea of the arrangement and appearance of the room.

The point to which special attention should be called, however, relates to the active effort made by Mr. Edwin M. Jenks, who is in charge of this department, to make it as useful as possible to those who may be helped by it. A liberal appropriation is made yearly for the purchase of new books, and this is expended, as far as possible, on the recommendation of practical men interested in the various subjects with which the collection of books is concerned. A careful lookout is kept for the scientific books in the circulating department of the library which are most often taken for reference, and such

books are either placed in the reference room or, if the circulating demand is also large, a new copy is bought.

Furthermore, Mr. Jenks has been making a survey of his district to locate the position and nature of the various industries represented there. From this information an industrial map is being prepared which is expected to be of considerable service. Visits are made to manufacturing establishments from time to time, when the library is brought to the attention of the different manufacturers, and permission is asked to post notices about the plant and to distribute cards calling attention to the equipment of the reference room. In addition to this, classified lists of the available books concerned with the various industries are being prepared by men who are familiar with the practical conditions involved. These lists give not only the name of the book and that of its writer, but describe in a few words the nature of its contents and the manner in which the subject is treated, thus saving much trouble on the part of the user. Of these lists, the catalogue of books on electricity has been completed. Another innovation is the collection of mounted cuts which have been clipped from various books and periodicals and indexed in such a way as to be available for reference. This includes a great variety of pictures of machines and mechanical devices which may be used in the room or taken away if desired. A man desiring to get ideas in the line of chucks, for instance, would find a large collection of illustrations here from which he might get helpful suggestions.

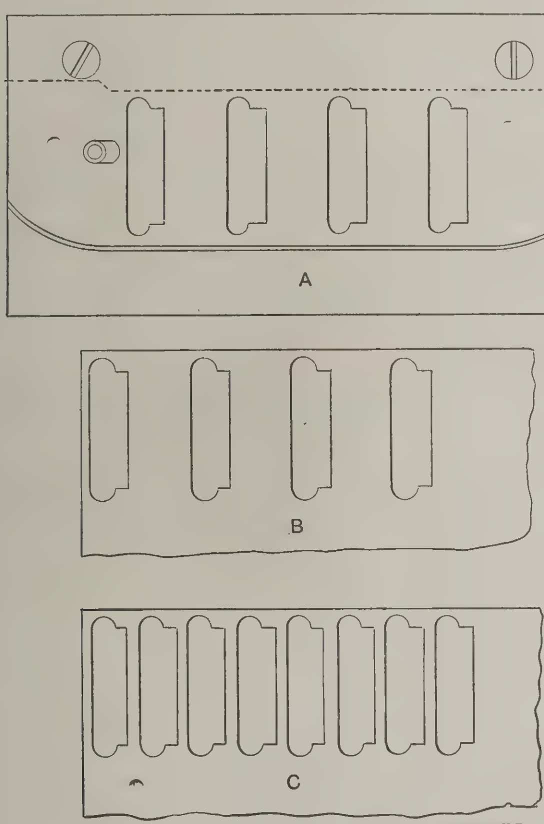


Fig. 40. Arrangement of a Multiple Die.

In general those responsible for this reading room appear to have their ears to the ground, if the expression may be used, and give evidence of being sincerely desirous of making it a useful institution. With these intentions so plainly evinced it would seem to be the fault of the user of the library if it did not prove to be of service to him in his work. This example is commended to the attention of other similar institutions.

[Since the above was written, we have received the catalogue of books therein mentioned. The pamphlet is entitled, "Books on Electricity, an Annotated List." It measures 4½ x 7 inches, and describes some three hundred works. These are classified in a way which is convenient for reference. Any one to whom this list would be useful may obtain a copy by addressing a request to the Pratt Institute Free Library, Brooklyn, New York.]

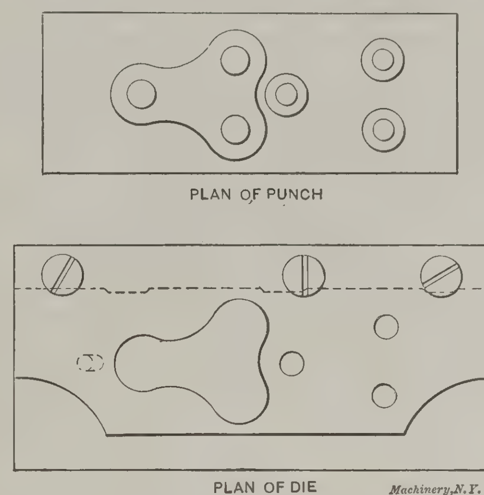
PUNCH AND DIE WORK.—3.

E. R. MARKHAM.

Multiple Dies.

The reduction of the cost of manufacture is often possible by the use of multiple dies, whereby two or more pieces are punched out at a time. In punching perforated steel work it is no uncommon thing to see punches and dies in use where several hundred punches are working into one die.

If an article, for example, of the form shown in the die in Fig. 40, were to be punched in lots of several thousand, the die should punch a number at a stroke. Such a die and the stock left are shown in Fig. 40, where the die is shown at *A* and the stock after the first punching at *B*. It will be noticed that the distance between the openings is considerable. This is necessary, as it would not be possible to place the openings in the die as close as they should be to economize stock, since there would not be stock enough between to insure the die sufficient strength to stand up when working. For this reason the openings are located as shown. After punching as shown at *B*, the stock is moved along the right distance so the intervening stock can be punched out, as at *C*.



Figs. 41 and 42. A Gang Punch and Die.

Gang Dies.

If it were desirable to punch a piece like that at *a* in Fig. 43, it would be possible to make a blanking die and punch which would produce the blank of the right size and shape, but without the holes; then, by means of another die, with three punches working into it, we could punch the holes. It is apparent that such a method would be more expensive than one that made it possible to punch the holes and the piece at one passage of the stock across the die. This may be done by the use of a die of the description shown in Figs. 42 and 43. When using this die the stock is placed against the guide and just far enough to the left so the large punch *b* will trim the end. Then, when placed against the stop or gage pin *c*,

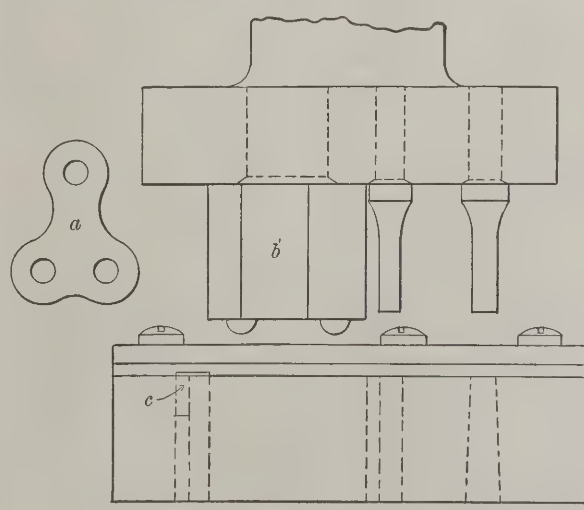


Fig. 43. Elevation of Gang Punch and Die.

bring the guide pins in end of punch *a* in line with the holes punched at the first stroke of the press at the time the end was trimmed.

When the stock is purchased of the proper width for one piece, it is fed through and the scrap thrown aside. At times it is purchased just wide enough for two pieces, in which case one edge is placed against the guide *d* and the stock fed through; after which it is turned over and fed through with the opposite edge against the guide, thus using all the stock except such portion as went into scrap.

However, if the stock is purchased in the commercial sheet, it is necessary to trim the edges every time a row is punched along each. If no power shears are located handy to the press this may prove to be a more costly operation than the punching, and no matter how conveniently such a shear may be located, the operation adds a considerable cost to the product. To avoid this trouble and expense another punch and opening to the die may be added. The object of this punch is to remove the scrap between the openings in the sheet and also trim the edge of the sheet, thus making it straight and in condition to bear against the guide on the die. The die and punch with the addition mentioned are shown in Fig. 44.

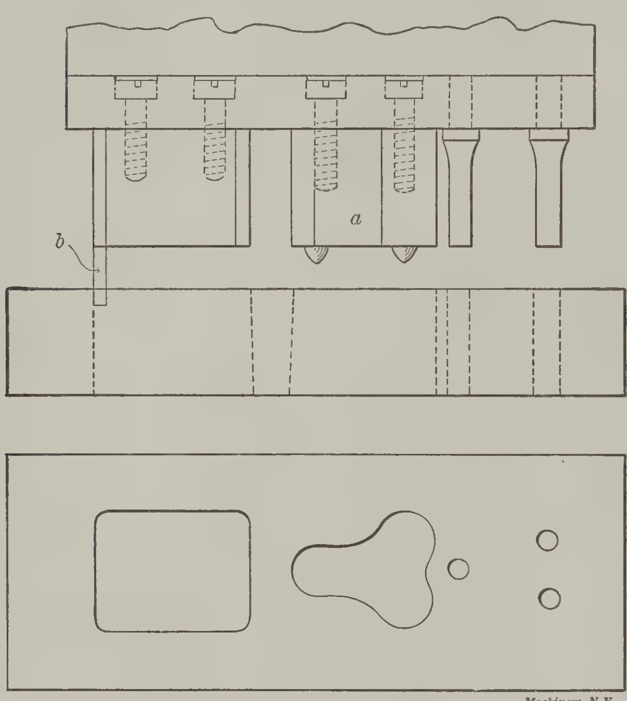

Fig. 44. Gang Punch arranged to use Sheet Stock.

When using a trimming punch as described above, it is necessary to use a stop of the description shown at *b*. The end of the scrap striking this governs the location of the stock, and when the punch descends the scrap is cut away.

When making dies of this class it is necessary to have the blanking die *a* the longer in order that the locating pins on the end may engage in the holes in the stock and locate it right before the other punches reach the stock. It is also necessary to place the stop, or gage pin, so the stock will go a trifle further than its proper location—say 1-100 inch. Then when the locating pins engage with the holes they draw the stock back to its proper location; whereas if the tool maker attempted to locate the stop exactly any dirt or other foreign substance getting between the end of the scrap and the stop would cause trouble.

Bending Dies.

While it is possible, in certain cases, to bend articles during the operation of punching it is usually necessary to make a separate operation of bending. There are instances where bending fixtures which may be held in a bench vise, or attached to the bench, answer the purpose as well and allow the work to be done more cheaply than if bending dies were used. But as a rule the die used in a press provides the more satisfactory method and allows the work to be done at a fraction of the cost.

It is sometimes possible to make the dies so the various operations can be done in different portions of the same die block, the piece of work being changed from one portion to another in order as the various operations are gone through. At other times it is necessary to make several sets of bending dies, the number depending on the number of operations necessary. When a "batch" of work has been run through the first die it is removed from the press and the next in order placed in, so continuing until the work has been brought to the desired shape.

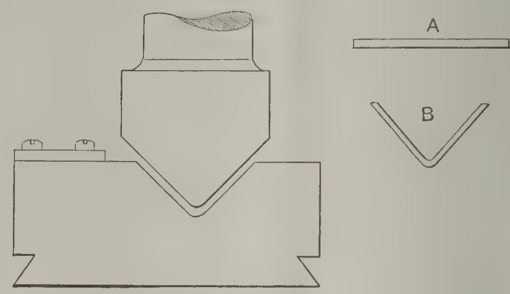

FIG. 45

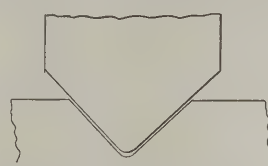

FIG. 46

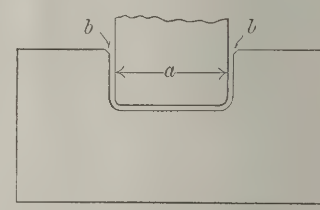

FIG. 47 Machinery,N.Y.

Examples of Bending Dies.

When a comparatively small number of pieces are to be bent to a shape that would require a complicated and consequently costly die in order that the work might be done at one operation, it is sometimes considered advisable to make two dies, which are simple in form and inexpensive to make, to do the work.

At times the design of the press is such that a complicated die could not be used; and as a result additional dies of a simpler form and which can be fitted in the press must be made.

We will first consider the simpler forms of bending dies. Fig. 45 represents a die used in bending a piece of steel *A* to a V-shape, as at *B*. In the case of a die of this form it is necessary to provide an impression of the proper shape as shown; this impression, if the die is to be used for bending stiff stock, must be of a more acute angle than if stock having little tendency to spring back when bent to shape be used. Under ordinary circumstances the upper portion or punch would be made of the same angle as the die. It is necessary to provide guides and stops as shown to locate the work properly.

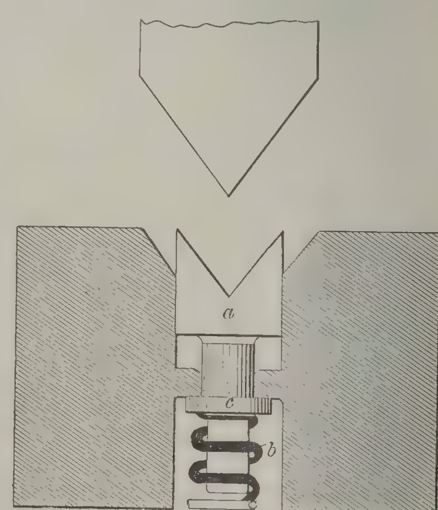

Fig. 48. A Bending Die for Accurate Work.

If the stock used in making the pieces is of a high grade and the product is a spring or similar article which must be hardened, it will be found necessary to cut away the die somewhat in the bottom of the impression, making it a little different in shape from the punch as shown in Fig. 46. This is to prevent crushing or disarranging the grain of the steel to an extent that would cause it to break when in use.

If the die is of the form shown in Fig. 47, it is, of course, necessary to make the length *a* of punch shorter than the distance across the opening of the die. It must be somewhat shorter on each end than the thickness of the stock being

worked. If possible, the upper corners *b b* of the die should be rounded somewhat, as the stock bends so much easier and with less danger of mutilating the surface than when the corners are sharp. When bending thin ductile metal the corners need but little rounding. If the stock is thick, or very stiff, a greater amount of round is needed.

While the form of bending die in Fig. 45 answers for ordinary work, there are jobs where such a die would not insure a degree of accuracy that would answer the purpose, and it will be found necessary to make one similar to Fig. 48, where a riser or pad *a* is provided as shown. This is forced upward by the spring *b* and is gaged as to height by means of the

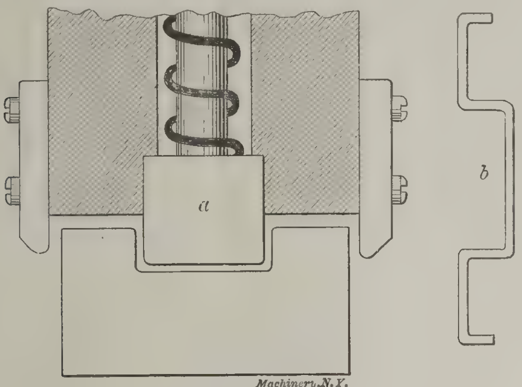

Fig. 49. A Case of Progressive Bending.

washer *c* bearing against the shoulder as shown. It will be observed that the spring gets its bearing against the washer, which in turn bears against the shoulder of the riser as mentioned before.

When making this die the hole is drilled and reamed and the groove milled or planed for the riser, which is put in place sufficiently tight to hold it while the V groove is cut, after which it may be relieved until it works freely.

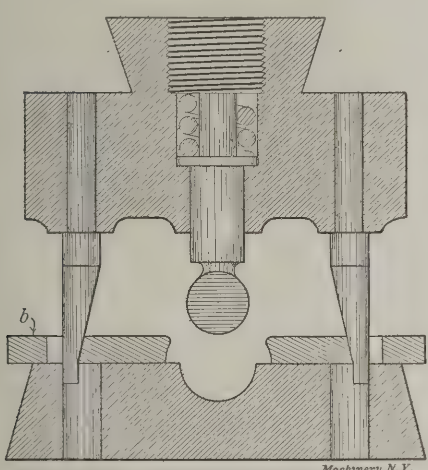

Fig. 50. A Die for Bending Bow Springs.

The spring *b* gets its lower bearing on the die holder. If it is considered advisable a screw may be provided for the spring to rest on. By moving this screw any desired tension may be given the spring, although generally speaking this is not necessary.

When bending articles of certain shapes it is necessary to design the tools so that certain portions of the piece will be bent before other portions. Should we attempt to make the tools solid and do the work at one stroke of the press, the piece of stock would be held rigidly at certain points and it would be necessary to stretch the stock in order to make it conform to other portions of the die. In the case of articles made from soft stock, this might be accomplished, but the stock would be thinner and narrower where it stretched. However, as a rule it is not advisable to do this, and dies are constructed to do away with this trouble.

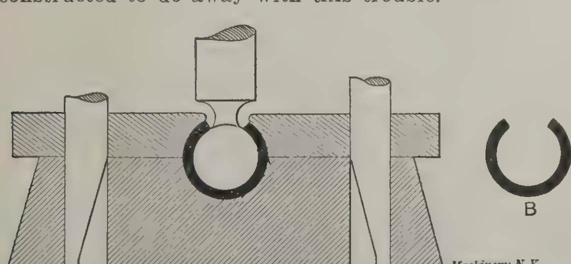

Fig. 51. Action of the Die in Fig. 50.

Fig. 49 represents a die, the upper part of which has the portion *a* so constructed that it engages the stock first, after forcing it down into the impression in the lower portion. Part *a* recedes into the slot provided for it. The coil spring shown is sufficiently strong to overcome the resistance of the stock until it strikes the bottom of impression. The article is shown bent at *b*.

Fig. 52. Successive Loops Formed in a Wire.

Compound bending dies are used very extensively on certain classes of work, especially in making looped wire connections and articles of thin sheet stock.

Fig. 50 shows a die used for bending a bow spring. As the punch descends the stock is bent down into the impression in the lower half and forms the stock to a U-shape. As the end of the punch with the stock comes in contact with the bottom of the impression it is forced into the upper portion, the spring keeping it against the stock while movable slides—side benders—*b b*, are pressed in by means of the wedge-shaped pins so as to force the upper ends of loop against the sides of the punch as shown in Fig. 51, forming the piece as

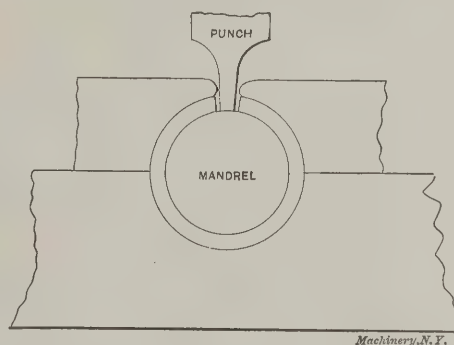

Fig. 53. Forming a Stiff Bow Spring.

at *B*. When the punch ascends, the finished loop may be drawn off. If the stock used is stiff it will be necessary to make the punch somewhat smaller than the finish size of spring, as it will open out somewhat when the pressure is removed.

When making looped wire work, a loop may be formed and the wire moved along against a stop; another loop formed, and so on, as in Fig. 52. When forming looped wire work it is customary to make the punch ball-shaped rather than as shown in Fig. 50. The ball answers as well on wire work and allows of the easy removal of the loop.

It is sometimes desirable to close the upper end of an article nearly together and if the stock used is extremely stiff,

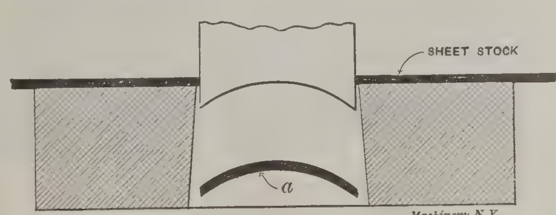

Fig. 54. Punching and Bending at One Operation.

as bow springs made from a grade of tool or spring steel, it may be necessary to heat the bow, which has previously been bent, red hot, and finish bending it by a special process. In the case of articles made from a mild grade of stock this may be accomplished at the time of bending by substituting a mandrel as shown in Fig. 53, for the cylindrical portion of the punch.

A great variety of work may be done by modifications of the forms of bending dies shown. Where but a *few* pieces are to be bent it is not advisable to go to the expense of costly bending dies; but when the work is done in great numbers they will produce work uniform in shape at a low cost.

Blanking and bending dies are made which not only punch

the article from the commercial sheet, but bend it to the desired shape at the same operation.

As a rule it is advisable to blank the article at one operation and bend it at another, but there are certain forms of work where it is possible to do it in a satisfactory manner at one operation and at a cost not exceeding that of the ordinary blanking operation. This also effects a saving in the cost of tools, as the special bending die is dispensed with.

Fig. 54 represents a punch and die used in punching the shoe *a* to the shape shown, while Fig. 55 is one used for producing the tension washer shown.

Gun and other irregular shaped springs are many times punched to form by this style of die, although when stock suitable for use in making springs is employed it will be

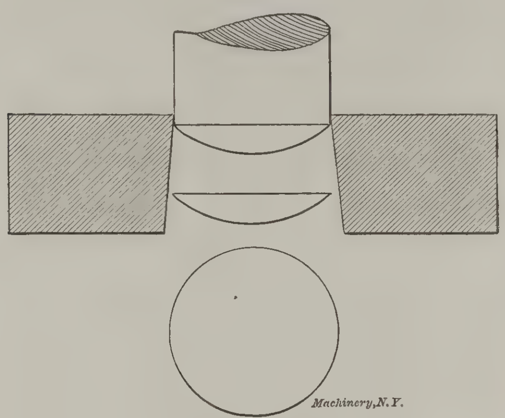

Fig. 55. Making a Tension Washer.

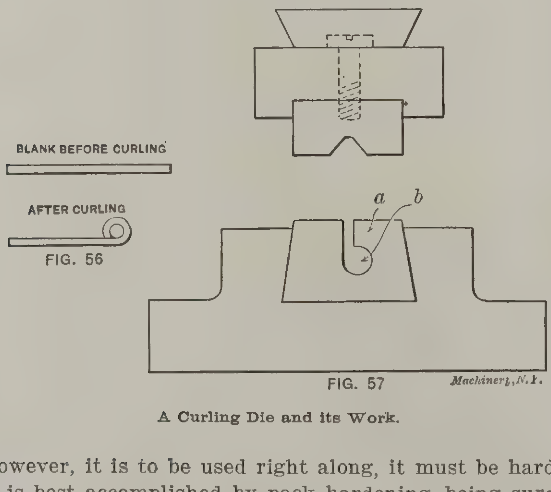
found necessary to make the face of the punch somewhat different in shape from that desired, as the piece will straighten out more or less after it is punched.

If it is desired to curl a form on a piece of work, making a loop as in Fig. 56, it is accomplished by various methods, sometimes by a modification of the die of Fig. 51. A die of the description shown in Fig. 57 is used with excellent results.

In making this die the blank *a* is first machined to size. The hole *b* is drilled and reamed to size and polished to produce very smooth walls. This may be accomplished by using a round revolving lap of the right size. The slot is then milled as shown.

If the die is not intended for permanent use and the stock is comparatively soft or easily bent, it need not be hardened.



A Curling Die and its Work.

If, however, it is to be used right along, it must be hardened. This is best accomplished by pack hardening, being sure that the heats are low. As in the use of this method the die is quenched in oil, there is little or no danger of its going out of shape. Draw to a full straw color.

The punch is made with a V-shaped impression in its face as shown. This may be rounded in the bottom as indicated or left sharp, as desired. If hardened, it may be drawn to a brown color.

It is possible with presses and tools adapted to the work to form pieces to shapes that to one not familiar with this class of work would seem well nigh impossible.

CONCERNING THE VARYING VALUE OF THE DOLLAR.*

Forty years ago, at the close of the Civil War, the United States was doing business with a depreciated paper currency, worth only half and at times even less than half of its face value in gold. While the situation was clearly understood by the financial experts of that day, it was not understood by people in general. Buying and selling, lending and borrowing, went on as if the dollar were an unvarying standard of value, and with no foresight of the impending change. The debtor who borrowed a thousand dollars for a term of years had seldom any idea that he would actually at the end of the term have to pay the creditor in dollars twice as valuable as those he had originally received. The hardships growing out of this change in the value of the dollar were enormous and widespread. They were in large degree responsible for the greenback craze of a decade later and for other financial vagaries which have afflicted us since. No one who clearly understands the situation resulting from the depreciation of paper money in the '60's and '70's can doubt that a currency of fluctuating value is one of the worst evils that can befall a people.

While the financial issue on which public attention was concentrated a few years ago did much to educate the public in the elements of sound finance, there is one fact now pressing on public attention which was rather obscured in the discussion. We refer to the fact that the dollar, even when based on the gold standard, is not by any means an unvarying standard of value. The enormous production of gold during the past twenty years appears to have been one important factor in the depreciation of the dollar which has recently occurred. Theorists have often speculated as to what the result would be if a deposit of gold should be somewhere uncovered from which the metal could be produced in unlimited quantities at a labor cost much below the present value of gold. It is evident enough, of course, that such an event would absolutely reduce the purchasing power of gold everywhere; and to a certain extent, it is claimed, the great production of gold in South Africa, Alaska, and Colorado has tended to produce a similar result.

That a great change in the value of the dollar has occurred is apparent to even the dullest observer. The value of money is measured, of course, by what it will procure. Dollars are worthless except as a universally accepted medium of exchange. If a dollar to-day will buy no more in food, clothing, shelter, personal service or other commodities than half a dollar would procure half a century ago, then it is a fair conclusion that the value of the dollar has diminished by one-half. One has but to refer to records of the first half century, showing prices paid and cost of living in those days, to be absolutely convinced that a great change has taken place in the value of the dollar in that period. We do not, however, need to go so far back by any means. In the current number of *Moody's Magazine*, a writer compares the average commodity prices in 1897, at the end of a long period of financial depression, and those of the current year. According to these figures, as compiled by R. G. Dun & Co., there was an average increase in price in that period, nine years, of 47 per cent. That means that it now takes $1.47 to buy what $1 would have bought nine years ago.

It is curious to note that this rapid change in the value of the dollar (and the gold dollar, too) has exactly reversed the situation between debtors and creditors that existed in the early '70's. Then the creditor got back from the debtor—if the debtor remained solvent—much more than he originally lent. To-day, if a man loaned money nine years ago at 5 per cent and were now to be paid back the principal with simple interest, he could not purchase as much with the whole as he could with the principal alone when he lent the money. In other words, the shrinkage in the value of the dollar has more than offset all the interest it has earned.

This decline in the value of the dollar must not be confused with another decline which has been going on at the same time, the decline in the rates of interest; yet to a certain extent the two react upon and influence each other. Twenty-

* *Engineering News*, June 28, 1906.

five years ago a hundred dollars loaned would earn six dollars interest every year. Now a hundred dollars loaned will earn only three dollars and a half a year; and that three dollars and a half will only purchase as much as a dollar and seventy-five cents did at that time. The "bloated bondholder," who has so long been held up to scorn, therefore, is now actually receiving from the same principal an income less than a third as great as that which he enjoyed twenty-five years ago.

It has seemed to us that these facts are worth bringing to the attention of engineers. While they may, in a way, be well known, we are all too prone to forget them. We unconsciously think of the dollar as a standard of value; but if it is a standard it is one whose dimensions are varying like a piece of india rubber. We think of wages and salaries as if the dollars could be compared with the dollars paid in wages and salaries twenty years or even ten years ago. It needs but the least thought to see that this is not at all the case. The man, be he president, chief engineer, college professor, surveyor, blacksmith or ordinary laborer, who is paid the same number of dollars per day or per year that he was nine years ago, has actually suffered a reduction in his salary or wages of nearly one-third. He can actually buy only two-thirds of the necessaries or comforts of life to-day that he could nine years ago. On the other hand, these changes of values are creating riches on every hand. Those whose property consists in actual things—real estate, railways, ships, mines, stores and what not, have often seen a jump in the value of their holdings which was due only partially to their shrewd business judgment and largely to the fact that the dollar has depreciated in value and thus made their property worth more dollars.

Will there be a return to the lower prices of a former day? So far as the value of the dollar is influenced by the rate of gold production, there is no prospect of any reduction in the output of the world's mines. Rather, with the constant exploration of new countries and the rapid development of chemical and mechanical processes for treating low-grade ores, a steady increase in the world's gold production seems probable, at least for a long period to come. There are, moreover, causes tending toward higher prices for various commodities, such as the growing scarcity of lumber and various metals, or the inability of the sources of supply to keep pace with the expansion of demand. It will be understood, of course, that an increase in price of any important commodity, to whatever market conditions it may be due, operates to decrease the value of the dollar. Inevitably, too, there must be a further readjustment of wages and salaries in many departments to correspond with changed conditions above set forth. All these things tend to make permanent the decreased purchasing power of the dollar and to bring about still further decrease.

[Of direct bearing on the above is the following quotation from a letter recently published in the *Outlook* (London): "There is every reason to believe that prices in the next fifteen years will rise enormously, reverting to the price level of the decade 1867 to 1877. This rise will be unfairly ascribed to the operations of the trusts and to the advance which should equitably take place in railway and steamship rates. The real reason, however, will be the depreciation of gold by reason of its abundance. So recently as 1883 the yield of the mines was only 4,614,588 ounces. For 1905 it was 18,211,419 ounces. If Mr. Bryan in 1896 and bimetallists the world over merely desired inflation they have since got inflation with a vengeance, and inevitably far vaster inflation awaits us."]

* * *

The increasing interest in "industrial betterment" is shown in the work being done in Kinkora, on the Delaware River, 10 miles below Trenton, N. J., where John Roebling's Sons are reported to be expending $4,000,000 in providing homes for their employees. Expansion of their business led to the erection of new mills near Kinkora, and the consequence was the building of homes for the workmen, including a hotel conducted on the plan of a private club, and a department store. A single man will be enabled to enjoy life for $2.50 per week and the houses will be rented for from $8 to $14 a month.

THE RANSOM CYCLOMETER OR SPEED INDICATOR.

The not unusual conception of the motion of a steam engine flywheel is that of uniformity of angular velocity, varying somewhat, of course, in number of revolutions per minute but not to any great extent within a revolution. This, however, is a mistaken idea as any one knows who has made an analysis of the subject, or has had to do with the operation of even very closely regulated multiple cylinder steam engines driving large alternating current generators, required to work synchronously in pairs or in multiple. The accompanying cut, Fig. 1, shows in diagrammatic form, steam engine fluctuations varying 5 per cent from perfect regularity of angular motion, and gas engine fluctuations varying 6¼

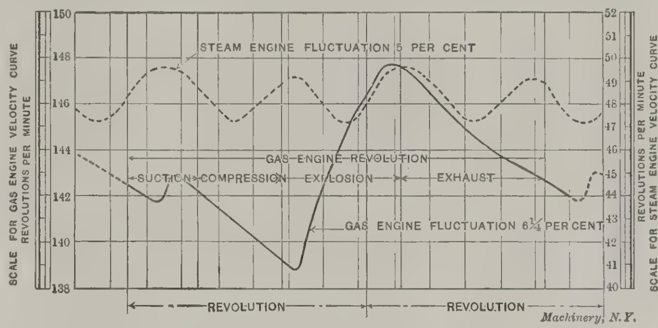


Fig. 1. Comparative Speed Variations of Gas and Steam Engines.

per cent. The Ransom cyclometer by which these variations were detected is of considerable interest and through the courtesy of the makers, Messrs. Manlove, Alliott & Co., Ltd., Nottingham, England, we are enabled to present herewith photographs of the instrument and the accompanying description:

The Ransom cyclometer shown in Fig. 2 is an instrument by means of which the time of rotation of any shaft may be measured to the one-five-thousandth part of a second and not only is the total time of each revolution recorded but also the time taken in turning through any minute angle or portion of a revolution may be obtained with equal accuracy. The principle upon which this speed recorder works is very simple. A cylinder or drum covered tightly with smoked paper is connected to the end of the engine shaft or other shaft whose speed it is required to measure. On one side of

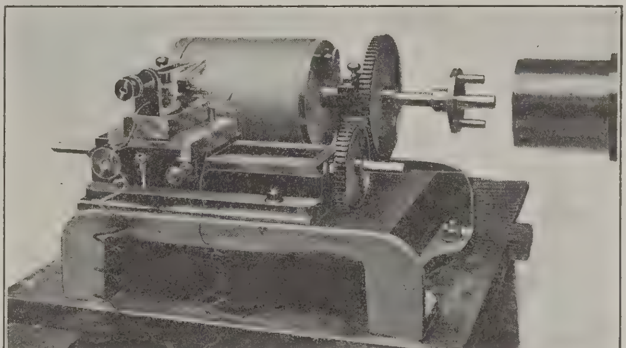

Fig. 2. The Ransom Speed Indicator.

this drum is mounted a tuning fork of known pitch one arm of which carries a small needle or style. When the fork is vibrating this needle oscillates in a line at right angles to the direction of rotation of the drum and lightly touches the surface of the smoked paper. Fig. 3 shows a short section of a record made by a standard tuning fork making 512 vibrations per second. It is one of the fundamental laws of sound that each vibration must be made in an equal interval of time, the amount of which is known from the pitch of the fork, hence each of the cycles represented on the surface of the smoked paper represent equal intervals of time. Knowing the pitch of the fork and having given a section of paper on which the style has traced a record, it can be readily deduced how long a period of time was required for the traverse of any portion of it while passing under the style.

In order that more than one revolution of the drum may be recorded the tuning fork is arranged to travel automatically along the whole length of the drum, or any portion of it that may be desired. The record then presents the appearance of a fine helix composed of waves on the surface of the paper. The records made on smoked paper are removed from the drum and the marks rendered permanent by a thin coating of varnish.

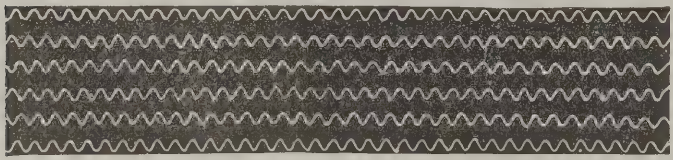

Fig. 3. Record Made on the Smoked Paper.

The diagram shown in Fig. 1 was plotted from tests made on a good tandem compound steam engine indicating about 15 horsepower, and on an "Atkinson cycle" gas engine. The gas engine shaft, of course, receives only one impulse to four impulses received by the steam engine shaft, and although both engines make about the same number of revolutions per minute it will be noted that there is a considerable difference in angular velocity. The gas engine was regarded as an uncommonly steady running machine, although the cyclometer showed fluctuations in speed of 6¼ per cent during a period of one revolution.

Fig. 2 shows the cyclometer; a spur gear is mounted on the drum shaft which meshes with another gear mounted on a lead screw. This latter traverses the carriage on which is mounted the tuning fork shown on top. Between the prongs of the fork is a small electro-magnet connected to a battery by means of which the action of the tuning fork is stimulated, and by the use of which a trial may be prolonged for any required time. The end of the drum shaft is provided with suitable connection for the shaft to be tested. It is thus evident that the construction and use of the instrument is quite simple and readily within the grasp of any one competent to test machinery. The fact that the tuning fork has an unvarying rate of vibration is, of course, the fundamental idea on which the machine is founded. The principle has been much used for time recording in physical science experiments but its application to machinery testing is of comparatively recent date. Fig. 4 shows the application of the instrument to an Atkinson cycle gas engine.

* * *

BUILT-UP CRANK SHAFTS FOR MULTI-CYLINDER ENGINES.*

In some of the very earliest gasoline vehicle engines of the high speed European type, built-up crankshafts were employed. That is, the shaft, its cheeks or webs, and the crank-pin were not made integral, but of separate elements, mechanically joined. In many of the early enclosed flywheel engines two balance wheels were used, each wheel being keyed to the closely abutted ends of the halves of the shaft. The crank-pin being passed through and made fast in the rims of both balance wheels, the halves of the main shaft were thus mechanically joined.

The built-up crank-shaft was early abandoned in favor of shafts hand or drop-forged out of a single piece of stock, the shaft proper, as well as the cranks and crank-pins for the number of throws desired, being formed integrally. Some of the highest quality automobile engines have been fitted with shafts not forged but machined or cut very laboriously out of a solid rectangular slab of steel, large enough to include the extreme outside dimensions of the shaft, cranks and pins.

* *Horseless Age*, July 4, 1906.

Crankshafts for four-cylinder engines are expensive pieces of mechanism, and the shafts required by six- and eight-cylinder motors are necessarily much more so, especially if they are constructed in accordance with the best precepts of the art.

Rather recently the built-up crankshaft has been proposed for modern motors, and several designs have been brought out. Such shafts are constructed upon a sort of unit system. The units from which a crankshaft of any number of throws may be built up are identical and consist of the forged cheeks of a crank, the crankpin and two short stubs forming parts of the shaft proper.

The ends of these stubs are made in the form of jaw couplings and two of the units may be united by interlocking these jaws, so that neighboring throws shall stand at any desired angular relation, one to the other, as required in the construction of multicylinder shafts of all types. The interlocked parts of neighboring units form the bearing portions of the shaft itself and the ball bearings in which the shaft runs do not, under this construction, have to be threaded over the cheeks of the cranks. The internal diameter of the ball bearings may therefore be reduced with an advantage in point of strength of the bearing.

It is probable that crankshafts built up in this manner from a number of similar units can be produced quite economically. The burden of keeping on hand ordinary crankshafts for motors of various types and numbers of cylinders is quite serious, and there should be a certain advantage in being able to build up a shaft for a motor of any number of cylinders upon this unit system.

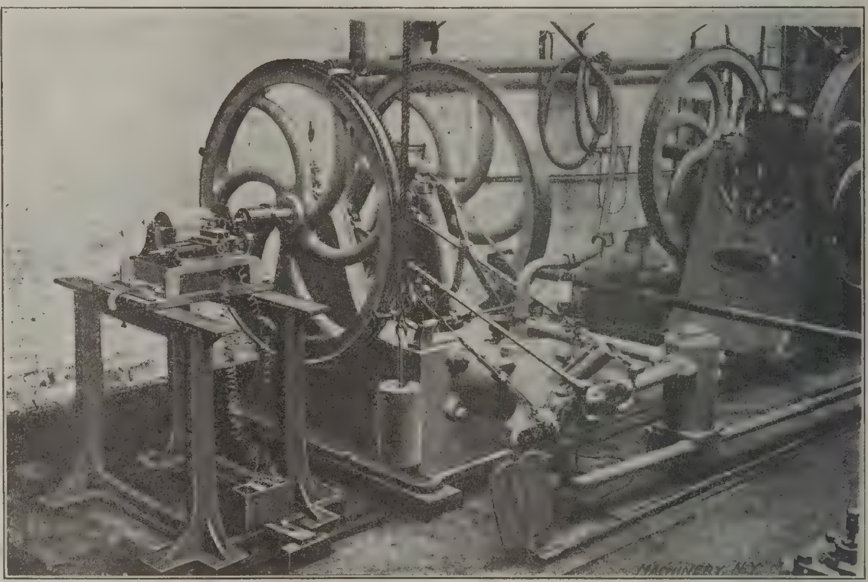

Fig. 4. The Apparatus in Use in Testing an Atkinson Gas Engine.

Damage sustained by any part of a built-up shaft should be more readily repaired than a corresponding accident to an integral shaft—a fracture of which is usually fatal, despite the claims put forth for the electric welding process in this connection.

* * *

Every flywheel acts in a measure like a fan, taking in air at the hub and discharging it at the rim. The current of air set up in this way is often disagreeable and sometimes injurious to processes of manufacture. In any case it means a waste of power which with a large wheel running at high speed may be a considerable item. A writer in *Power* recommends that all flywheels be encased, the casing being made a part of the wheel itself and not in the form of a box surrounding it. A box casing surrounding the wheel only partially reduces the loss of power and is not as easily and cheaply made as drumhead casings applied to the wheel itself. These casings may be made of canvas supported on radial wires, and segments of wood fitted in the rim and a wooden clamp collar at the hub. With this construction the air within the wheel revolves with it without escaping; with a box casing it is being continually agitated, the fanning action being only partially suppressed.

WILLIAM B. COGSWELL.

REPRESENTATIVE AMERICAN MECHANICS AND ENGINEERS.

William B. Cogswell, mechanical engineer and general manager of the Solvay Process Company and the Tully Pipe Line Co., Syracuse, N. Y., was born in Oswego, N. Y., September 22, 1834. From seven to ten years of age he attended the Hamilton Academy; he afterward attended a school kept by Joseph Allen of Syracuse, and also a school kept by Prof. Orin Root, in Seneca Falls, N. Y. During the two years, 1848-9, Mr. Cogswell worked with an engineering party on the survey of the Syracuse & Oswego R. R. and the Syracuse & Utica R. R. His natural tastes impelled him strongly toward engineering as a profession, and when his surveying experience ended, he entered the Rensselaer Polytechnic Institute, at Troy, N. Y., May 1, 1850, in the class of 1852. He remained three years but owing to an extension of the course no class was graduated in that year. In the year 1854 the degree of C. E. was conferred on him by this institute.

Soon after leaving the school Mr. Cogswell began an apprenticeship in the Lawrence machine shop, under the superintendence of John C. Hoadley. He came out of that apprenticeship three years later with a theoretical and practical education in engineering, mechanics and physics with their allied branches, not often secured in so short a time by so young a man.

Returning to Syracuse in 1856 he was selected by George Barnes of the same city to assist him in taking charge of the machinery of the Marietta & Cincinnati R. R. at Chillicothe, of which road Mr. Barnes had been made superintendent. He remained in that position only three years when the railroad became crippled in the financial panic of 1857. The year 1859 Mr. Cogswell spent as superintendent of the Broadway Foundry in St. Louis, Mo., and in 1860 returned to Syracuse, and in conjunction with William A. and A. Avery Sweet, started the works which were the inception of the present Whitman & Barnes Manufacturing Co. Here the breaking out of the Civil War found him, and in 1861 he was appointed civil engineer in the United States Navy. In this position he performed an enormous amount of labor in fitting up separate repair shops for five stations on the Atlantic seaboard and lived at one of them erected on shipboard at Port Royal, S. C. In 1862 he was transferred to the Brooklyn Navy Yard and placed in charge of steam repairs where he remained four years. The following two years he lived in New York City. In 1870 he was called to take charge of the completion of the Clifton Suspension Bridge at Niagara Falls and at the same time gave his attention to the construction of two blast furnaces at the Franklin Iron Works in Oneida County, N. Y.

In 1874 he was solicited to go to Mine La Motte, in Missouri, to assume charge of the lead mines of the same name at that point. This mine was owned by Mr. Rowland Hazzard, who brought all arguments in his power to induce Mr. Cogswell to take this step. He remained there five years until the spring of 1879, when he decided to remove to Syracuse, although retaining the management of the Mine La Motte lead mines. After returning to Syracuse, and while in quest of some kind of employment, Mr. Cogswell decided on a step which has had a most important influence on Syracuse as it called into existence a new industry that has grown to great proportions. Through a friend he had made the acquaintance of Messrs. Solvay & Co., of Brussels, Belgium, who are the most prominent manufacturers in the soda industry in Europe, and he decided to go to Europe to investigate it. The result was that Mr. Cogswell was given a commission to inspect the various points in this country where a manufactory would be practicable, and report. After the receipt of the report steps were taken for the formation of a company for the manufacture of the various soda products. It was decided that Syracuse was the best point for the works and they were located there, for it was believed by Mr. Cogswell that rock salt might be discovered in the vicinity. Several experimental borings were made in 1881 and 1883, but without success; but information was obtained which led to the experiments in Tully valley in 1888, and the discovery of two veins of rock salt, each about fifty feet thick, at a depth of 1,200 feet. The company now receive their entire supply from the Tully wells. The company also put in a plant of such capacity that a large quantity of saturated brine is sold to the salt manufacturers of Syracuse. This industry led to the formation of the Tully Pipe Line Company, for conveying brine from the wells to the works.

A branch of the Solvay Works at Syracuse has been built at Detroit, and the output of the two works has probably tripled in the last fourteen or fifteen years. (In 1892 the output was 75,000 tons soda ash; 20,000 tons caustic potash; and 6,000 tons bicarbonate of soda.) An organization known as the Semet-Solvay Company is a branch of the same organization in the coke industry, and it grew out of the demand for ammonia required by the Solvay Company in their business. This branch has extended until they have banks of ovens located in twelve or fifteen different cities in the country, and is in extent probably as great as the soda ash business itself. Other industries have been engrafted on the original industry of making soda ash which was the first to be started by Mr. Cogswell, and in the introduction of others he has been instrumental, and when his best judgment has been followed there have been few mistakes.

The Hannawa Falls power plant, where the Racket River two miles above Potsdam, St. Lawrence County, offered a favorable opportunity, Mr. Cogswell organized and mainly financed the company that erected. Electric power is furnished to Potsdam and Ogdensburg.

Mr. Cogswell has in his life made the most of favorable conditions; inherited a good constitution; was brought up as a gentleman; started young in civil engineering; had a good technical education; learned the machinist's trade in one of the best shops in the country; and has coupled with these advantages a wide experience, and an abundance of good common sense. He is a member of the American Society of Civil Engineers; a member of the American Society of Mining Engineers; a member of the American Society of Mechanical Engineers; a Fellow of the Geographical Society; a member of the Society for the Advancement of Science; a member of the Society of Chemical Industry of England; and president of Warner's Portland Cement Company.

For the foregoing we are indebted to Memorial History of Syracuse published in 1891, and for later information to Prof. John E. Sweet, Syracuse, N. Y.

* * *

A movement inaugurated by Mr. Carnegie has resulted in the planning of a memorial building on the site of the birthplace of James Watt at Greenock, Scotland. The building will contain classrooms for the study of navigation and marine engineering, together with facilities for taking astronomical observations. Mr. Carnegie will bear a large part of the cost of this undertaking.

Entered at the Post-Office in New York City as Second-Class Mail Matter.

RAILWAY MACHINERY

A SPECIAL EDITION OF MACHINERY FOR THE RAILWAY SHOP, DEVOTED TO LOCOMOTIVE AND CAR EQUIPMENT AND MECHANICS.

Published monthly by

THE INDUSTRIAL PRESS,

66-70 WEST BROADWAY, NEW YORK CITY.

DOMESTIC SUBSCRIPTIONS, $2.00 A YEAR. FOREIGN, $3.00 A YEAR. SINGLE COPIES, TWENTY CENTS.

The receipt of a subscription is acknowledged by sending the current issue. Remittances should be made to THE INDUSTRIAL PRESS, and not to the Editors. Money enclosed in letters is at the risk of the sender. Changes of address must reach us by the 15th to take effect on the following month; give old address as well as new. Domestic trade is supplied by the American News Company or its branches.

We solicit communications from practical men on subjects pertaining to railway machine shop practice, for which the necessary illustrations will be made at our expense. All copy must reach us by the 5th of the month preceding publication.

SEPTEMBER, 1906.

We are informed by Wilhelm Schmidt, the inventor of the Schmidt locomotive superheater, that 1,150 locomotives (in use on forty-five railroads) have been fitted with his type of superheater up to June, 1900. The Prussian railroads have agreed to pay him a royalty on at least 1,200 locomotives within six years and during the past year have ordered 420 superheater locomotives.

* * *

A note in the *Engineering News* gives the length of the greatest stretch of straight railroad track in the world as 65 miles, placing its location in the pampas of the Argentine Republic. A correspondent of a Los Angeles paper gives 175 miles as the length of a tangent track in the Argentine Republic, and states that the character of the ground would have permitted the road to continue for thirty miles further.

* * *

A news report states that the New York Central authorities expect to have the main line of that road out of New York operating with electric traction by October 15th of this year. On July 20th tests were made of two electric locomotives furnished by the General Electric Co. for this installation. A train was made up composed of one of these locomotives, a steel motor car designed for suburban service, and a steam locomotive. The make-up of this train allowed comparative tests to be made of each of these three forms of motive power, which were tried alternately. So far as ease of operation, handling, and rapidity in starting and stopping the train were concerned, the electric locomotive is said to have easily distanced its older rival. The announced present intention of the New York Central Railroad is to employ electric locomotives for all trains between Grand Central station and Croton, a distance of 35 miles north, where steam locomotives will be attached to the trains for the remainder of the journey to Albany. Meanwhile the third rail equipment is being hastened on other branch roads of this line.

* * *

One of the pressing troubles of railroading is that terminal facilities have not kept up with the growth of the locomotive. Roundhouses are too small, switches are inadequate, and turntables are notoriously too short for handling modern locomotives of the heaviest type. The expedients resorted to for turning long locomotives on short turntables are of a more or less varied nature; the one used by the Erie R.R. at the Jersey City terminal is quite novel. This turntable, by the way, is electrically operated, the feed wires being connected trolley-wire fashion to a pivot mounted on a bridge over the center of the table. The table is lengthened out for long locomotives by two rails tapering to wedge points at one end and supplied with clamps or stays which slip over the turntable rails; the rails stand at a slight angle above the turntable rails when in place. The locomotive is backed on from the opposite end and one pair of wheels of the tender truck runs upon the inclined rails sufficiently to clear the rails of the surrounding tracks. In this way a locomotive three feet or more longer than the turntable is handled after a fashion, and the expedient may be a hint to other railway terminals troubled with locomotives "too long for the bed."

* * *

LARGE LOCOMOTIVES.

In the course of a paper read by Mr. G. M. Basford before the Pacific Railway Club, February 17, 1906, mention was made of the surprising growth of the locomotive within the last twenty years. In 1888 Mr. M. N. Forney stated that in the previous thirty years the size and weight of passenger locomotives had doubled and a total weight of 100,000 pounds had been reached. He asked the question: "Will this rate of increase continue and in another twenty years, or 1918, will there be passenger engines running which will weigh 200,000 pounds and over?" The answer is that with twelve years yet to come we now have passenger locomotives weighing 236,200 pounds, having tenders weighing 163,000 pounds alone. In October, 1898, the large consolidation locomotives built for the Union Railway by the Pittsburg Locomotive Works were announced as the heaviest locomotives of the time. They weighed 230,000 pounds, but the Lake Shore Prairie type locomotive built by the American Locomotive Co. at the Brooks works in 1905 weighed 236,200 pounds, or more than the "enormous consolidation locomotives" of only six years ago.

Mr. William Forsyth, in an article published in June, 1900, predicted that in 1905 freight locomotives would have a tractive power of 70,000 pounds, and that the weight on the drivers would reach 280,000 pounds, with a total weight of 311,000 pounds; that the heating surface would be fully 4,000 square feet. The Mallet articulated compound locomotive built for the Baltimore & Ohio Railroad a year before the date mentioned by Mr. Forsyth has a total weight of 334,500 pounds and a total heating surface of 5,585 square feet. The point to be made is, of course, that the growth of the locomotive has exceeded the most sanguine dreams of men who were well qualified by reason of their experience to anticipate in some measure what the probable growth of the locomotive would be. The growth has been so rapid that it has outstripped the facilities of the roundhouses, terminal facilities, turntables and all other facilities of the railroad built for the accommodation of smaller motive power, and these limitations have been largely responsible for the so-called failures of the big locomotive. In regard to increased capacity, the tendency now seems to be to increase the boiler capacity rather than the tractive power. There are those who believe that the next advance in boiler power should take the form of boiler capacity without increasing the weight on the driving wheels. Greater boiler capacity would mean that trains could be handled at greater speed, although the tractive power for starting and accelerating would not be greater than heretofore.

* * *

A Western correspondent sends us a clipping from a local Iowa newspaper describing an oil burning motor passenger car recently put in service on the C. B. & Q. R. R. It is of interest to know that this engine is "160 pounds horse power," but its chief interest to railroad men is that nothing comes out of the stack of this engine, except the exhaust. Judging from the character of the article, we think that considerable "hot air" came from some source; but perhaps the engine differs from the reporter in that it provides for the consumption of its own product, while the reporter has to inflict his on the unfortunate public.

"The boiler of the engine has a capacity of 170 pounds of steam and is 160 pounds horsepower. The boiler is fed from a large water tank under the combination passenger and baggage car, which is built on the engine, having a capacity of 650 gallons of water. Next to the water tank is a large oil tank with a capacity of 110 gallons. Leading from the tank are pipes which carry the oil to the fire, hundreds of small burners having been placed in the interior of the fire box. That the burning of oil is much cheaper than coal is shown by the fact that but two gallons of the fluid are used to every mile, it being necessary to fill the tank at the end of every fifty miles. There is no smoke, nothing but the exhaust coming from the stack of the engine.

THE RATIONALE OF INDUSTRIAL BETTERMENT.

The editor of MACHINERY in a recent letter to the writer stated: "I find that while nearly all manufacturers with whom I have talked on the subject are entirely in accord with the efforts now being made to provide better surroundings for their operatives, some of them object to the introduction of social features in works management. The objection raised to these features is that they are liable to be construed as a form of paternalism which workmen strenuously object to. Perhaps I cannot do better than to quote the following opinion from a well-known manufacturer:

"'We do not believe that it helps a man to give him something for nothing, and we do not believe that he wants it. We have seen in a great many instances throughout the country where various plans of this kind have been tried, that men rather resent it and look upon it as a charity which is not desired. We believe in giving a man a chance to earn his recreations rather than provide them for him gratis, and we feel that all plans worked out on a basis of giving a man something for nothing are bound to fail, for the very reason that it can be nothing other than more or less of a charitable distribution, and that the American workman is above anything of this nature.'

"It seems to me that it is at this point where manufacturers frequently make a mistake, and any assistance that you can give to such of our readers as are looking into the subject will be appreciated, and I believe there is a chance that it will do a great deal of good."

The fact that the editor of MACHINERY feels that I can, from my experience in this new field of endeavor, be of assistance to the readers of his valued paper, who, I am glad to know, are interested in the subject, encourages me to seize the opportunity thus offered to meet the issue which is raised by the manufacturer above quoted, for, I feel that there are some who, like the latter, have a misunderstanding of the object of the features referred to, and there are also some, who, like those of whom he writes do not understand at all what these features mean. Before touching upon the phase of the subject which is here alluded to, let me for a moment consider the origin of the general movement in which it is involved.

Somewhat more than a quarter of a century ago the German government, impelled by paternalistic motives characteristic of its monarchial system, introduced into some of its subsidized industrial establishments certain features which were intended solely to improve the condition of the workers. These were appropriately termed Wohlfahrt's Einrichtunden, or "welfare institutions." These features, consisting of lunch rooms, rest rooms, libraries, emergency hospitals, gymnasiums, athletic grounds vegetable gardens, and the like, had been tried by certain manufacturers in England and elsewhere who were altruistic in their nature and co-operative in their beliefs. American manufacturers, driven by the fierce competition of the times to adopt every possible means of increasing the efficiency of their plants, were traveling abroad to study foreign industrial methods, and seeing these "institutions," were at once impressed not only with their novelty but with the improvement in the general prosperity of the enterprises in which they had been introduced. They saw at once that these improved conditions were attracting a better class of operatives, that the latter were doing more and better work, and that this resultant high-grade product was obtaining higher prices in the market. Impressed with the idea that there were economic principles involved in these features which they could not afford to ignore, they carefully investigated them, and on their return home proceeded to try them out under conditions as they existed in their own establishments.

It soon became apparent that fundamentally these institutions were not only ethical, but economic. That the so-called enlightened selfishness exemplified in the Golden Rule pays its possessor many fold.

It was evident that the better the operatives were housed and fed, and the better their habits were outside of working hours, the better would be their general physical condition and the more regular would be their attendance; that the higher their mental attainments the more intelligently they would conserve their strength and apply their knowledge and skill and the business would thereby be improved and the profits increased.

It became evident, however, that the democratic tendencies of American workmen would not allow these features to be applied in the paternalistic manner adopted by the German manufacturers. Our people had been brought up to be independent and self-reliant, and resented having forced upon them anything which savored of charity. Now, manufacturers had long learned that machines represent capital invested and that the only time this investment is earning interest is when the machines are running and turning out product to be sold, so that any means that could be adopted that would tend to keep the machines continuously productive and at the same time insure high grade of product, would raise the interest on the investment. They soon realized that these features which they were investigating were productive of exactly what they were desirous of accomplishing, and they lost no time in introducing them in their establishments with such modifications as they found were necessary in transplanting foreign institutions to new soil.

The remarkable results which attended the intelligent installation of these features, which were given the appropriate appellation of "Industrial Betterment" led other manufacturers to their adoption, but many of the latter, not realizing their fundamental object, applied them indiscriminately and scored failures. They seemed to think the motive was essentially altruistic and adopted paternal methods of applying them, calling them "welfare work" and arousing well-merited resentment. The correspondent to whom the editor refers says rightly that there are "a great many instances throughout the country where various plans of this kind have been tried" which have not met with success, but these failures have been due to a lack of understanding of the purport of the installation and accompanied by ignorance of the proper method of its introduction. He, himself, misunderstands the purport of the movement and cannot see the benefits which have accrued in those other instances where the installation of these features has been a great success. The term "welfare work" has misled him.

There are plenty of men who mistake the substance for the essence who "cannot see the forest for the trees." There is no "welfare work" about it. It is "Industrial Betterment."

It is efficiency of organization that the modern business man is anxious to secure, and this can be obtained by "Industrial Betterment" intelligently installed. This is no longer in the experimental stage; it has too often proved successful, and the manufacturer who delays its adoption is simply closing his eyes to the advance of the times and to one of the most potent means of promoting his own interests.

H. F. J. PORTER.

* * *

The novelty of an invention very often consists in the recognition of a want rather than in the specific form in which this want is satisfied. Many of us go through life knowing in a vague way that certain ways of doing things are not quite satisfactory, but when some one recognizes this fact and provides a tool or device which accomplishes the work much more easily and satisfactorily than before, we are all prone to wonder why we had not thought of the same thing ourselves. The point is, that when the need was fully recognized the tool or device necessary for forming the required work was a comparatively simple accomplishment. The need of some devices, however, is so obvious and has been recognized by so many people that thousands of inventions have been devised to fill the want, as, for example, the car coupler and the non-refilling bottle. To make the business of inventing pay, the inventor must, in general, recognize a need before others do.

* * *

The use of opaque or ground glass for the lower sections of shop windows is often desirable, but it is not advisable unless the interior has a clear unobstructed view in some direction of, say, one hundred feet. The reason is that men working on anything requiring close attention of the eyes are likely to suffer from eye-strain if they cannot occasionally relieve the strain by focussing them on some distant object, and this cannot be done in a small room with opaque glass in the windows.

ENGINEERING REVIEW.

CURRENT EVENTS, TECHNICAL AND MECHANICAL—LEADING ARTICLES OF THE MONTH.

The *Engineering Record* reports the use of the electromagnet in recovering lost drill points at various places in Pennsylvania. At Greenburg a heavy point stuck at a depth of 250 feet in a well, but it was readily loosened and brought to the surface by an electromagnet.

It is reported that the Carnegie Steel Company will drill a well 6,000 feet deep in the gas field near Waynesburg, Pa. It will be done to test a theory that the gas sands now being developed are only the top or secondary sands, and that the primary and principal producing sand strata will be found underlying it several thousand feet. The experiment is attracting considerable attention, not only because of the possible discoveries but for the special derrick and machinery required for drilling such a deep bore.

It is reported in *Page's Weekly* that there is a likelihood of a revision of the agreement entered into by the English Engineering Employers' Federation and Amalgamated Society of Engineers. This historic agreement was adopted after the great strike in 1897. The scope of the proposed changes may be indicated by three suggested amendments. One is that the Federation shall recommend the preferential employment of society men, instead of leaving firms to employ whom they choose, a freedom of management for which the federated employers sacrificed so much in 1897; another seeks to limit the number of apprentices; and a third asks that the maximum overtime shall be 20 hours per man per month, instead of 40 hours, as at present.

It is stated in the *Engineering Record* that in the survey of a new 14-foot water way between Chicago and St. Louis the leveling for a distance of 334 miles was done with a probable error for the whole length of only about 13.55 millimeters, or slightly over one-half an inch. The level was protected from the sun by one large umbrella, while another, held by a rod stuck in the ground, cut off the wind. When the immense distance covered is considered, the error is so slight that the instrument used ranks in accuracy with the finest tools employed in machine shop measurements. It is quite possible that the transit as employed to some extent by the Westinghouse Electric and Mfg. Co. and others, deserves a larger field of usefulness in the machine building business.

The United States Consul at Venice says that some of the high-power motors in the Monte Carlo races had a universal joint in the shaft, between the motor and the thrust bearing, so that the possible deviation of the shaft from a straight line, through vibration, or the straining of the boat, would not affect materially the running of the motor. This feature is believed to be valuable even on the smaller boats. Another feature of interest was the seemingly exaggerated precautions against eddies, such, for example, as tapering the end of the shaft to a point beyond the propeller, and also the knife-edge of the stem. In a series of experiments made last year by a Scotch designer, the difference in the fineness of the stems of ships has been shown to influence their speed very materially, and this seems to have been taken into account in the construction of the racing boats of this year.

There has long been a demand for some arrangement by which the amount of material remaining in a bolt of ribbon or cloth can be ascertained at a glance. As a means of doing this the suggestion was made that a tape be wound up with the ribbon, the tape being marked with inches, feet and yards, but when this was tried, it was found that there was a serious discrepancy in the respective lengths of the two pieces. This difficulty has now been overcome by slitting the paper tape at regular intervals, and passing the ribbon in and out through these slits. This innovation, which is the invention of a Chicago ribbon manufacturer, will not only be of great assistance in the shop, where the ribbon may be measured off in the required quantities without the use of a yard-stick, but will be also found to greatly facilitate the work of stock taking, which in the case of ribbons, cloths, and similar materials is a very tedious operation.—*Scientific American.*

In connection with the recent launching of the *Lusitania*, *Engineering*, of London, gives some figures showing the total tonnage of the recent launches on the river Clyde. The month of June, 1906, will long be remembered for its record in this respect, the total being 124,544 tons, which is very much greater than the figures for any previous month. This great increase is of course accounted for by the coincidence that the Cunard liner *Lusitania* and the battleship *Agamemnon* both happened to be ready for launching about the same time. Without these two larger vessels, however, the other 34 craft make the very respectable aggregate of 75,544 tons. The total for the last six months stands at 335,258 tons, a record which probably will not be surpassed for some time to come, as new contracts are not being placed so rapidly now as they were two or three years ago.

A correspondent of the *London Times* in the engineering supplement of that journal states that what is believed to be the largest and heaviest lathe yet built has recently been furnished by Messrs. Hulse & Co., of Mancheser, England, to the shipbuilding firm of Messrs. R. & W. Hawthorne, Leslie & Co., of New Castle-on-Tyne. This lathe is to be used in machining the rotor and other parts of the steam turbines which are building for the Cunard express steamer *Mauritania*, sister ship of the *Lusitania.* It will take work up to 16 feet in diameter over the carriage or 18 feet over the ways if the work is held on the faceplate. The bed is 18 feet wide by 68½ feet long and work 50 feet in length may be held between the centers. The machine is operated from platforms, and short ladders are necessary to enable the workman to mount the platform from the level of the bed. While longer lathes have been built for such work as gun turning and boring, and lathes of larger swing have been built for turning flywheels and other such work, it is doubtful if a larger lathe for general purposes has ever been built.

A commercial combination of a peculiar character is reported from England. The firms manufacturing coal cutting machinery have been troubled by colliery owners who have asked to have machinery put to work in their mines on trial. Owing to the competition in this class of machinery the builders have been forced to do this. The mine owners have taken advantage of this competition and have lengthened the trial period by all means possible from month to month, thus getting extended service from the machinery without having to go to the trouble of purchasing it. When they could no longer use them free, many of them have sought to enter into arrangements whereby they could rent the machines for a comparatively low price. This has also proved unprofitable from the manufacturer's standpoint, since rented machinery is very naturally used much harder and is less well-cared for than that which is owned by the users. The new combination is based on an agreement of the builders of coal cutting machinery to refuse to rent their product and to refuse trial of the machines except under certain definite restrictions.

The *Engineering Record* reports some tests of steel at low temperatures made during the past year at the Watertown Arsenal in Massachusetts. The steels tested varied in quality from 0.16 to 1.09 per cent carbon. The elastic limit of the steel in one of the bars was 80,000 pounds per square inch, with an elongation of 10.7 per cent at the low temperature of the liquid air. A similar specimen tested at a room temperature of 76 deg. Fahr. showed an elastic limit of 52,800 pounds per square inch, an elongation of 29.3 per cent, the effect of the very low temperature being to increase the elastic limit of the steel 51 per cent, while the ultimate strength of the steel was raised to 97,600 pounds per square inch, or 35 per

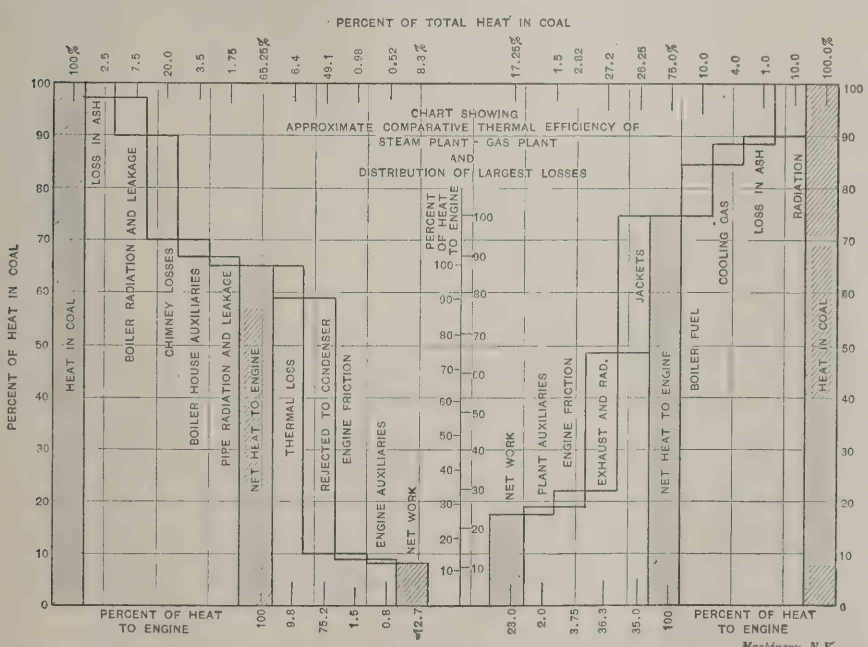
cent above the ultimate strength at ordinary temperatures. The results of these experiments are similar to those that have been obtained by numerous other experimenters, who have investigated the properties of steel under the same conditions, in that it is shown that a great increase is produced in the tensile strength of steel at low temperatures, with a corresponding decrease in ductility.

THE ACTION OF THE CAPPED SHELL.

There is something mysterious in the action of the well-known soft metal cap for armor piercing shells, such as was illustrated in the article on projectile manufacture in the August issue. Perhaps the most commonly accepted theory to account for its effectiveness is that which considers it as melting at the instant of impact, and acting as a lubricant for the nose of the shell during its passage through the armor. This idea is untenable, however, since it would hold true in the case of penetration of soft armor only, and not in the case of hardened steel where the metal is cracked and shattered. In reality the device is more effective when piercing hardened materials than it is for softer ones. An army officer contributes to the *Journal of the United States Artillery* a translation of a paper read by a German engineer, who ascribes the effect to a different cause. He considers it to be due to the fact that the point of the projectile is by this means saved from deformation at the instant of the impact. The mass of soft metal in which it is imbedded acts as a cushion and distributes the pressure over a fairly large cross section, instead of allowing it to concentrate on the point, which it would otherwise fracture. This point is thus preserved to act as an effective chisel in piercing through the hardened outer layer of the armor plate; the wedge shaped body of the projectile following, serves to increase the opening thus effected.

RELATIVE ECONOMY OF STEAM AND GAS ENGINES.

At the recent meeting of the Ohio Society of Mechanical Engineers, Mr. J. R. Bibbins presented a paper on "Gas Engines in Commercial Service," which was accompanied by a chart that showed very clearly the comparative economy of steam and gas engines, in so far as fuel is concerned. This chart is presented herewith. The performance of the steam



Comparative Efficiency of Gas and Steam Power Plants.

engine, from the coal pile to the work done is shown on the left side, and the performance of a producer gas engine on the right side. In reference to this chart, Mr. Bibbins says:

"In the accompanying chart the writer has attempted to make an approximate distribution of losses in various parts of the plant, based upon observations from numerous sources on each of its component parts. It is believed that the estimates are not unduly partial to either a gas or steam plant of moderate size.

"Starting with the heat in a fair grade of steam coal, 13,500 British thermal units per pound, we find 35 per cent of this heat dissipated in the boiler plant and piping system, and 25 per cent in the producer plant. Fifty-seven per cent is, however, dissipated in a steam engine, and approximately the same in the gas engine, leaving 8⅛ per cent net output for the steam plant and 17¼ per cent for the gas plant. Thus on a heat basis, gas is twice as efficient as steam. Part of the advantage lies in the more efficient converting properties of the producer and the remainder in the higher thermal efficiency of the gas engine. In natural gas plants where no producers are necessary there is, of course, no question as to the superior economy of gas.

"Granted the superior economy of the gas plant, it is also necessary to take into account not only operating costs, but investment costs or fixed charges to arrive at a proper conclusion. Without going into this economic problem here, it is sufficient to say that plants of a few hundred kilowatts capacity may quite possibly cost more per kilowatt than a steam plant of corresponding size and character, but the saving in the operating expenses will soon wipe out the excess cost and eventually put steam 'out of the running.'" W. B. Jr.

ACETYLENE GAS FOR WELDING.

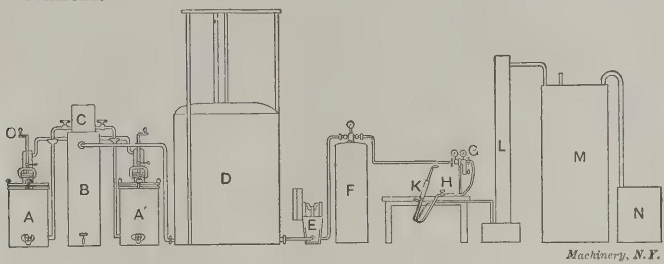
Under the heading "Autogenous Welding of Metals by the Oxy-acetylene Blowpipe," M. Andre Beltzer gives a description and illustration of apparatus for this process in the *Electrochemical and Metallurgical Industry.* The oxy-hydrogen blowpipe has been used for this purpose, but is expensive and unsatisfactory, where much heat or high temperature is required. Acetylene gas is more suitable on account of being cheaper, and also because the temperature of the flame is much greater, being about 6300 degrees F., while that of hydrogen is about 3600 degrees F. The obstacle that has stood in the way of using the acetylene blowpipe has been the high price of oxygen. M. Beltzer states, however, that oxygen can now be obtained at a reasonable price by the use of a newly-discovered product called "epurite." This substance contains oxygen in a latent form which can be easily liberated by contact with water, the same as acetylene is obtained from calcium carbide. When oxygen is obtained by this process, not only is the cost reduced to a reasonable point, but all danger of explosions arising from the use of gas confined under high pressure in tanks is removed. An oxy-acetylene blowpipe welding outfit provided with an "epurite" oxygen generator is illustrated diagrammatically on the following page.

One of the oxygen generators *A* is charged with water and epurite. In the receptacle *C* is a solution of sulphate of iron, which is allowed to flow into the generator to act as a catalytic agent for the generation of oxygen. The oxygen liberated passes into the gasometer *D*, and is compressed to 10 atmospheres by the compressor *E* in the tank *F*. From the tank the gas passes by a tube through the pressure regulator *G* and valve *H* to the blowpipe *K*, where the oxygen should arrive at a pressure of 60 inches water. The acetylene apparatus *N M* is arranged so as to give the gas at the above pressure. This pressure of 60 inches water is calculated so that the exit speed of the gas will counteract the possible back burning of the mixture before reaching the end of the blowpipe.

The blowpipe is provided with metallic gauzes to prevent the flame throwing back. The valve of the acetylene tube (fixed to the blowpipe) is at first turned on full, the pressure regulator being adjusted to about a one-half atmosphere. The flow of oxygen is controlled by a valve *H*, so that there is only one inner cone in the flame which will have only slight fluctuations. The flame now is neutral and ready for use.

A whiter color of the flame and the division of the inner

cone in two are indications that there is an excess of acetylene gas, and that the flame is carbureting, the molten metal emitting sparks like stars (formation of cast iron). When the flame is oxydizing (shown by the violet tint of the flame) the metal boils and is very bright. For proper welding (steel sheets, for instance,) the joint should be bright. The carbureting flame gives a gray porous and non-resistant welding. This flame, together with an oxydizing flame, gives a brittle welding, and is, moreover, very rarely used. Twenty different sizes of nozzles can be used on the same blowpipe in welding of all thicknesses, from 0.04 to 1¼ inch thick (0.024 inch for sheets 0.04 inch thick, and 0.16 inch for sheets 1¼ inch in thickness.



Apparatus Required for Welding with Acetylene.

During the process of welding, the apex of the cone must be from 0.08 to 0.12 inch distant from the object to be welded. The two edges (previously dressed) are fused, and simultaneously lined and slightly overloaded by the fusing of a rod of the same metal held in the flame. In this manner iron, steel, copper, brass, cast iron, etc., can be effectively welded. For thick metals or plates it is necessary to bevel the edges, which can be readily done by many mechanical methods.

For brass it is necessary to fill up the interstices of the two sheets to be welded with borax moistened with water, otherwise the volatilized zinc would be deposited on the welded part as oxide of zinc and spoil the welding.

From tests made by the International Bureau Veritas, in Paris, it has been found that the tensile strength of welds made by this process is within 5 per cent of that of the metal itself. The cost of the process for sheet metal work is less than riveting for thickness under about five-sixteenths of an inch.

IMPACT TESTING MACHINE.

In testing metals to determine their resistance to impact, two methods are commonly used. One is to strike a single blow strong enough to bend or break the test piece; the other is to strike numerous light blows and ascertain the number required to produce fracture or actual breakage of the specimen. The latter method is the most desirable because it gives the strength of the metal when subject to the conditions it has to meet in practice. When the test piece is struck many blows, it is necessary to rotate it through half a turn at each blow so that it may be bent or sprung back and forth with the successive blows. If this rotating is done by hand it takes considerable time, so that only a comparatively small number of blows can be struck, five or six hundred. For the purpose of conducting certain impact tests, the National Physical Laboratory of England has had designed and made a machine in which the test piece is turned through 180 degrees at each blow automatically. This machine strikes about forty-five blows per minute, which are recorded by means of a registering apparatus attached to the shaft. The construction and operation of the machine can be understood from Figs. 1, 2, and 3, together with the following description, which we reproduce from *Engineering:*

The hammer, *A*, is provided with a hardened-steel shoe where it comes into contact with the specimen, and two side-rods passing through the base-plate and terminated by a cross-head, *B*. The cross-head is fitted with a small roller for engagement with the lifting cam, *C*, and with two conical rollers working in vertical guides, *D*, which take the hori-

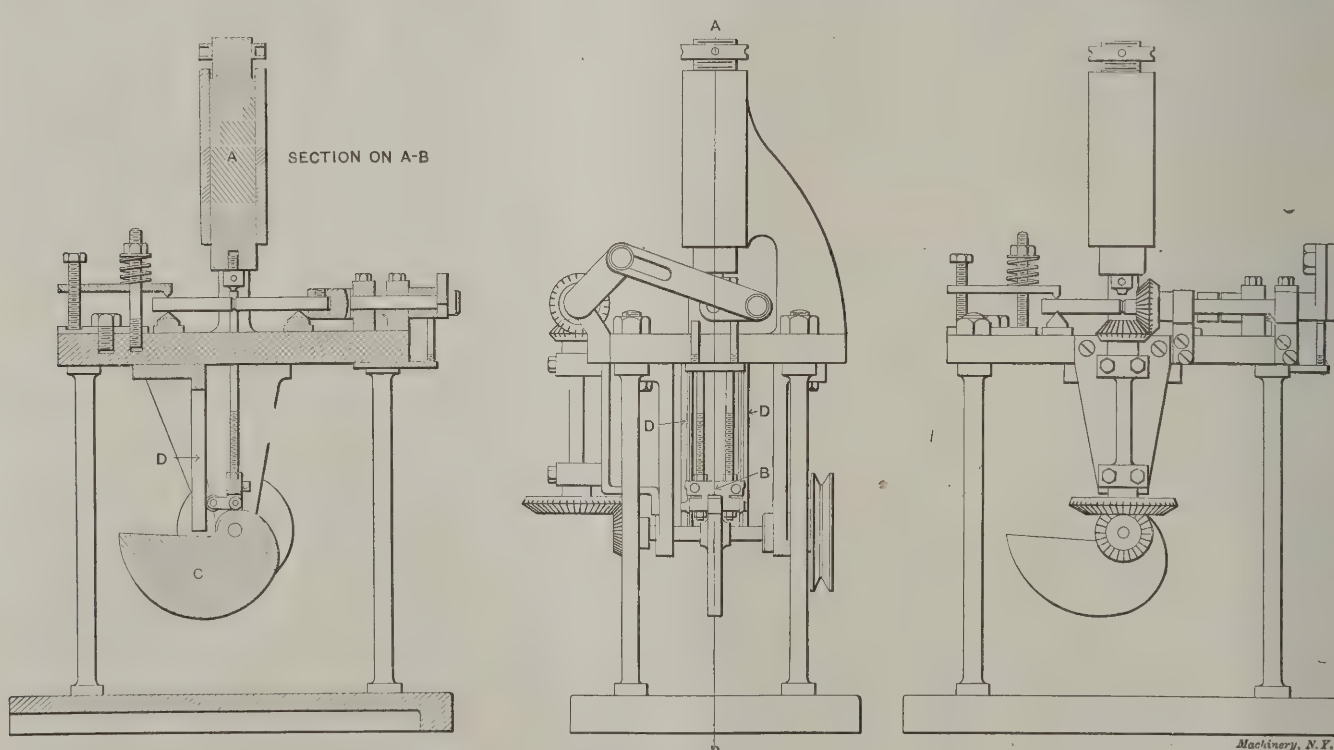

Fig 1. Fig 2 Fig 3.

An Impact Machine for Testing Steel Specimens.

Cast iron, which cannot be self-welded, must be brazed with copper.

One decided advantage of the oxy-acetylene flame over the oxy-hydrogen is, that it can be easily regulated by the workman, owing to its brightness. Another advantage is that the gases formed by the combustion are hydrogen and carbon oxide, which combine with the surrounding air, forming carbonic acid and water, thus protecting the molten metallic surfaces from the oxidizing action of the air,

zontal thrust of the cam. The side-rods are attached to the cross-head by lock-nuts, so that the fall of the striking hammer can be regulated from 0 inch to 3½ inches. The cam shaft makes approximately 45 revolutions per minute.

To rotate the specimen through 180 degrees between successive blows a link motion is employed, which is worked from a countershaft parallel to the specimen, and revolving at half the speed of the cam shaft. A second shaft, whose axis coincides with that of the specimen to which it is coupled,

receives its motion from the countershaft by means of the two cranks and slotted link shown in the figures. By correctly proportioning the length of the slot, it can be arranged so that when the motion of the crank on the countershaft is continuous, that of the crank on the second shaft is oscillatory through an angle of 180 degrees.

In order that the second shaft shall not interfere with the free vibrations of the specimen when struck, its attachment to the specimen is made by a semi-Oldham coupling, which is set so that the plane of its slot coincides with the plane of free vibration of the specimen. The knife-edges on which the specimen rests are made of V shape, so that there is no tendency for the specimen to move sideways. The specimens are ½ inch in diameter, the knife-edges being 4½ inches apart. The diameter at the bottom of the notch is 0.4 inch.

If the fall of the hammer is adjusted so that the specimen will bear not less than, approximately, two thousand blows before fracture, there is no appreciable permanent set in the specimen until a comparatively short time from the ultimate fracture. The manner of failure of the specimens, whether of soft or hard material, is that a crack is developed on each side of the specimen in the plane of the notch, the two cracks proceeding inwards as the test proceeds.

The machine seems likely to be of considerable service in the impact tests of mild steels which cannot be broken, even when notched, by the single-blow bending method. The following is an example of a set of tests made on a sample of mild steel:

Fall of Striking Hammer in inches.	Energy of Blow in inch-pounds.	Number of Blows for Fracture.
0.77	3.62	4,950
0.50	2.85	12,400
0.30	1.41	44,634

NEW GERMAN TURBINE.

The *Gesellschaft für Elektrische Industrie*, of Carlsrube, in Baden, Germany, has brought out a type of steam turbine which, while not new in principle, is different from the design that is almost universally used, at least by the large manufacturers. This turbine is shown in Figs. 1, 2 and 3, the first being a vertical section at right angles to the shaft, the second a vertical section parallel with the shaft, and the third a perspective view of the wheel. As will be seen from Fig. 1, this is a four-stage turbine, in which the stages are obtained

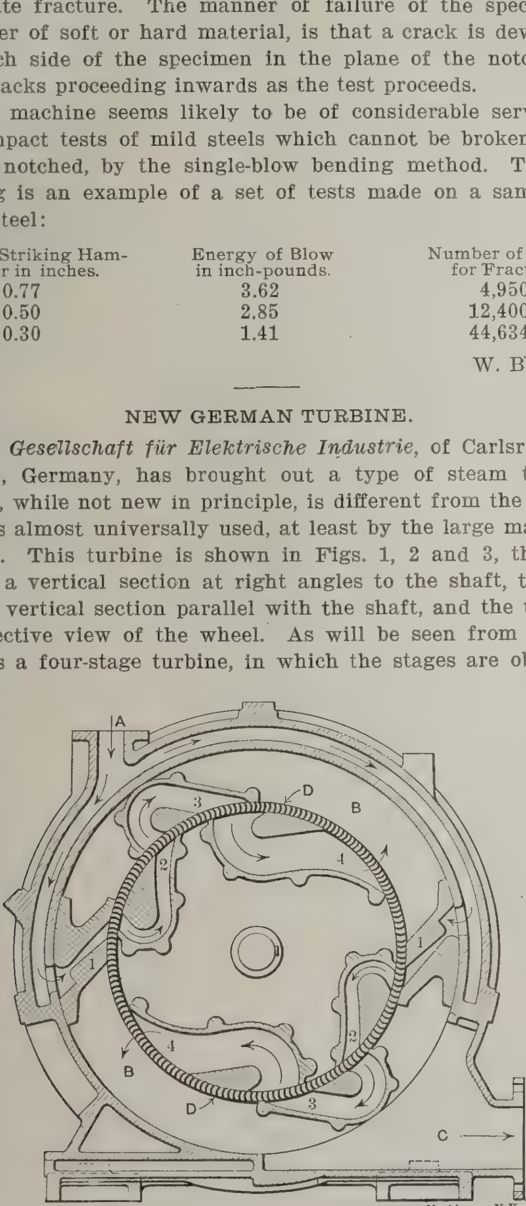

Fig. 1. Cross-section of a German Steam Turbine.

by passing the steam through the buckets of the wheel four times. Steam enters at A and passes from nozzles 1 through the wheel buckets to nozzles 2, thence through the wheel a second time to nozzles 3, and a third time through the wheel to nozzles 4; the fourth passage through the wheel carrying the steam to the spaces B, from whence it passes to the exhaust pipe C. When we consider that in the designs in which each stage requires one wheel, the first few wheels do not utilize more than a small portion of the periphery, we can easily see that the construction here shown should afford the means of producing a decidedly compact machine, and probably at a lower cost than the multi-wheel type. On account of the compact construction, this turbine should be well adapted to launches. Fig. 2 shows a reversible boat turbine. It is made with a wheel having buckets on both sides, the

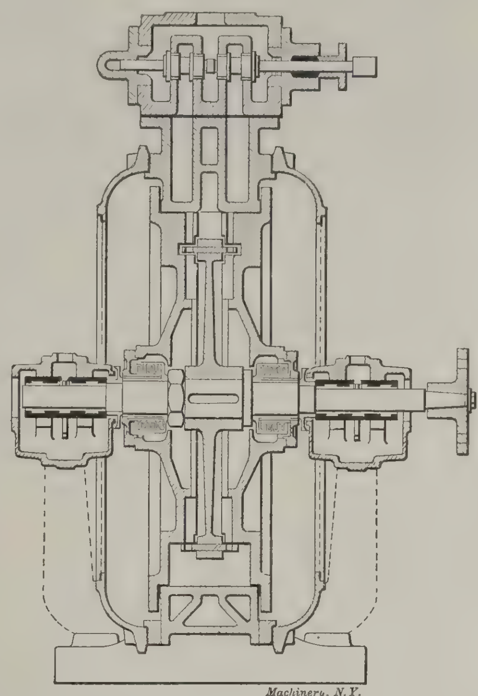

Fig. 2. Arrangement of Reversible Marine Turbine.

buckets and nozzles on one side running in the opposite direction of those on the other side. By means of the valve seen above the turbine casing, the steam can be directed to either side to produce rotation in whichever direction is desired.

OLD STEAM ENGINE AT THE VERSAILLES WATER WORKS.

Revue de Mecanique, May 31, 1906.

In the early part of the nineteenth century when the reconstruction of the pumping station for the Versailles water works was under consideration it was proposed that a steam engine be substituted for the water wheels previously used. The matter was placed in the hands of a commission in 1811, but it was not until October 14, 1821, that the matter was settled and the foundation laid.

The installation included a steam engine and boiler as well as the cast-iron piping a foot in diameter. Like the majority of steam engines of the day, the machine that had been proposed by MHessrs. Cooke and Martin was of the beam type, working under a low pressure and condensing. The steam cylinder had a diameter of 42.6 inches and a stroke of 76.77 inches with a thickness of shell of 1.42 inch. It was fitted with a steam jacket, and the steam distribution was effected by means of two valves driven by an eccentric mounted on an intermediate shaft to which the main crank was attached at the end of the beam on the opposite side from the cylin-

Fig. 3. Construction of the Wheel and Blades.

der. This eccentric also, by means of a lever, drove the pump by which the boiler was fed.

The piston rod of the condenser air pump was attached to the beam on the same side as the steam cylinder. The obtain a gradual and uniform tightening of the packing, as seen in Fig. 2.

After having done its work in the cylinder, the steam passed by way of a cast-iron pipe to the hot well of the condenser,

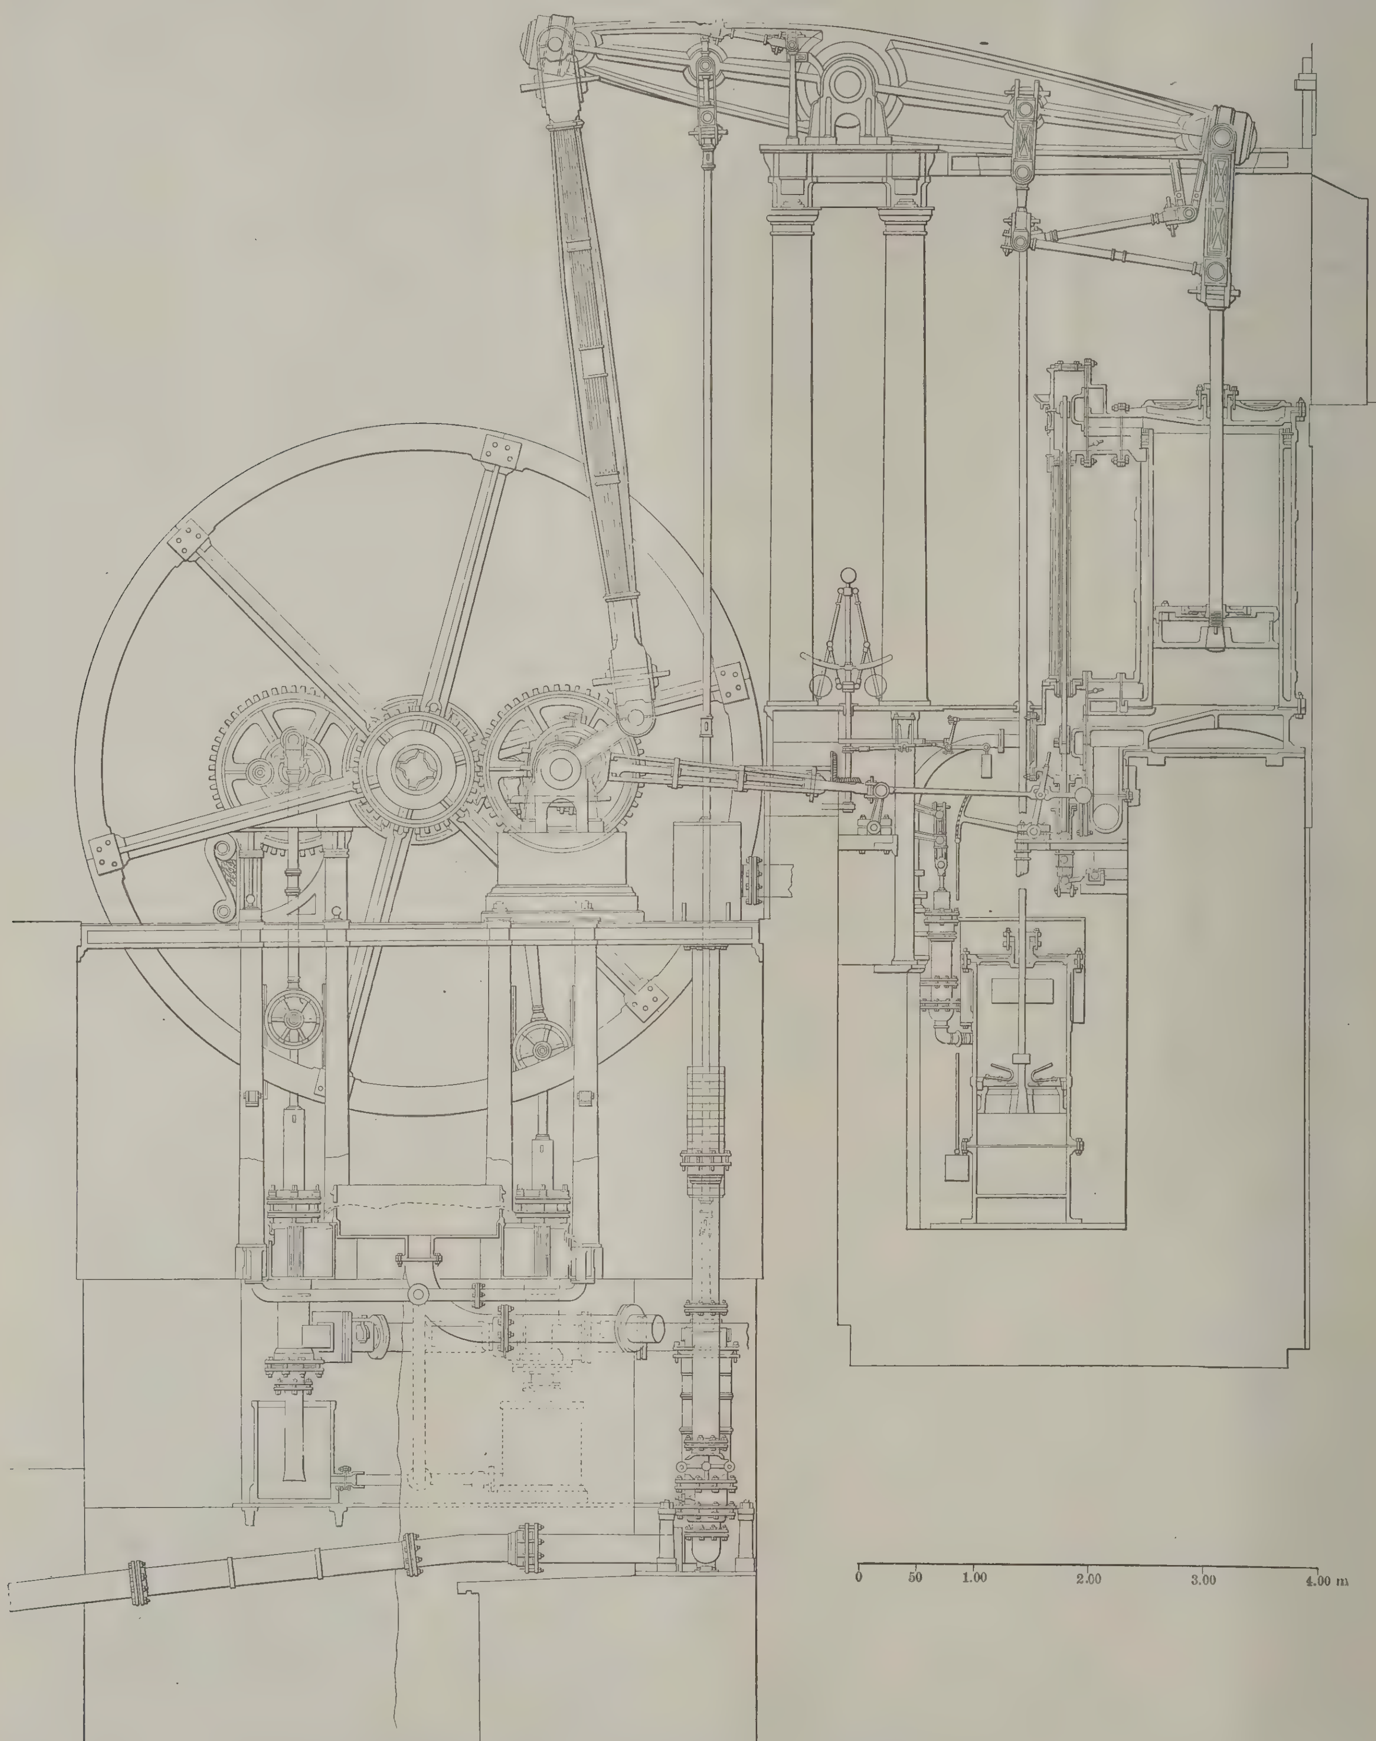

Fig. 1. Elevation of the Versailles Water Works Engine at Marley.

arrangement of the cylinder and the details of the valve mechanism are shown in the side elevation (Fig. 1) of the engine. It may be noted that the cover serving to form the joint of the piston was fitted with a toothed wheel so as to as shown in the side elevation and vertical section, Figs. 1 and 5. A jet of cold water was injected into this hot well and completed the condensing, the whole being encased in a large tank of cast iron, into which the water drawn from

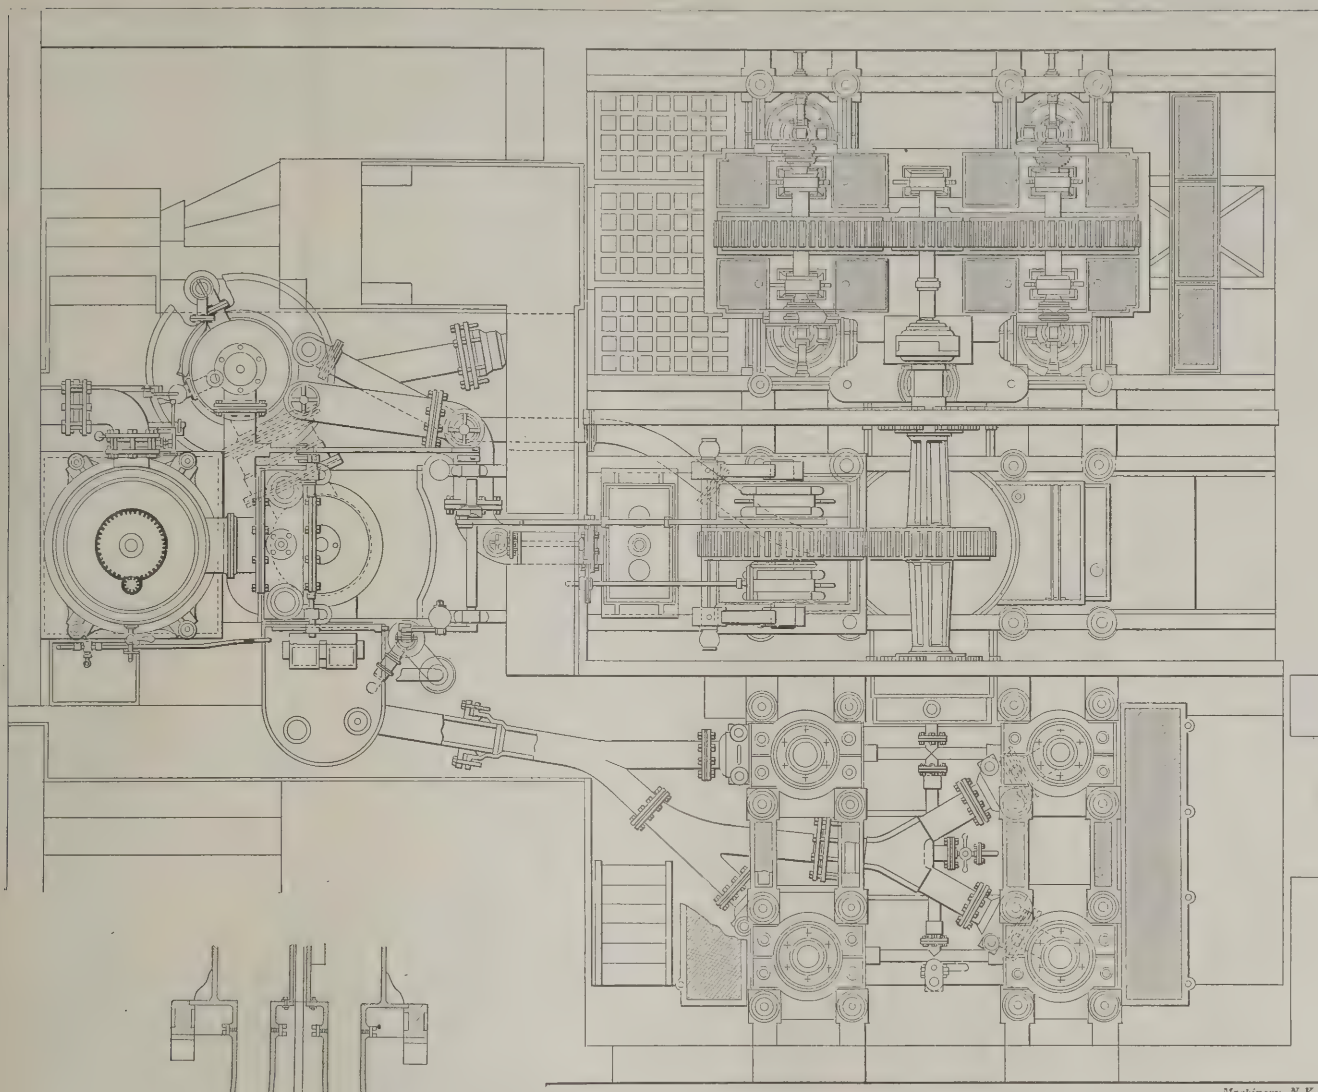

Fig. 2. Plan View of Pumping Engine.

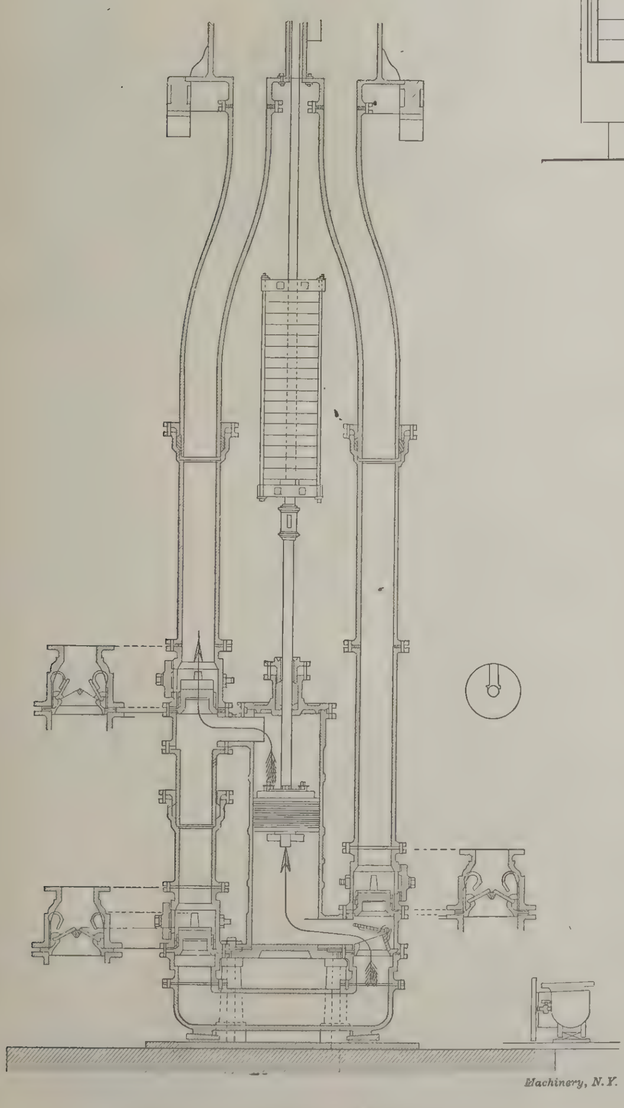

Fig. 3. Cross-section of Supply Pump.

the Seine went before entering the eight pump cylinders which forced it into the aqueduct.

The piston of the air pump is 29 inches in diameter, and delivers hot water into the tank which is to be seen at the left of the pump in Fig. 5, and from which the feed pump of the boilers also draws. The surplus of hot water which does not go to the boiler passes by a system of pipes to one of the cast-iron water tanks, located alongside the stairway of the approach to the building. All of this machinery, which is remarkable in its finish, was furnished by the Creusot shops. The trunnions of the beam are carried by four cast columns set upon a heavy masonry foundation, and an iron balustrade broken by monumental candelabra surrounds the steam engine.

The power of the cylinder was calculated to be sufficient to furnish 64 horsepower of 75 kilogrammeters per second at 14 revolutions or 14 double strokes a minute with a steam pressure of 4.5 inches of mercury or about 2 pounds per square inch. When working in this way, the engine was capable of raising 1,800 cubic meters (296,000 gallons) of water per day to the Louveciennes aqueduct. This work necessitates the consumption of about 10 tons of coal per day.

The two connecting rods fastened to the end of the beam drive cranks keyed to the ends of the first transmission shaft, which carries at its center a gear of 57 inches diameter. The eccentrics controlling the steam distribution are also keyed to this same shaft on either side of the gear. This latter meshes in with a second of 43.3 inches diameter, which is keyed to a second transmission shaft, which carries gears at each end driving a group of four pumps. On each side, between the central gear and those at the ends there is a large flywheel and a clutch coupling, so that either group of four pumps can be cut out if desired.

Each of the gears at the end of the second transmission shaft meshes with another of 57 inches in diameter, which is mounted

on the center of a shaft, at each end of which there is a crank driving a suction and force pump. Each shaft thus controls two pumps and as there are two groups of four pumps each, that forms the basis of the system.

The eight pumps just described do not draw directly from the river, but from cylinders placed directly beneath the body of the pump as shown in the side elevation, Fig. 1. These cylinders were fed from below by means of a system of piping starting from small cast-iron basins placed on a level with the upper part of the body of the pump. These basins were fitted with overflows and water-inch marks so that the amount of water which they delivered could be regulated according to the delivery of the force pumps, as shown in Figs. 1, 2 and 5.

The supply for the basins just mentioned was effected by means of a supply pump shown in detail in Fig. 3. This pump was driven by means of connecting rods attached to the beam of the engine and drew its water from the river through a pipe passing beneath the Saint Germain road. The delivery was effected through two columns fitted with bronze clap valves, and delivered into a rectangular cast-iron tank set above the pump, and slightly below the level of the transmission shaft. Cast-iron piping led from this tank to the envelope of the condenser.

From the envelope of the condenser a second system of piping led beneath the center of the cast-iron tank already mentioned. The water, after having reached the center of this cast-iron reservoir, went into three settling tanks, from which it flowed as previously stated, to the suction tank set beneath the force pumps.

This engine which was not finished until 1825, was run for the first time on July 20, but only for a moment, because of the breaking of the teeth of the gear driving the pump shafts. Trials were made the following year on February 15, March 5, April 17, August 5, and September 5 but it was not until May 5, 1827, that the engine was set regularly at work.

The following are the best results that could be obtained with this engine in the course of some accurate tests made in 1851, many years after it had been completed and after a number of improvements had been made:

Steam pressure	15 inches of mercury (7½ pounds.
Vacuum in condenser	25 inches.
Speed	16 revolutions per minute.
Power in cylinder	95 horsepower.
Water raised per day	548,670 gallons.
Power in water raised	50 horsepower.
Anzin coal consumption per hour	917.4 pounds.
Heating surface of boilers	343 square feet.

The boilers had a firebrick furnace set beneath a cylindrical shell 6 feet 9 inches in diameter and 9 feet long. These boilers were replaced ten years later by others having fire tubes inside and so arranged as to give the flames a triple circulation.

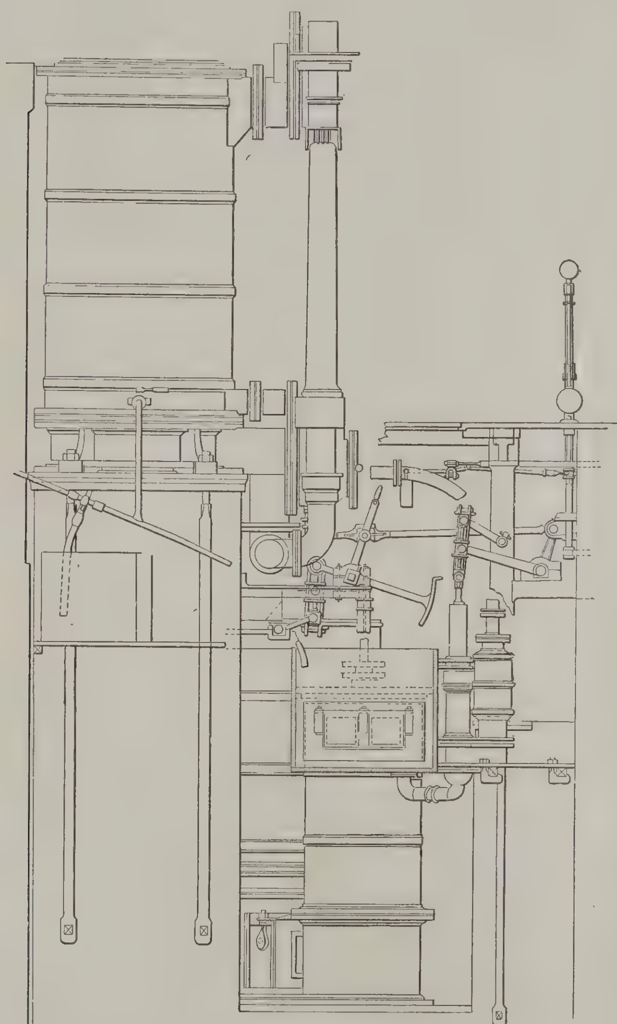

Fig. 4. Elevation of Condenser and Valve Mechanism.

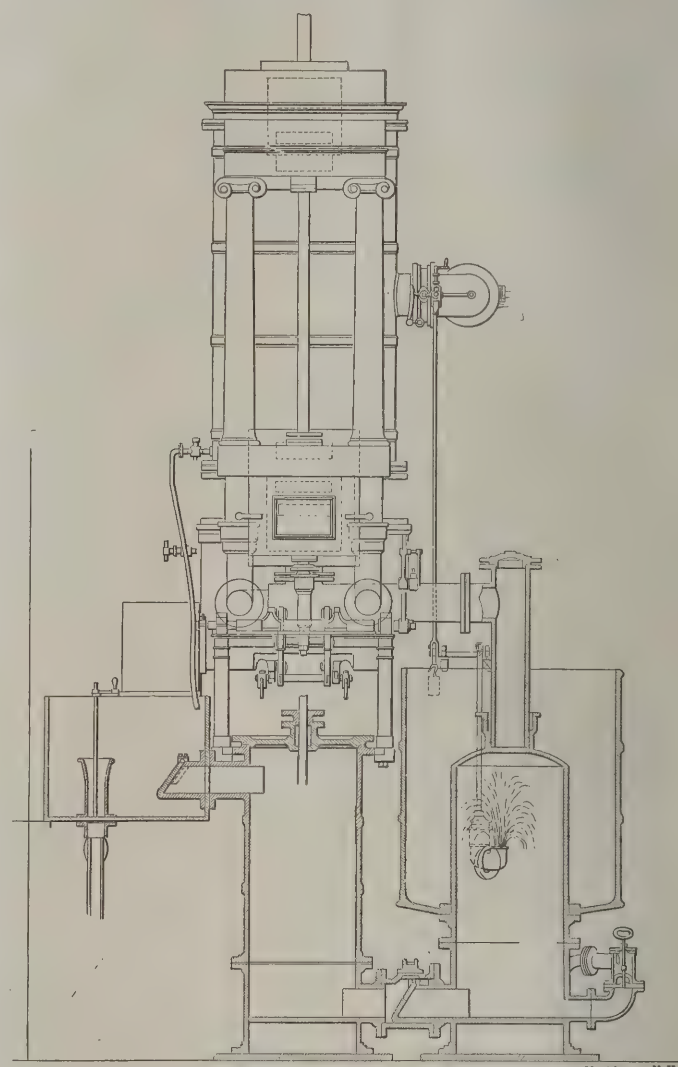

Fig. 5. Section through Condenser and Air Pump.

It appears that this engine was run for the last time on June 9, 1859, and it was removed between 1900 and 1905 to give place to the Barbet and Hersent engines, but the building in which it was housed has been preserved.

According to a report of M. Usquin, rendered in 1837, this steam engine cost more than 3,000,000 francs ($600,000), inclusive of the piping and the location of the same. It burned about 250 bushels of coal on a day's run and the cost of maintenance for the whole plant at Marly amounted to about 130,000 francs ($26,000) per year. In this report the author pointed out the deplorable condition of the maintenance of the dam intended to keep the waters of the Seine in the bay of the machine. "The result is," he said, "that the water does not flow directly into the bay, so that, when it is low, only a small amount of water comes beneath the Marly

wheels and cannot give them the power that they were intended to have." It must not be forgotten, however, that these two wheels formed a supplementary machine, set up, according to this author, to be run during the construction of the steam engine, and that, under the circumstances, the manager of the works would have been in an awkward posi-

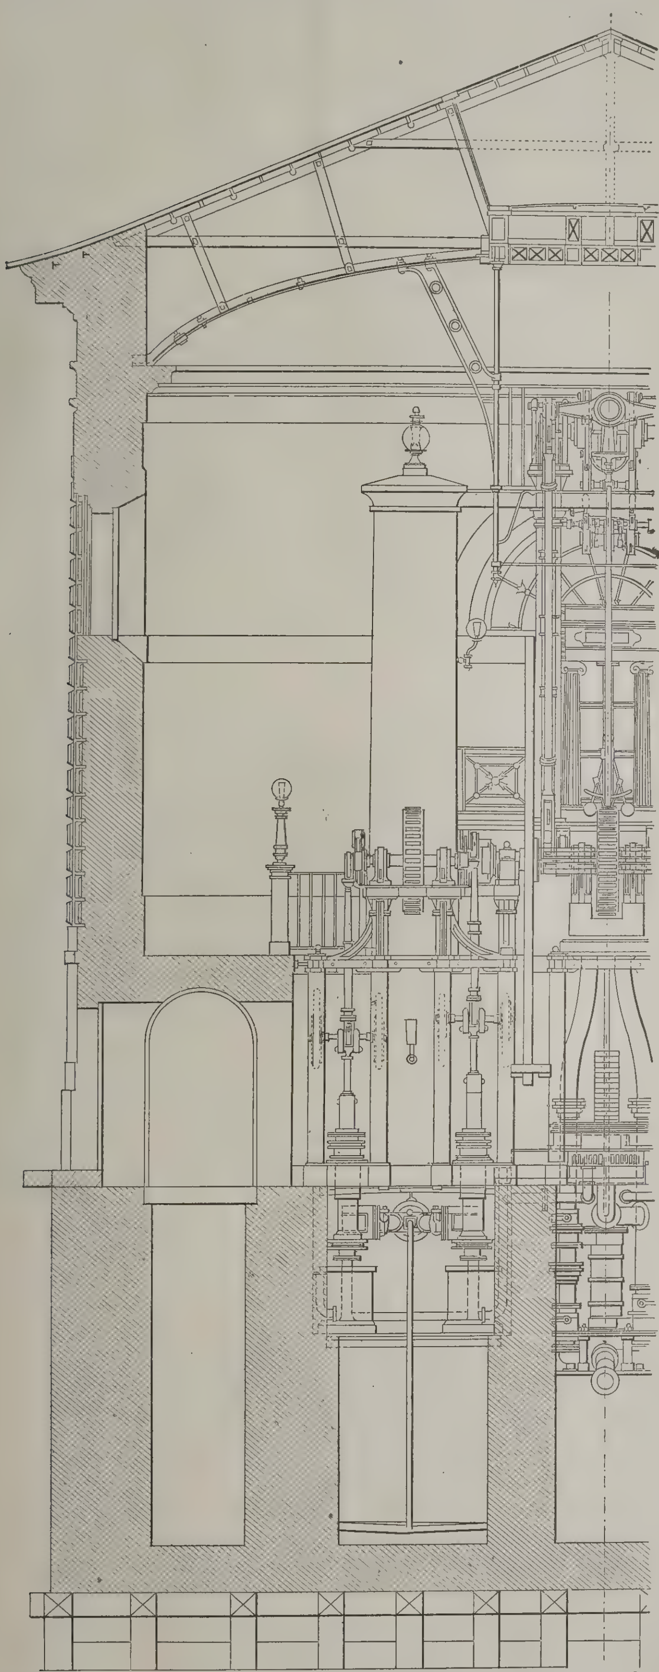

Fig. 6. Details of Building and Arrangement of Pump Cylinders.

tion had he asked from the Civil List the funds needed to repair the dam, which was considered useless after the steam engine had been completed.

In this interesting report, M. Usquin called attention to the irregularity of the service of the water pools as well as the unhealthfulness of the water itself. He also emphasized the cost of water raised by the steam engine, and ended his work by demanding "the construction of a new hydraulic machine at Marly, according to present practice."

"This construction should be made with due attention to the desired solidity. Wheels should no longer be made of wood, but of iron, and they should not be carried upon wooden beams, but upon stone piers."

According to this report, dated in 1837, it appears that the work of this engine was even then unsatisfactory, and an estimate calling for an expenditure of 3,000,000 francs ($600,-000) was called for to replace it with other works, that were really not completed until more than twenty years afterward, when the engine was shut down and taken out of service.

G. L. F.

HIGH-LIFT TURBINE PUMPS—THEIR DESIGN AND EFFICIENCY.

Prof. J. R. Durley, *in Engineering Magazine*, July, 1906.

Under the above heading the author presents a valuable paper; the subject is treated in a clear and simple manner, the general principles and design of high-pressure centrifugal, or turbine pumps being fully exemplified by the aid of line drawings, while the appearance of the pumps of several of the best known makers is shown in numerous halftone illustrations. The paper is lengthy, but in the following abstract we have endeavored to give all the important features:

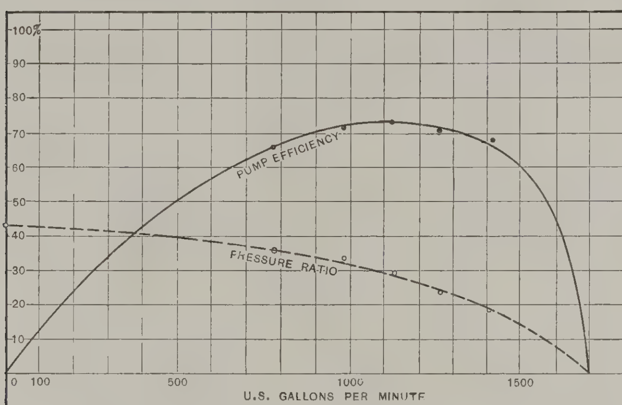
The centrifugal pump, in which there is only one moving part, the impeller, is the simplest form of pump from a mechanical point of view. Unfortunately, the commercial use of such pumps has hitherto only been possible under certain conditions, and for low heads, but a machine of the same simple construction, having only one moving part is now available for high heads in the shape of the high-lift turbine pump, which is practically a reversed inward flow turbine, but differing from the latter in the shape and curvature of the wheel vanes and guide blades.

The ordinary centrifugal pump has a low efficiency when working against high heads, due to the fact that with high speeds the frictional and eddy losses bear a very high proportion to the amount of useful work actually expended in pumping the water. A typical centrifugal pump of ordinary design, showing a maximum efficiency of say 70 per cent at 20 feet lift, will show only about 20 per cent at 80 feet. Efforts to utilize such centrifugal pumps for higher lifts by running two or more in series have not achieved commercial success.

The water streaming from the rim of the impeller of a centrifugal pump possesses kinetic energy, derived from the work expended in rotating the pump. If the vanes of the impeller were radial in an ideal frictionless centrifugal pump, and if the whole of the kinetic energy of the water at the rim of the impeller could be transformed into pressure energy, then the pressure against which such a pump could just deliver, would be calculated by the expression $v^2 \div 32.2$, where v is the linear velocity of the rim of the impeller in feet per second.

If we take the case of water delivered from an ordinary centrifugal pump with a velocity of 10 feet per second in the discharge pipe, under 50 feet head, the total energy possessed by each pound of water delivered is 51.55 foot-pounds, of which 1.55 foot-pounds is kinetic energy and 50 foot-pounds is pressure energy. An ideally perfect pump would attain this result by the expenditure of 51.55 foot-pounds of work per pound of water pumped, and the impeller would have a peripheral velocity of about 41 feet per second. An actual pump, however, working under these conditions, and having an efficiency of perhaps 50 per cent would require the expenditure of twice as much work per pound of water pumped, and the impeller would have to be driven at a considerably higher speed, depending on the design, probably about 60 feet per second. To judge of the performance of a centrifugal pump, under any given conditions, it is necessary to know two things: the efficiency and the "manometric coefficient," which is the ratio of actual pressure in the pump discharge to the pressure which would be attained in an ideally perfect pump with the same peripheral velocity of impeller. Curves of these two quantities, plotted with regard to the amount of

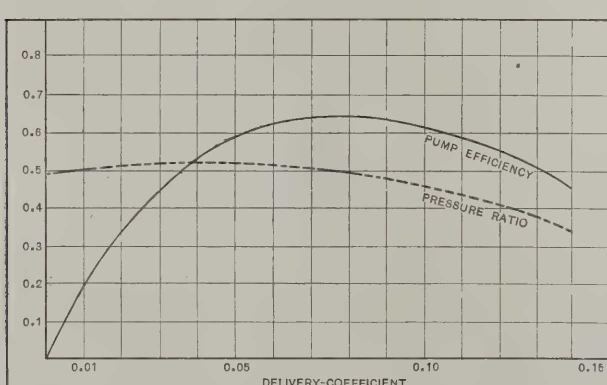
water discharged will give all necessary information as to the performance of a pump at a given speed throughout its whole range, from the point at which the discharge is zero and the pressure large, to the point at which the pressure is zero and the discharge a maximum. The forms of these curves are affected considerably by the shape of the vanes of the impeller, and can be varied by a skillful designer to suit special conditions. Fig. 1 shows the efficiency and pressure curves for an 8-inch low-lift centrifugal pump tested by Messrs. Denton and Kent. The pump was designed for a delivery of 1,200 U. S. gallons per minute against 45 feet head when running at 2,000 revolutions per minute, and it will be seen that while the maximum efficiency of the pump occurs at very



Machinery, N.Y.

Fig. 1. Efficiency and Pressure Curves for Low-lift Centrifugal Pump.

nearly the designed rate of discharge, it falls off rapidly when delivering larger quantities of water. The curves of Fig. 1 correspond to the forms usually shown by pumps in which the vanes are curved backwards at the tip, and such impellers may be used in cases where a pump has to work with fair efficiency at constant speed while the head is varied over a considerable range. It is possible by modifying the shape of the vanes, making them nearly radial, to obtain a pressure-coefficient curve approximately horizontal for a considerable variation of the amount of water pumped; indicating that with such an impeller, when the demand for water is changed, the pressure will remain nearly constant while the pump runs at constant speed. Such a design is suitable for a pump supplying a boiler-feed system. By still further changes in the design of the vanes, we are even able to obtain a pump in which the head increases as the delivery is increased.

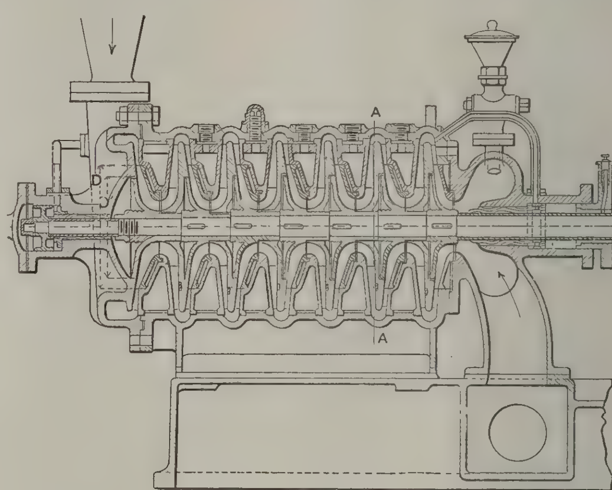


Machinery, N.Y.

Fig. 2. Efficiency and Pressure Curve for a Four-stage Turbine Pump.

Such curves as those just given may be called the characteristic curves of the pump, although they apply only to the particular pump and speed for which they are drawn. M. Rateau has shown that instead of measuring the quantity of water along the base line of such curves, a quantity he calls the "delivery coefficient" may be used with advantage. This coefficient is numerically equal to the amount of water discharged, divided by the peripheral velocity of the impeller, and by the square of the radius of the latter. A given characteristic curve plotted in this way becomes applicable to pumps of all sizes of the same design, the correct speed being used for each size. This result follows because the quantity delivered by an ideal centrifugal pump varies as the peripheral velocity of the impeller, and as the square of the linear dimensions of the pump. A characteristic curve of this kind, for a four-stage pump is given in Fig. 2. The improvement which differentiates the high-lift centrifugal pump from the ordinary low-lift centrifugal pump, consists in the addition, outside of the impeller, of a "diffusion ring" containing stationary guide blades (Fig. 4). By means of these blades the water leaving the impeller is smoothly conveyed to the annular discharge chamber, and its velocity head is more effectually converted into pressure head. The high peripheral velocities of impeller necessary for high heads can then be employed without a corresponding diminution of efficiency. The practical result obtained by this method of construction is that pumps having a simple impeller can deal with heads exceeding 100 feet with good economy; the efficiency possible depends on the design of the pump, and especially on the relation between the diameter of impeller, the required number of revolutions, and the amount of water to be pumped. By placing turbine pumps in series a multiple-stage pump is obtained, and it is possible to pump against greater heads; under these conditions a pump efficiency of over 70 per cent is frequently attained. The greatest head dealt with commercially up to the present time appears to be about 1,500 feet, but for such a lift the usual practice would be to use two or more multiple-stage pumps in series. The usual head for a single multiple-stage pump is from 300 to 600 feet.

It must not be supposed that such results as those just stated have been attained without much trouble, and overcoming many practical difficulties. One of the first difficulties to make itself felt was end thrust on the pump shaft. In a single-stage turbine pump the water at entrance to the impeller is flowing parallel to the axis of the shaft, and in being deflected so as to move in a radial direction it exerts a considerable thrust along the shaft. The simplest way of avoiding this thrust is by using an impeller that takes water on both sides, but when a number of impellers are placed in series on the same shaft, as in Fig. 3, this construction cannot be used. In Fig. 3 the impellers take water on one side only and the end thrust is taken care of by suitably proportioning the areas of the two sides of each impeller, and by the use of a rotating balance piston, one side of which is exposed to the pressure in the discharge pipe. It will be noticed that in this pump the impellers have a larger diameter on the inlet side than on the side nearest to the pump discharge; these areas are chosen so that the difference of the total pressures on the two sides of each impeller balances its own end thrust as nearly as possible.



Machinery, N.Y.

Fig. 3. Seven-stage Pump, Piston Balanced.

One of the first multiple-stage pumps adopted an arrangement in which the impellers were placed in pairs back to back (Fig. 5). In the Buffalo pump, Fig. 6, we have a somewhat similar design, in which the spaces between the outer faces of the impellers and the adjoining casings are used as pressure chambers. Packing rings are fitted, so as to prevent leakage from the delivery to the suction side, and the areas of the two pressure chambers of each impeller are arranged

so as to make the total difference in axial pressure approximately equal to the thrust due to the difference of inlet opening in the two impellers of the pair. In this way each pair of impellers is balanced perfectly.

Another method which can be employed to balance a single-suction impeller involves the use of radial vanes formed on the outside surfaces of the impeller, and therefore rotating the water in the pressure chambers. By proportioning correctly the length and clearance of these vanes, the pressures existing in the various pressure chambers while the pump is running can be brought to the amounts required for balance. These so-called "triple-vanes" increase slightly the power required for driving the impeller, but it is questionable whether the power wasted in the thrust bearing of an imperfectly balanced pump would not be greater than any loss due to the triple vanes.

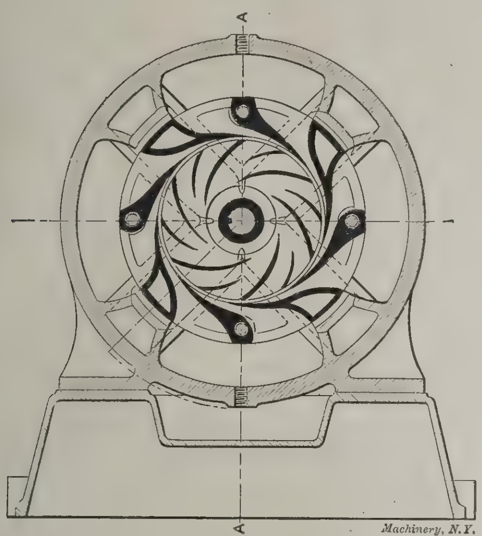


Fig. 4. Characteristic Arrangement of Blades in a Turbine Pump.

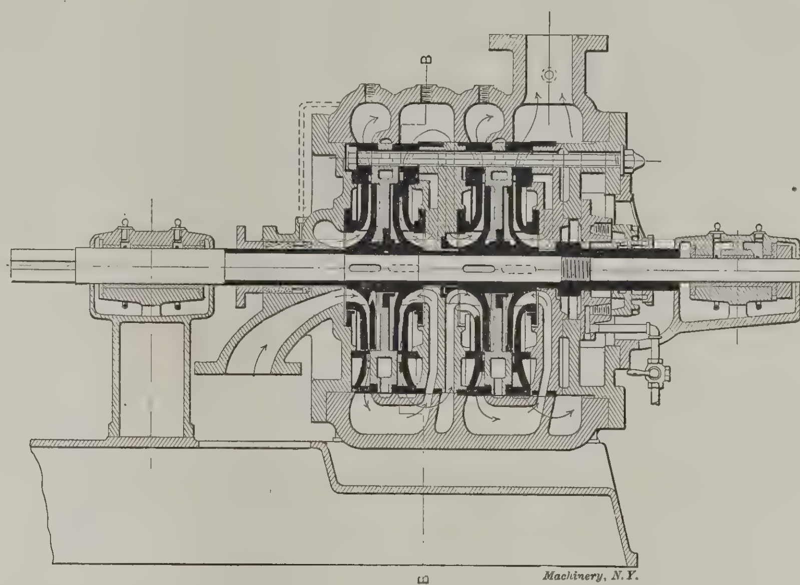

Fig. 6. Longitudinal Section of Pump shown in Fig. 4.

The construction of the main bearings and stuffing boxes in a high-lift turbine pump has to be carefully considered. It is good practice to arrange the design so that the bearings and stuffing boxes are quite separate; in this way the weight of the shaft and its impellers is carried by easily accessible bearings, no grit from the water can get to the journals, and the stuffing boxes are able to perform their own duty without taking any load. The tightness of the stuffing box on the suction side of the pump is specially important, and this box is generally provided with a water supply, so that any leakage into the pump will be of water and not air. Fig. 6 shows an arrangement of double stuffing box for the suction side fitted with such a water-logging attachment. A comparatively small air leak on the suction side will suffice to prevent the pump from working at all. The pump may be constructed so that water leaking from the last pressure chamber is used to cool the bearings.

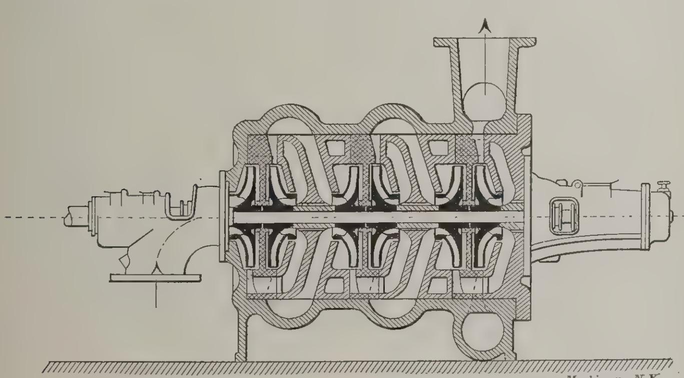

Fig. 5. A Balanced Multi-stage Pump.

Other points requiring attention in design are, the protection of the exposed portions of the shaft from corrosion; the prevention of leakage from one stage to the next, by fitting brass packing rings; and the arrangement of the impellers and division plates so as to admit of easy assembly and removal without interfering with permanent pipe joints or connections. The form of the guide passages in the diffusion ring, and the shape of the ports or passages leading from one stage to the suction of the next, have considerable effect on the efficiency of the pump.

The results attained by the modern high-lift centrifugal pump may be stated generally as follows; an efficiency in most cases of from 70 per cent to 75 per cent can be obtained, and under suitable conditions this may even reach 80 per cent on trial. The pumps can be so proportioned as to give a fairly constant efficiency over a considerable range of discharge. When running light, the power absorbed is generally from 25 to 40 per cent (see Fig. 17) of that at the rated output of the pump.

In good practice the head to be overcome by each stage is from 100 to 200 feet. When the head is more than 200 feet it is difficult to obtain high efficiency, owing to the high velocity of the water. The maximum speed of the impeller is limited by the rapidity with which water can flow into the suction. The greatest number of stages now used is eight, but there seems to be no reason why the number could not be increased.

It is probable that further progress will soon enable efficiencies corresponding with the best water turbines to be obtained. Tests of turbine pumps after some years' work have shown that when properly constructed there is little falling off of efficiency on account of wear and corrosion. Turbine pumps can maintain their original efficiency much better than is usual with large piston pumps.

Turbine pumps are lighter and smaller than reciprocating pumps. A reciprocating pump driven by a 300-horsepower motor and occupying a floor space of 50 x 25 feet was replaced by a turbine pump driven by a 500-horsepower motor that occupied a floor space of 31 feet 6 inches by 8 feet 6 inches; and the weight of the latter is about one-half that of the former. The reciprocating pump delivered 4,500,000 gallons per twenty-four hours, and the turbine pump 6,500,000, the head being 300 feet.

High-lift turbine pumps of the largest size are now being employed to supply water for cities and towns. They are also used extensively in mines. In the latter service they are not only employed as permanently located drainage pumps, placed conveniently in chambers excavated near the bottom of the shaft, but also as sinking pumps, in which case they are suspended in the shaft in suitable frames; and, owing to their small size, they leave ample room for the passage of the

cages or tubs of the hoisting apparatus, even when of considerable power.

High-lift pumps are finding a wide application for purposes of fire protection, both in factories and cities. A fire protection system now being installed in Toronto comprises two two-stage Worthington pumps, each directly connected with a steam turbine of 1,000 horsepower capacity.

In Europe high-lift pumps driven by electric motors have been used as portable fire engines with considerable success. For elevator service these pumps give good results if arranged to be controlled electrically or mechanically, so as to vary the discharge automatically in conformity with the demands of the elevator.

A number of successful pumping installations have been carried out in which a high-lift pump has been driven directly by a water turbine. Such a turbo-pump, as built for mine service in Central America, consists of a four-stage Rateau pump having impellers 9½ inches in diameter, and driven at 2,200 revolutions per minute by a reaction turbine placed within the same casing. The 120-horsepower turbine, taking its water under a head of 520 feet, has a single wheel 11¾

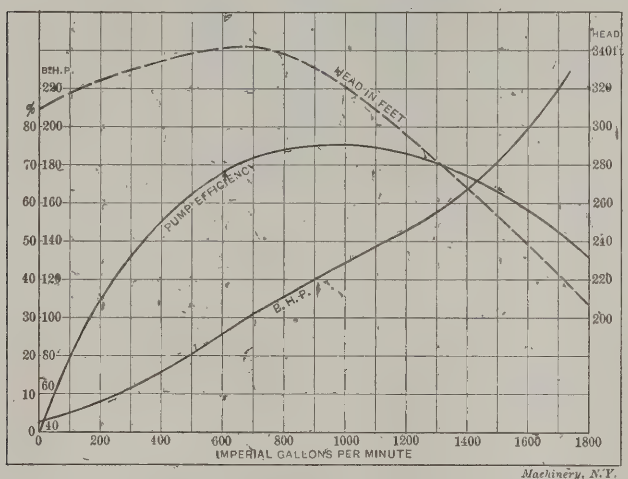

Fig. 7. Characteristic Curves from a Turbine Pump Test.

inches in diameter, and delivers the water it has used into the discharge pipe of the pump; the pump works under a head of 390 feet and delivers 400 imperial gallons per minute. The combined efficiency of the pump and turbine is 48 per cent.

High-lift centrifugal pumps directly connected to steam turbines are used in many cases and have shown good results as far as steam consumption is concerned. Under favorable conditions a consumption of 22.6 pounds of saturated steam per pump horsepower per hour has been shown on a seven-stage pump delivering 900 imperial gallons per minute under 1,180-foot head, and taking about 320 horsepower.

Although high-lift centrifugal pumps have been on the market for only about nine years in Europe, and four years in America, their use has become widely extended. Such pumps are now commercially available for almost any service, so long as the amount of water to be dealt with is not too small in comparison with the head at which it is to be delivered.

W. B., Jr.

* * *

The Anglegraph is the name of a device for draftsmen manufactured by the Cassady-Fairbanks Mfg. Co., 6106 La Salle St., Chicago, Ill. It consists of a triangular piece of sheet metal, nicely finished and nickel plated, in which is drilled a series of holes, so spaced that a variety of geometrical figures can be constructed by its aid. By placing a tack or pin through one of the holes as a pivot, circles of different diameters can be drawn by means of a lead pencil, the point of which is inserted in any one of the holes desired. Certain of the holes are numbered and by the aid of directions given they may be used in connection with a pencil point to divide a circle into any number of equal parts up to 16 and by the use of the several gages of the instrument, in connection with the numbered holes, geometrical figures of complicated construction can be drawn.

DYNAMO AND MOTOR TROUBLES.

WITH CHART WHICH APPEARS IN THE SUPPLEMENT.

F. W. S.

A number of small volumes have been written on the care of electrical machinery, particularly dynamos and motors. Most of these books are very useful in assisting the operator in the proper maintenance of the apparatus and the discovery of the causes of faults and breaks which are constantly liable to occur. Almost any given symptom of distress in a dynamo or motor, however, may be due to a number of different causes. This fact, together with the lack of method in the arrangement for some of the books dealing with the subject, often handicaps the beginner in locating the particular fault to which any given trouble is due.

Roughly speaking the various diseases to which dynamos and motors are subject may be placed in six general classes. First, sparking of the brushes; second, heating of the parts; third, noises; fourth, variations in speed; fifth, miscellaneous derangements peculiar to motors as distinguished from dynamos; sixth, miscellaneous derangements peculiar to dynamos and generators as distinguished from motors. It is again possible to divide each of these major symptomatic indications into minor ones. The sparking of the brushes, for instance, may be due, first, to faults of the brushes; second, to faults of the commutator; third, to excessive currents in the armature; fourth, to faults in the armature. Each of these divisions may be again subdivided and an appropriate individual remedy indicated.

To make this clearer I have prepared a chart showing the arrangement I have in mind. This chart appears in the Supplement and to illustrate its use we will suppose, for instance, that the armature of a motor becomes dangerously hot after running for a time: The chart is consulted and under the heading of "heating of parts" the sub-head "armature" is found. There are seven different causes given here for heating of the armature. It may be due to overload of the motor, to a short circuit due to carbon dust, etc., on the commutator bars, or it may be caused by a broken circuit, a cross connection, moisture in the coils, eddy-currents in the core, or heat conveyed from a hot box or journals through the shaft. Each of these seven causes may be investigated in turn. For instance, it may be found that the armature coil is warmer than the winding which surrounds it. If this is the case, the trouble is due to eddy-currents in the core, or to heat conducted through the shaft from a hot box. If the latter the shaft will of course be hotter than the armature, and the bearings still hotter than the shaft. If the trouble is due to eddy-currents the armature will be found to be made of solid metal, or to be not sufficiently laminated. In either case the trouble is readily discovered.

There are two advantages in using a chart of this kind. In the case of trouble with a motor or dynamo, a text book is generally too voluminous to be easily used and, quite likely, is not well enough arranged to permit a quick diagnosis. Then again, after a person has carefully read over such a work several times, he will still find the chart very acceptable, as a guide which will show him where to look and what to do—something that can be glanced over quickly and can be readily found, which will outline the proper course to pursue. The trained mind will then quickly recall from the book the details of the proper method of procedure.

* * *

About 40,000 tons of tin are consumed annually in the United States, about half of which is used in the manufacture of tin plates and solder. It is interesting to note that improvements in the manufacture of cans for fruit, vegetables, meats, etc., has decreased nearly one-half the amount of solder required per can, thus illustrating how machinery may in some cases work out an economy of the use of materials as well as a saving of labor. The annual consumption of tin is about 90,000 tons for the whole world and the scarcity of the product is constantly forcing the price upward. A tin mine would be one of the most profitable holdings that a man could own, the price being about 38 cents a pound.

LEATHER MEASURING MACHINE.

H. A. DUDGEON.

The following description of what is really an area measuring machine may be of interest to many of the readers of this journal as it embraces several novel mechanical ideas in its construction, the machine being designed to overcome the objections met with in all previously designed machines for a similar purpose.

It is first perhaps necessary to explain that leather from which the uppers of boots and shoes are cut is sold by superficial measure, or so much per square foot and owing to the irregularity of the outline of the skins themselves, which is something like Fig. 1, it is very difficult if not impossible to obtain an exact measurement and so the near approach to this has to suffice; for whilst being very close to the actual measurement the results obtained are more or less only an approximation and, whilst the machine about to be described is no exception to the general run of machines in that respect, it perhaps approaches being exact more nearly than the others.

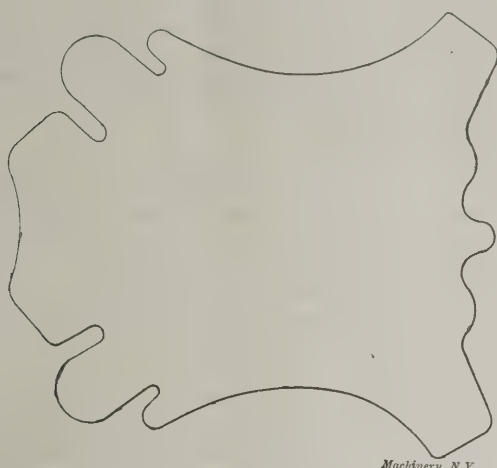

Fig. 1. Sketch showing Typical Outline of Hide.

To put it in simple language the underlying principle of the machine is this: If a wheel of known circumference is traveled along a surface it is an easy matter, by counting its revolutions to calculate the length of surface passed over. If such a wheel were to account for a surface between lines parallel to the motion of the wheel and of known width, and the ends of the surface were straight and square with the sides then the length multiplied by the width gives the area. Now if the skins to be measured were of such a shape the problem would be much easier, in fact would hardly need a machine at all but such, however, is not the case, and as in an engine indicator diagram the surface must be divided into imaginary parallel strips and the mean length or height of each strip measured by providing a measuring wheel for each strip, the results being added together for a final result. Now, if, instead of passing the measuring wheels over the surface the surface is made to pass under the wheels the result is the same, and in the machine this is done, the following description showing how it is carried out in practice and the means adopted for recording the revolutions of the measuring wheels and adding them together.

Referring to Figs. 2 and 3, *A A* are the measuring wheels placed equidistant apart and carried by the arms *B B*, being placed directly above the feed-roller, *C*, which is belt driven. On one side of each wheel is a small boss, and attached to this and wound once around the boss is a fine cord, *D*, the other end of the cord being attached to a movable weight, *E*, there being as many cords and weights as there are wheels. These weights are carried on inclined arms, *F*, secured to a shaft, *G*, the shaft being carried on centers, a ball race being formed in the end of the shaft, the balls resting on the centers, thereby reducing the friction to a minimum. To one end of the shaft *G* is secured a lever, *H*, the outer end of the lever being supported by the coil spring, *J*. In the normal position the weights, *E*, are nearly at the botttom of the inclined arms, and so near the center of the shaft, in that position exerting a certain pressure tending to revolve the shaft *G* about its axis; this is resisted by means of the lever *H* and spring *J*. If one or more of the weights are moved up the inclined arms by any means a greater turning tendency is imparted to the shaft and a greater deflection of the spring takes place.

This then is what happens in the machine: The leather is placed on the table *K* and fed between the feed roller *C* and the measuring wheels, *A*, some of the latter being caused to revolve, the number in action being governed by the width from left to right of the skin, each revolving just so much, according to the length of the surface passed under them. And this, by means of the cords draws the weights up the inclined arms a certain definite distance, their combined action thereby deflecting the spring *J* through the shaft *G* and lever *H* a predetermined amount proportional to the position of the weights. It is an easy matter to record the movement of the shaft. This is done by means of the rod *L* attached to the lever *H*. At the top of the rod is a rack which meshes with suitable gearing actuating the hand *S*. This hand moves in front of the dial *M* placed in a convenient position on the

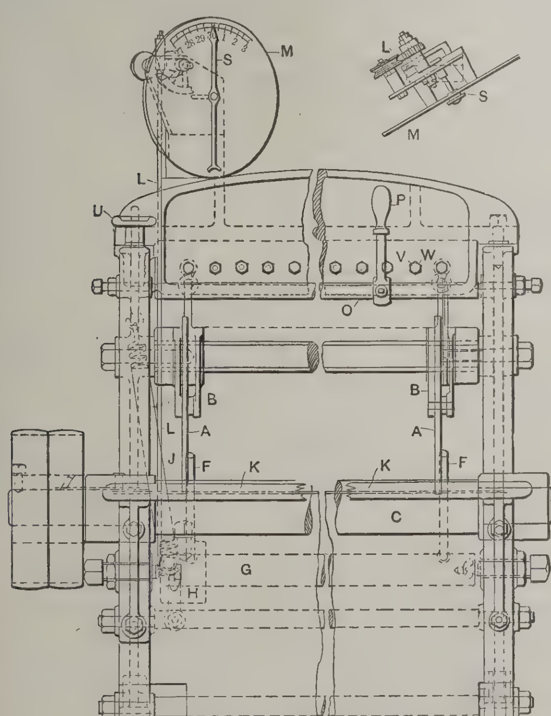

Fig. 2. Front View of Leather Measuring Machine.

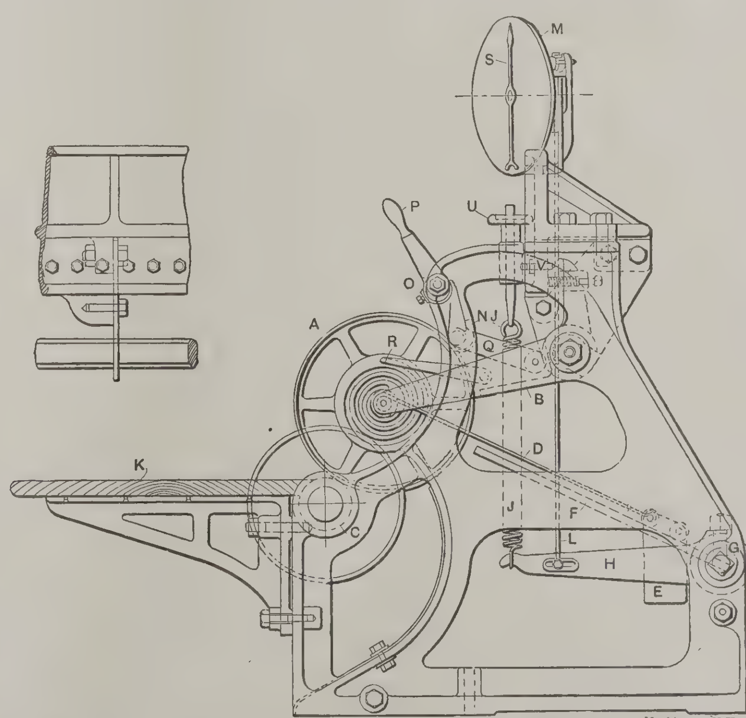

Fig. 3. Side View, showing Measuring Wheels and Weighing Mechanism.

machine, the graduations giving a direct reading in square feet.

A brake N is provided for each measuring wheel to retain it in position until the reading has been taken, the brakes all being released simultaneously by means of the eccentric shaft O and handle P, the shaft in its normal position being just clear of the extension on the brake lever Q when the brake is resting on the wheel. By turning the eccentric shaft, all the brakes are lifted from the wheels together, and the weights travel down the inclines into their normal position. To insure the weights stopping in their proper positions at the bottom of the inclined arms a scroll is formed on the face of each measuring wheel in which a small projection on the end of the lever R lies. As the measuring wheel revolves forward this projection follows the path of the scroll, and when the wheel revolves in the reverse direction the end of the scroll strikes the projection on the lever.

An interesting feature in the machine is the method adopted to prevent registering *surface* when only *thickness* has passed through. The measuring of this can be best shown by means of a diagram. In Fig. 4 let A represent the measuring wheel, C the feed roller, K the table, and N the brake. Now if a solid represented as an end view by the triangle T be passed through the machine it is evident that the measuring wheel

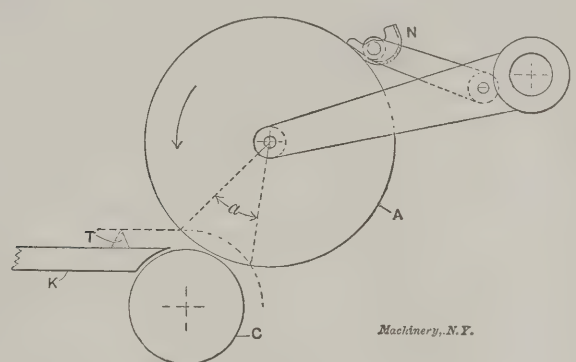

Fig. 4. Compensating Device for Thickness of Hide.

A will rotate a certain amount equal to the angle a, although obviously the line representing the apex of the triangle has no area.

Similarly any substance passed through the machine will move the measuring wheel through a similar angle proportional to the thickness of the substance *in addition to the surface of the substance* and unless provision is made this angle will be added to the reading, giving an incorrect result which, considering that on an average 30 wheels are in action on each skin measured, is a serious matter. To overcome this the brake was made of such a form that for part of a revolution of the measuring wheel the brake turns with it, the amount being calculated from the angle through which the wheel turns for an average thickness of leather. Any further movement of the measuring wheel in a forward direction shown by the arrow causes the brake to slip but as soon as each wheel ceases measuring the part of the skin passing under it, the weight on the inclined arm revolves the wheel in the reverse direction just the predetermined amount, this reverse movement of the weights being therefore deducted automatically from the reading.

The nut U is for adjusting the indicator to zero when first setting up the machine and the screws V are used for setting the measuring wheels A just clear of the feed roller, being locked by means of the nuts W.

A motor-driven rail mill is now in operation at the Edgar Thompson plant of the Carnegie Steel Co. at Bessemer, Pa. It is equipped with two 1,500-horsepower, 30-pole, 220-volt, direct-current motors overcompounded 15 per cent, which operate at from 100 to 125 R. P. M. Each motor carries a 125,000-pound cast-steel segmental flywheel which frees the motor from the extreme shocks of rolling. The power delivered by each motor ranges from 950 to 1,450 horsepower in rolling rails with occasional jumps to 1,700 horsepower, while the friction load on the mill running light is about 500 horsepower.—*Engineering Record.*

NEW DUTY RECORD ESTABLISHED FOR THE PUMPING ENGINE.

Tests which were made upon a twenty-million-gallon Allis-Chalmers triple expansion pumping engine at the Bissel's Point Station of the St. Louis Water Works in the latter part of February, 1906, determined the production of an indicated horsepower per hour on an average consumption of 10.59 pounds of dry saturated steam. The average heat supply was at the rate of 201.39 B. T. U. per minute horse power, giving a thermal efficiency of 21.06 per cent. The mechanical efficiency was 97.4 per cent; the duty per 1,000 pounds of steam 181,068,605 foot pounds, and per million British thermal units 158,581,000 foot pounds. The guaranteed duty was 135,000,000 with a bonus of one thousand dollars per million foot pounds, so that the engine earned its builders $46,068.61 above the contract price.

The engine tested is the last of a series of three installed at the above station, and is of the vertical triple-expansion, self-contained type, with single-acting outside-packed plungers located directly under each cylinder. The lower bed-plates rest on solid rock foundations; the main pillow block bed plates are supported upon cast iron frames resting on the lower bed plates and the cylinders are supported by frame of the "A" pattern.

The cylinders are 34, 62 and 94 by 6 feet stroke with water plungers 33⅞ inches in diameter. Before the official test the plungers were carefully calibrated by micrometer calipers checked by steel tape measurement of circumferences. The strokes of all plungers were also carefully measured. The pump valves were inspected and found to be tight under full pressure.

The specifications and contract required that, "In order to determine the amount of steam used by the engine, the water will be weighed twice; that is, the feed water going into the boiler and the condensed steam coming out of the engine." Accordingly, the condensation from the condenser, jackets, receivers and drips from stuffing boxes was weighed as received from the engine and delivered in the boiler room, and was found to check by 0.12 of one per cent. This being a reasonable check the water as weighed in the engine room was taken as the steam used.

The gallons of water pumped in twenty-four hours was 20,070,590 against a head of 100.021 pounds at the discharge pipe, the contract requiring 100 pounds pressure. The head in the discharge main was read by means of a mercury column and the suction head by a float gage. The plunger leakage was weighed and found to be 16.77 gallons per hour. Steam of 140 pounds pressure at the throttle was furnished containing 0.13 per cent moisture.

RESULTS OF DUTY TEST.

Duration of test	24 hours
Diameter of cylinders	34, 62 and 94 inches
Stroke of engine	72 inches
Diameter of plungers	33⅞ inches
Average steam pressure at engine	140.24 pounds
Average first receiver pressure	26.36 pounds
Average second receiver pressure	2.77 pounds
Average vacuum pressure by cards	13.21 pounds
Average barometer pressure	14.46 pounds
Average net head pumped against	238.2323 feet
Average revolutions per minute	16.539
Piston speed per minute	198.44 feet
Total water pumped	20,070,690 gallons
Total water received from engine	220,129 pounds
Average moisture in steam	0.13 per cent
Indicated horse power	865.22 horse power
Delivered horse power	842.69 horse power
Per cent friction	2.60 per cent
Average moist steam per I. H. P. per hour	10.60 pounds
Average dry steam per I. H. P. per hour	10.59 pounds
Average B. T. U. per I. H. P. per minute	201.39 B. T. U.
Mechanical efficiency	97.4 per cent
Duty per 1,000 pounds of steam	181,068,605 foot pounds
Duty per 1,000,000 B. T. U	158,851,000 foot pounds
Thermal efficiency	21.06 per cent

The yearly index for MACHINERY is now ready and will be sent to all subscribers upon request.

THE COST OF RUNNING MACHINERY.

D. C. EGGLESTON.

The cost of running machinery is such an important subject in factory economy that a discussion of the items making up the "Machine Expense" may be of interest to readers of MACHINERY. Cost accountants have used the term "Machine Expense" to include the total charges incurred in running the machine equipment of a factory. It costs money to maintain a machine, repair it, pay taxes on it, rent floor space for it and so on, as well as it does an operator to live, and oftentimes the machine is the more expensive of the two. The "Machine Expense" is always more difficult to figure than the labor expense and more economies can usually be made by a study of it. The importance of studying this subject will be realized when it is known that the "Machine Expense" in one factory was 70 per cent of the cost of labor on jobs passing through all departments. The more expensive and intricate the machine is the more the "Machine Expense" will be, but this does not vary with labor. One operator will oftentimes tend a half-dozen automatic screw machines, and it is easily seen that the "Machine Expense" is greater in proportion to the cost of labor than if he were tending only one drill press. This variation in the cost of maintaining the machine equipment of a factory with the labor is one reason why the percentage plan of figuring costs leads to erroneous results wherever the machines in a factory are of different types.

As soon as a machine is installed certain expenses called fixed charges begin. A machine which has been used cannot be sold for as much as it cost. Not only has the wear and tear on it made it less valuable, but perhaps the manufacturer can supply a newer and more efficient type, which makes the old machine less valuable. In short, longevity and obsolesence must be considered in fixing the rate for depreciation. The engineer must use his best judgment in estimating the probable life of a machine and then enough money must be set aside each year from the profits if put at compound interest to redeem the machine when the time comes for replacing it. As high as 15 per cent of the face value is oftentimes written off, but it varies so much that the best judgment must be exercised in all cases.

Insurance must be taken after deducting the reserve for depreciation. Taxes are also an element of expense and belong to the fixed charges account. In a Pratt & Whitney No. 1½ hand screw machine costing $731.25 the fixed charges amounted to $66.81 a year.

The cost for power is an important item in most machinery and the exact amount used should be found by metering it. In estimating the cost of power all fuel, oil, wages of firemen and sundry expenses should be included. In the machine mentioned the yearly charges for power were $142.90.

The machine occupies floor space in the building and should bear its share of the expense incurred in maintaining the building in an efficient state for conducting the work of the factory. The best way is to charge all repairs, changes, fixed charges and expenses for cleaning to rent expense and then prorate this according to the floor space occupied, making the machinery bear its proper part. In the machine previously used for illustration the rent expense amounted to $41.90 a year.

All administration expense, including salaries of superintendent, foremen, clerks, traveling, entertainment, stationary, and so on should be summarized and prorated according to the number of productive employees. If one employee works at a hand screw machine the administration expense which must be included in the cost of running that machine is the amount allotted to one employee. If two employees work at a multiple drill press the administration expense is double that for one employee, and so on.

All repairs, changes and expense incurred in behalf of the tool equipment, salaries of tool inspectors, tool clerks, and fixed charges on small tools should be distributed among the different machines by estimate and analysis. It will be found that tool expense is the largest item of "Machine Expense" and a careful study of the items making it up will suggest valuable economies.

Sundry expense is designed to cover all items not chargeable to other branches of "Machine Expense" such as oils, chemicals, water other than for boilers, defective work and stationary. Although this expense is only about one-fifth as much as tools expense it ought to be divided among the various machines by estimate so that each machine will bear its proper share.

For purposes of cost accounting it is necessary to include the cost of running non-productive machinery in the cost of productive machinery. Thus the cost of running a filing machine which is used for filing the saws for eight saw tables would be assessed equally against the saw tables.

The sum of the fixed charges, power, rent, tool and sundry expense, together with the non-productive machinery assessed against a machine, is the total cost of running it. If the total cost for running it one year be divided by the yearly number of working hours the hourly machine rate can be found. Then this "Machine expense" can be charged on the job ticket the same as the operator's time. If the cost of material, including material expense, is added to labor and "Machine Expense," we have the total cost to make an article. If the machines are grouped together in classes, it is not a very difficult task to estimate the rates, and the accuracy of figuring costs where this system is employed justifies the trouble incurred in accurately finding the cost of running machinery.

* * *

CHINESE RAILROADS AND CHINESE GRAVES.

Speaking of the difficulties experienced by railway builders in China in pacifying the descendants of the numberless dead, disturbed by the building of the road, Mr. Ashmead, head engineer of the Canton-Hankow railway, in the course of an interesting contribution to the *Engineering News* states that, while the prices of graves are variable, the average is 4 taels (about $2.80) per coffin. There being no grave yards in China, as with us, and the location of each separate coffin having been chosen previously by geomancer, according to immemorial Chinese custom, it requires much tact on the part of the native and foreign officials of the road to accomplish the removal of coffins from the right of way, as graves cover much of the ground, being thickly scattered over the lowland, as well as on the hills and mountains. This observation as to the vast number of graves met with in China calls to mind a remark made by a gentleman who had lived for some years in that country to the effect that the Chinaman has carried out to its logical extreme the idea of the reduction of waste. Forced as he is to live in a country so thickly populated that its inhabitants are barely able to find food for themselves, great effort is made to protect the constantly worked soil from loss of productiveness. Not only is every particle of garbage and household waste from each village collected and returned to the adjacent land to refertilize it for next year's crops, but the Chinaman himself, when his end comes, feels that he also must return to the soil from which he has drawn his sustenance. His body is therefore carried outside his native village and buried just a few inches below the surface, where the fertilizing properties which he has drawn from the food during life will be available for the plants growing around him, destined for the future support of his friends and neighbors. How much this idea of returning to the soil everything he has taken from it is accountable for the Chinaman's desire to be buried in his own land, it is hard to say, but his careful economy of phosphates and nitrates is in sharp contrast with the customs of the inhabitants of Europe and America, whose rivers, as Huxley, we believe it was, pointed out many years ago, are constantly carrying to the ocean untold treasures of fertilizing material.

* * *

The danger attending the pouring of melted lead into a cavity without making sure that the hole is perfectly dry is illustrated by an accident befalling a Herkimer, N. Y., man some weeks ago. He poured some hot lead into a hole in the cement floor for the purpose of filling around a pipe and it turned out that there was some water in the hole. The melted lead was thrown out with tremendous force, striking him in the face and badly burning him in several places. Fortunately, eyeglasses saved his sight.

DOWEL MAKING MACHINE.

An interesting woodworking machine was described, in principle, several months ago in *Wood Craft*, being a dowel making machine built by W. C. Farnum, Arlington, Vt. The machine makes the dowels from the log, the logs being first cut up into bolts of the length of the finished dowels. These bolts are then mounted on the machine and the dowels sawed out round and to finish size by means of a tubular saw. During this latter operation the dowels are cut out of the bolt from positions corresponding to those of the cells in a honeycomb; that is, in rows which cut each other at an angle of sixty degrees. It is asserted that by this method a saving of about one-third is obtained over the old process, both in material and time.

Fig. 1 is a plan view showing the operation of the tubular saw and shaper head cutting cylinders out of the block of wood, or, in other words, milling dowels out of bolts. Fig. 2 is a perspective view of the shaper head. Fig. 3 is a perspective view of the tubular saw and a portion of its spindle.

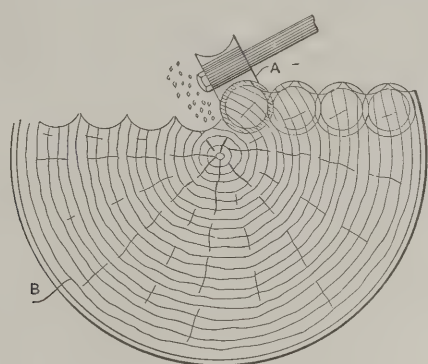

Fig. 1

Fig. 2

Fig. 3

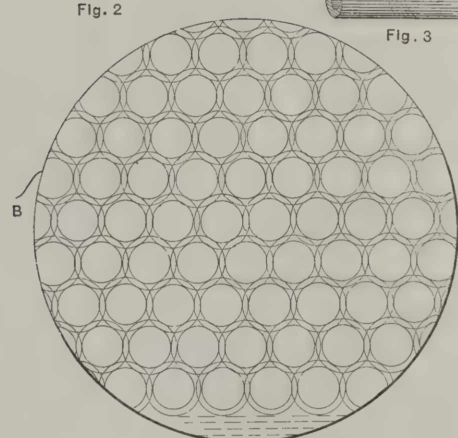

Fig. 4

A Dowel-making Machine.

Fig. 4 is a diagram illustrating the arrangement of the dowels in the wooden bolt, or the cylinders in the wooden block. The logs are mounted on a saw carriage and sawed into sections of the length of the finished dowels. The dowels then cut by the tubular saw are a finished commercial product but, usually, are intended as blanks for the making of spools, clothes pins, handles, etc. As shown in the perspective view, Fig. 3, the edges of the throats of the saw teeth back of the cutting faces are beveled or flared outwardly. The purpose of this arrangement is to cause the sawdust to be thrown outward by centrifugal force when the saw is cutting instead of allowing them to remain in the throats and clog them.

The forming cutter, Fig. 2, supplements the work of the tubular saw as may be seen in Fig. 1 at *A*. Here the cutter *A* is shown at work on the bolt of wood, *B*, cutting in advance of the tubular saw and removing the surplus stock for the periphery of the dowel. The section of the saw is seen surrounding the dowel. The cutter *A* routs out and forms nearly one-half of the dowel, thus providing ample room for the escape of sawdust out of the throats of the teeth on the circular saw as well as greatly lessening the amount of work to be done by the saw in cutting out the remainder of the periphery and finishing the dowels, freeing them from the wood. In Fig. 1 the corresponding parts to be cut out by the saw in the succeeding dowels of the same tier are indicated by dotted lines. The dowels and the material cut out by the saw cuts are graphically illustrated for the entire bolt in Fig. 4, together with the small portion at the lower edge of the bolt which is required for gripping in the holder of the machine.

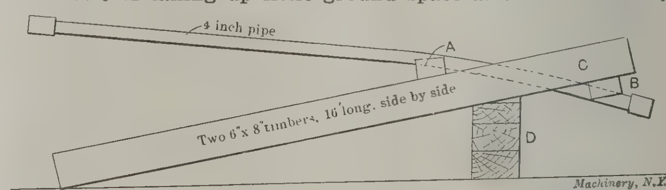
EMERGENCY RIG FOR BENDING PIPE.

While the streets of New York have a never-ending human interest it not often that the editorial eye sees therein anything of marked mechanical interest that might be classed as a "shop kink," but here is an exception. The job of bending heavy 4-inch pipe in a city street, giving each length two offset bends, is one that most of us would rather not tackle; it would be bad enough to do it in a shop equipped with some suitable appliance. The cut illustrates a street rig that works well, provided enough "dagos" are at hand to give the necessary avoirdupois when the bending operation is done. It has the merit of taking up little ground space and can be readily



Pipe Bending in the Street.

extemporized from standard lumber sizes. Two 6 x 8-inch timbers about 16 feet long are laid side by side about 5 inches apart with one end elevated on blocking, *D*. The pipe is placed between the timbers and the cross pieces, *A* and *B* are placed as shown so as to form a fulcrum and a point of resistance for the short end of the pipe when the weight of the men is applied to the long end. It will be observed that the forces of action and reaction are balanced within the rig itself so there is no tendency for it to shift position. It is not exactly what might be called a labor-saver for six or seven men were employed on the job noticed, but for emergency work, where labor cost is a secondary consideration, it is certainly a meritorious scheme.

* * *

It has not been an uncommon experience for an invention to be made and used without patent protection, and if it should occur that the invention comes into general use the natural inference is that the inventor has lost a large monetary return because of his neglect to protect his idea. While not denying that such may be the case, it is interesting to consider the other side of the question. For example, we might mention the ring-oiling device, first used, we believe, by Prof. John E. Sweet on the crankshaft of his famous "straight-line" engine. The device attracted little attention outside of the engine builders until the advent of the electric generator, when Edison recognized that the ring-oiler was an excellent device for lubricating the journals of this high-speed machine. His use of it was immediately copied by the builders of electrical machines generally, and now it is in common use throughout the world. But the fact that the invention was not patented undoubtedly to a large degree explains its immediate general adoption when it became known. A designer usually feels averse to using any device in a new machine for which royalty will have to be paid if another device, even if not so good but in common use, can be used instead. He is responsible to a large degree for the cost of the machine, and the specification of a patented part which may mean considerable dickering with outside parties before permission can be obtained for its use, is distasteful. If the patented device is something of a concrete nature which can be bought in manufactured form and applied with no further transaction the matter assumes a different form than when it must be manufactured as part of the machine and royalty paid thereon.

LETTERS UPON PRACTICAL SUBJECTS.

MOTOR EQUIPMENT.

I have read with much interest the article on the light machine shop in the June issue. The author gives a table of average horsepower required by various machine tools, which is only applicable to group driving and is by no means of general application. Every case has to be considered on its own merits, and in laying out the equipment of a machine shop it should be the object to have as many machines worked to their full capacity as possible. By this means their earning power is increased, as is also the actual power necessary for driving each tool; in other words aim to make the average power as near as possible to the maximum power required for each machine. This means the adoption of automatic machines wherever possible, and calls for much thought, but will produce results impossible by any other means. It is impossible to set any limit of power required for machines where it will pay to install individual electric drive; although at present it is generally considered more economical to operate machines requiring less than five horse power each by the group drive. Yet such ideas are liable to be changed if we look at a modern printing establishment, where it is universal practice to install individual drives on ¼ horse power presses, and it must be admitted that the equipment of the press room is more advanced than that of the average machine shop.

It should always be remembered that production is the principal consideration, and a greater production is possible where each machine is independently driven.

In the case of the 80 lathes requiring an average of 24 horse power, a good arrangement would have been to use three motors of 10 horse power each, as it is better to run short lengths of shafting, and in case of a break down less time would be lost.

Very important points to be considered are light and cleanliness in a shop, as they have considerable influence upon production. The fewer the belts the lighter and cleaner a shop will be.

Countershafts are quite unnecessary in a manufacturing machine shop, and for group driving an excellent method is used in Woolwich Arsenal, England, described by Colonel Holden in a paper before the Institution of Electrical Engineers, November, 1905. There is one main line shaft having a cone pulley over each machine. These cone pulleys are not carried on the main shaft, but on tubular bearings through which the main shaft passes clear, the bearings being supported on brackets (see illustration No. 6, opp. page 48, Journal of Inst. E. E., Vol. 36). The cone pulley carries the armature of an electromagnetic clutch and the electromagnet is keyed to the shaft. These clutches are quite reliable and very efficient as they do not require more than one-fourth of a watt per horsepower, or 1/3000 part of the power transmitted. Although individual electric drive is apparently too expensive for small machine tools at present, the time will come when the motor will be an integral part of every machine. C. H. Haddrell.

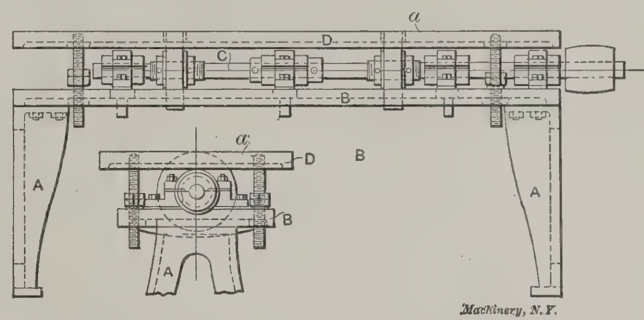
Cincinnati, O.

A SURFACE GRINDING MACHINE.

The accompanying sketches show a surface grinding machine, as used by a large eastern establishment for grinding surfaces that have to be scraped; it can be used for a great variety of work, with a considerable saving of files and time. It is very simple in construction, and not very expensive; one of those handy home-made tools the boys wouldn't do without after its usefulness has once been appreciated.

In almost any shop there is a lathe or other machine, whose time of service has ended, which is fit only for the scrap heap. Its legs can be used for the grinding machine as shown at *A A*. On these legs is fastened a cast-iron plate *B*, to which are attached the shaft bearings *C*, provided with double grinding wheels to accommodate two men. A machine with one wheel can be constructed in the same way, where there isn't much grinding to be done. The two wheels are held in place by means of large nuts with right and left threads screwed on the shaft. *D* is the upper plate, and has screwed to its under surface four long studs, each furnished with double nuts. These four studs fit in four holes drilled on plate *B*, as shown. Face *a* must be perfectly true. By means of the nuts, plate *D* can be set in such position that the two grinding wheels, which must be of the same diameter, will be tangent to the upper face *a* of the plate *D*.

When the upper plate is set properly, the four upper nuts are tightened, to keep it in the right position. Two collars, one on each side of the central bearing, keep the shaft in place. The wheels should run very true.



Front Elevation and End View of Double Surface Grinder.

Evidently any irregular surface that slides on face *a* will have its irregularities ground down. I have seen large piston rings and ring segments, badly sprung, that otherwise would have been filed or machined over again, ground easily and almost to perfection in a short time on one of these grinding machines. J. M. Menegus.

Los Angeles, Cal.

[The means provided for adjustment of the table *D* are primitive, as might be expected in a "homemade" tool, but the very fact that the adjustment is not easy to change undoubtedly is one reason for its success. The ordinary commercial grinder of this type is not a great success because of the difficulty generally found in keeping the wheel in good condition, and this is largely the fault of the operator in "monkeying" with the table adjustment so as to make the wheel cut faster. Such machines should be set so that a very thin cut is taken, and then they work very well.—Editor.]

A MILLING ATTACHMENT FOR DIE SINKING.

I enclose herewith a sketch of an attachment for milling long semi-cylindrical grooves with a vertical milling machine or die-sinker. This device is used in the die-sinking shop of a large drop-forging plant making many automobile parts, such as axles, etc.

The shaft *A* is connected to the spindle of the milling machine or die-sinker, and carries a bevel pinion *B*. This pinion drives the spur gear *D* through the medium of the bevel gear *C*. The gear *D* meshes with the teeth of the milling cutter *H*, thus driving it. In order to make the device as compact as possible, the face of the bevel pinion *B* is recessed to clear the spur gear *D*. The milling cutter has no arbor, but is carried by two gimbals or centers, *K*, of which a separate sketch is given. These, when adjusted, can be held in place by the setscrews *J*.

The whole apparatus is mounted in an extremely heavy and stiff frame, *F*, braced by arms *G* to the milling frame. This bronze frame takes the thrust of the cutter, and steadies it. The shafts run in bronze boxes with ample provision for oiling. The spur gear is also of bronze, so that by no chance can the teeth of the cutter be injured by failing to mesh with those of the gear.

The length of groove which can be milled with this attachment is limited only by the longitudinal travel of the bed of the machine to which it is attached. The writer has seen grooves three feet in length which were the work of this appliance. Previous to the introduction of this device into the shop, it was customary to rough plane the grooves, and then

finish them by clipping and filing, a laborious and time-consuming operation requiring highly skilled labor, as accuracy was necessary. "DIDYMUS."

[It is not quite clear from the letter given above whether the cutter is fed through the work axially, or in the same way that it would be in an ordinary horizontal miller. Presumably,

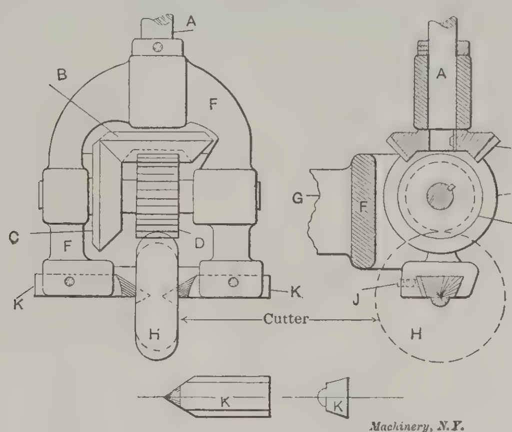


Fig. 1. Milling Attachment for Die Sinking.

however, the former method is used, since otherwise this attachment would offer no advantage over an ordinary milling machine. This device, rearranged to be driven by a horizontal spindle and thus requiring no bevel gears, has been used for many years in die-making for such work as that shown below in Fig. 2. It will be noticed that the design allows a cutter

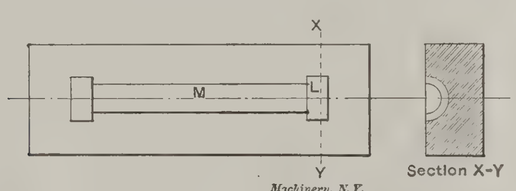

Fig. 2. Sample of Work which may be Done with the Device.

to be sunk in the metal clear to the center line. Semi-cylindrical pockets like those shown at *L* can then be easily machined in the die. The groove *M* may be afterwards either milled or planed, as desired. Other uses will readily suggest themselves.—EDITOR.]

AN ADJUSTABLE HOLLOW MILL.

An adjustable hollow mill is by no means a novelty for such tools were long ago put on the market by the Brown & Sharpe Mfg. Co. One difficulty with the Brown & Sharpe tool, however, is that the adjustment to an exact diameter is somewhat troublesome and requires considerable skill on the part of the workman. The hollow mill shown in the cut, Fig. 2, was made to simplify the matter of adjustment and its construction is plainly shown in the line cut, Fig. 3. The adjustment is effected by a threaded ring, *A*, which is bored out conical at the front end where it bears on the ends of the

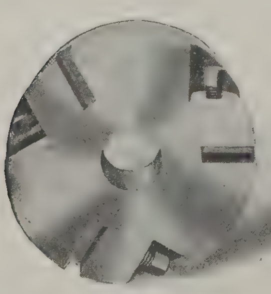

Fig. 1. Jig for Grinding Blades.

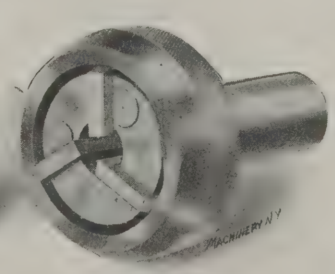

Fig. 2. Improved Adjustable Blade Hollow Mill.

cutting blades. The position of the three blades, *C*, is such that their cutting edges are radial and they are clamped with bolts, *B*, with nuts at the back in a similar manner to the regular Brown & Sharpe tool. The ring not only effects simultaneous adjustment of the blades but prevents them working out in case the clamping bolts loosen.

It is important when the blades are reground that they all be ground to the same length. For this purpose the jig shown in Figs. 1 and 4 was made. The blades are clamped in the three slots by the setscrews shown, being reversed so that the bevel ends rest on the cone piece *A* and this of course puts the cutting edge out; they are then sharpened exactly the same as a cutter with inserted teeth, the sharpening of the edges taking place on the cylindrical surface as well as

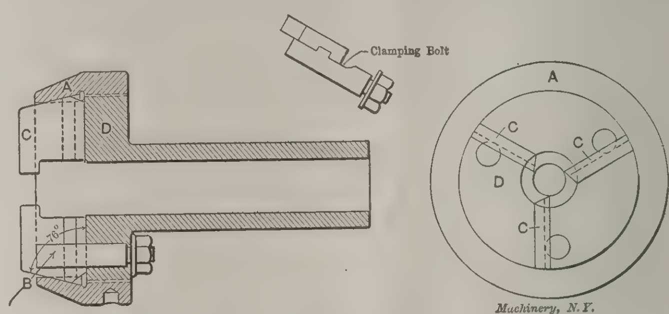

Fig. 3. Construction of Hollow Mill.

on the face. The grinding operation is effected by mounting the jig on a mandrel and treating it the same as an inserted tooth cutter, as already stated. It is quite evident that all the blades must be ground to the same length in this manner and when mounted in reversed position in the tool-holder they will all stand with the cutting edges the same distance from the center of the tool. OTTO ECKELT.

Berlin, Germany.

BOILER HORSE POWER FOR STEAM HAMMERS.

In the March issue of MACHINERY there is a communication giving rules for finding the capacity of steam hammers, and the horse power required for operation. Outside of the question of the kind of steam hammer in use—whether one in which the steam merely lifts the tap, which latter operates on the work only by its own weight, less friction, or one in which there is a direct blow caused by live steam on the upper side of the piston—there is a much more important question, as to what the "horse power" of a boiler really is. The hammer certainly exerts a definite horse power; that is, there is a certain weight lifted a certain number of feet in a minute, or a certain number of pounds pressure exerted through a certain definite distance per minute; but the same boiler will do different amounts of work in the two different types of hammer, or to put it the other way, the two different types of hammer, rated at the same capacity in pounds, will get dif-

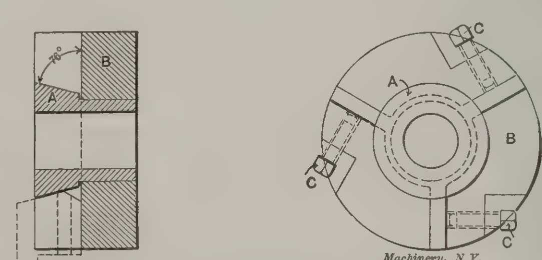

Fig. 4. Construction of Jig for Grinding.

ferent amounts of work out of the same boiler—that is, one type will work at its rated capacity with a boiler which can not supply the other.

And as to the "horse power" of a boiler, that is the worst kind of a misnomer—one engine will get three times the horse power out of a given boiler, that another will; and a duplex steam pump or a steam hammer will take many times more steam to exert a given horse power, than any engine in use to-day.

Another question comes in, as to what "constantly" means. One hammer is running "constantly" when it is making ten strokes a minute and another will take a hundred and fifty strokes to be entitled to be working "constantly"—this, independently of pauses. The same hammer, rated in pounds of blow, will have to work twice as fast on one kind of work, as on another.

The rule seems to me to be something like the way to get the weight of a pig by balancing him against a stone and guessing at the weight of the stone. ROBERT GRIMSHAW.

Hanover, Germany.

CHANGING DRAWINGS.

Probably one of the most important problems coming up to draftsmen in general, is making changes on drawings. The changes I particularly refer to are those required in shops manufacturing standards, when some fellow comes along and wants his order filled a little different. He just changes from the standard enough, probably, so that the original drawings cannot be used, and then it's up to the draftsman to make a new drawing or change the original. As the original is standard, it is not desirable to make erasures on it; therefore, the problem is at hand. To make a new drawing would require a lot of time, and as time is money with the boss, it is our duty to devise some means of saving it for him. A method for doing this which I have found that reduces expenses to a minimum may be briefly described as follows:

From the original drawing make a brown print, using a thin, tough paper. This gives a print with clear white lines on a brown background, the brown being impervious to light. Paint out on this print, with ordinary drawing ink, the lines not desired on the changed drawing, after which make a second brown print from the first. The print thus obtained has dark brown lines on a white background. Draw in on this print the changes and you have the new drawing desired, from which blue prints can be made.

The writer has used this method for some time and finds it a very desirable one. G. L. P.

TO DETERMINE THE ANGLE OF A DIE-BLOCK SLIDE TO MATCH THE KEY.

There appears to be a mistaken idea regarding the taper of die-blocks and their keys. It is quite common to see drawings with the same taper per foot indicated on each. This is not correct, and in cases where they are so marked it always requires an extra fitting of the key.

From the sketch it can be seen that when looking at the key in the position marked *A* the normal taper is apparent,

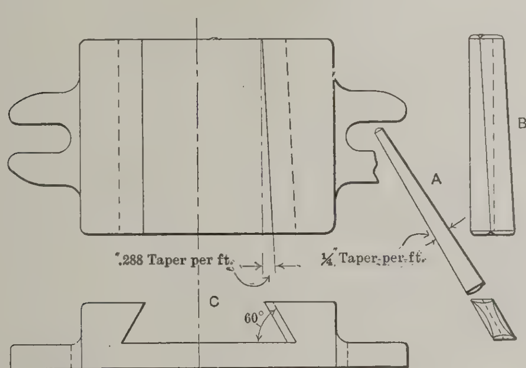

Fig. 1

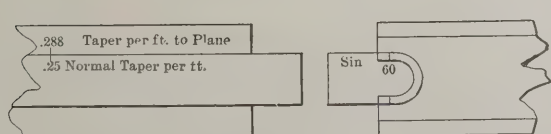

Fig. 2

Variation in Angle of Die Block Slide Due to Angle of Key.

but when viewed as in position marked *B* it assumes an oblique position which makes the angle in the die-block differ from that of the key.

The angle of the die-block can be found by dividing the normal taper per foot of the key by the sine of the angle of the slide. For instance, taper per foot of key is 0.25, the slide is 60 degrees and the sine 0.866; therefore $0.25 \div 0.866 = 0.288$ inch, which is the taper per foot of the die-block. To avoid questioning in the machine shop, it is well to state that the 0.288 inch taper per foot is equal to the normal taper of ¼ inch per foot of the key.

Although alluding principally to die-blocks and their keys, it is of more importance that machine slides and their taper gibs should be dimensioned correctly, as they (especially long ones) are not so easily fitted.

The method of making this calculation on the slide rule is also shown. Set rule to the sine of the angle *c* and set the runner on the scale *B* over the normal taper per foot of the gib or key, and on scale *A* read the taper, to which plane the die-block. The difference in angles is more noticeable as angle *c* decreases; for instance, should it be 20 degrees and the taper of the gib remain 0.25 inch per foot, the angle for planing would be 0.731 inch per foot. WINAMAC.

PRACTICAL SYSTEMS.

Manufacturing establishments of the present day are run to make money and not for the purpose of affording lucrative positions wherein men can show to the world what brilliant talent they possess. It matters not how much of a genius a man may happen to be, or what his scientific attainments are, if they cannot be utilized for the practical results that are required and for the financial gain and benefit of the man or the concern which employs him. Results count, and if one man cannot produce them he is likely to be turned down in favor of a man who can.

The up-to-date manager, eager to make a good record and to have the business of the establishment of which he is the head, come out on the right side of the ledger at the close of the year should not be misled by the man with the brand new system, the like of which was never before seen or heard of; that will produce such astonishing results; that will fill the office with an expensive lot of filing cases, cards, blanks, charts, and other marvelous devices, and such an elaborate and intricate method of indexing, filing and handling the information derived from a mass of technical reports ornamented with symbols and strange hieroglyphics, and received every ten minutes from all parts of the plant, until it requires an extra dozen clerks to run the thing and gives him such a mass of figures and scientific deductions about a whole lot of things that he doesn't want to know and hasn't time to wade through if he did. But what he wants to know is: How much consumable supplies cost last month; why they cost 20 per cent more than the month before; what was the cost of the stock used on that job for Billings; why did Johnson's job get "hung up" for three weeks; how does it happen that there are five idle machines in Smith's department when an order from Jones has been in the office for a week that might just as well have been pushed along on those idle machines; why Robinson is getting just the same pay as Oliver and turning out only about half the work; why Porter's name did not get on the pay roll and no one in the office knew anything about him until he turned up on pay day.

When to get these and a thousand other practical items of information that are needed every day, but that the new-fangled and technically elaborate system does not give, he has to go out in the shop, just as he used to, and dig out the facts for himself, it is high time to get down out of the clouds, have a house-cleaning and get a system that will tell what he wants to know, and tell things pretty soon after they happen, and tell wrong things before they have an opportunity to happen at all; not minding about the more theoretical matters, however alluring it may seem from the scientific or technical aspects of the system, because if it does not produce practical results and give, not only a detailed but a comprehensive idea of what is going on in the establishment, from the office to the shipping room, it is not wanted and the practical business manager cannot afford to have his administration loaded up with it.

This is not a tirade against systems, as such, but is just a few remarks in reference to the impractical systems that one finds in some of the would-be-up-to-date establishments of to-day; against the conditions in this respect which may be well described as system gone to seed. A proper, practical system, devised to suit the local and individual conditions, which have been carefully studied, comprehensively considered, and the

means adopted to suit their peculiar needs, is all right and cannot be too highly commended.

"Red tape" is good when we use the expression as meaning that condition wherein the business is transacted through regularly authorized channels, by properly authorized methods, and the transactions noted by correct records, but when the "red tape" is used for the sake of having "red tape," then it degenerates into what we might call "green tape," and the sooner we drop it the better it will be for the welfare of the business, the pocket of the owner, and the reputation of the manager.

Neponset, Mass. OSCAR E. PERRIGO.

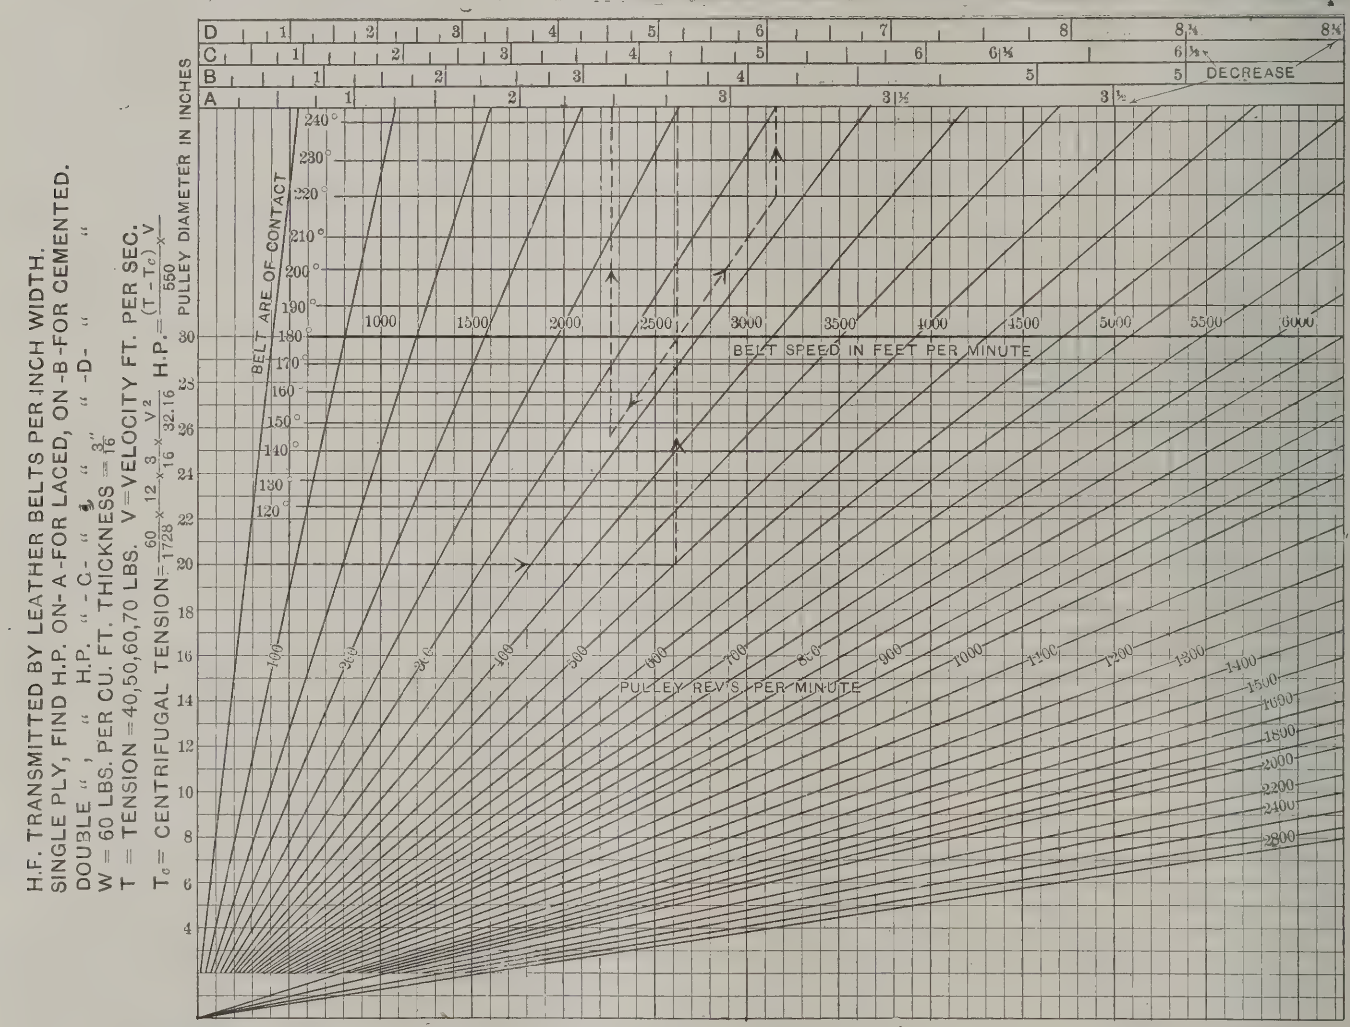
HORSE POWER TRANSMITTED BY LEATHER BELTS PER INCH OF WIDTH.

In laying out a diagram for the horse power of belting, the points to be considered are: pulley diameter, pulley revolutions per minute, belt speed in feet per minute, belt arc of contact, centrifugal tension of belt, and the belt itself. To my mind the ideal diagram should contain all of these. In the past many diagrams have been published but none, which have come to my notice, seem to fill all the conditions. One of the best was the one of Prof. J. J. Flather, published as a supplement to Machinery in March, 1900, but even this one does not start with diameter of pulley and number of revolutions. The belt speed must be known. Taking the illustration as shown by dotted lines in Prof. Flather's diagram, one must make four movements to find the horse power when the belt speed and arc of contact are known. This seems to me unnecessary. With a belt contact of 180 degrees it should be possible to read the horse power direct from the belt speed. With any other arc of contact one additional movement ought to give the desired result. A diagram to be complete should also give all data upon which it is based, for in many cases a range of sizes, etc., which will answer in nearly every case will not do for some special case which may be needed, and, as is common with most special cases, needed in a hurry. For instance, leather belting is met with most frequently, but a case may arise where camel's hair belting is specified, and the weight and tension given.

Among all the diagrams which I have collected, I have been unable to find one which would answer all the conditions arising in my work. For the benefit of others who may be in like predicament, and for those who may be interested in the subject, I submit a diagram of my own which, so far, has proved very satisfactory to me and to those to whom I have given copies.

Referring to the diagram, it will be seen that with the belt speed given the horse power for single or double, laced or cemented belts can be read directly with an arc of contact of 180 degrees. Any other arc requires one additional movement, as is also the case when the pulley diameter and revolutions are given. The data are all given and may be used for any conditions outside the range of the diagram.

Bound Brook, N. J. F. W. HOWLAND.



Horse-power Transmitted by Leather Belts per Inch of Width.

[The method of using this diagram will perhaps require a little further explanation. Suppose that the problem is to find the horse power transmitted by a 6-inch single belt, cemented, driving a 20-inch pulley at 500 revolutions per minute; the arc of contact is 145 degrees. On the left-hand margin we read the diameter of the pulley which is 20 inches. Follow toward the right the horizontal line marked 20 to its intersection with the diagonal mark 500 which represents the number of revolutions per minute. From this point of intersection run a vertical line to the heavy horizontal line which is graduated for belt speed in feet per minute. This will be seen to be about 2,550. This vertical line may be continued to the top of the diagram across the four scales *A B C D* shown there. In accordance with the directions at the left of the diagram *B* is the scale we use for a single cemented belt. The vertical line, continued to the scale *B*, gives us about 3.6 horse power per inch of width of belt. This result, however, is true for an arc of contact of 180 degrees only, for any other arc of contact we must make a correction. Our problem

requires an arc of 145 degrees. From the point of intersection of the vertical line with the heavy horizontal line on which are marked the speeds in feet per minute, run a diagonal line toward the lower left-hand corner, as shown by the dotted lines. At the point where this diagonal line intersects the proper horizontal for the required arc of contact, graduations for which will be found near the left edge of the diagram, erect a second vertical line to the scales at the top of the cut. Following the dotted lines and arrows shown, this gives us on the scale *B* about 3 1/3 horse power per inch. Multiplied by 6 inches, the width of our belt, we have a capacity of $6 \times 3\,1/3$ or 20 horse power. To still further illustrate the effect of a variation in the arc of contact consider the same problem with 220 degrees contact. Continue the diagonal line drawn for the last problem in the other direction, through the horizontal graduations corresponding to 220 degrees. From the point of intersection of the diagonal and the horizontal, erect a perpendicular to the scale above. This gives about 4¼ horse power per inch on scale *B* or about 25½ horse power for a 6-inch belt. This operation is also shown by dotted lines in diagram. Toward the end of each of the four scales *A B C* and *D* will be found a figure marked "decrease." This signifies that after that point in the scale is passed further increase in belt speed per minute will result in a decreasing power transmitted, owing to the action of centrifugal force on the belt as it passes around the pulley. This has the effect of lessening the arc of contact, and the pressure between the belt and face of the pulley as well.—EDITOR.]

JIG KNOCK-OUT FOR TIGHT WORK.

I had the job of drilling some drop forgings, like that shown in Fig. 1, in a jig and had considerable trouble in getting them out of the jig owing to the chips, the forgings being a neat fit having been milled on all surfaces before drilling. There were three blind holes drilled in these forgings and the chips would rest on the bottom of the holes and stick up into the jig locking the jig and forging together so that it was necessary to drop the jig on the floor each time to jar the forging loose. I soon got tired of this performance and devised the fixture shown in Figs. 2 and 3 to loosen the forgings after drilling.

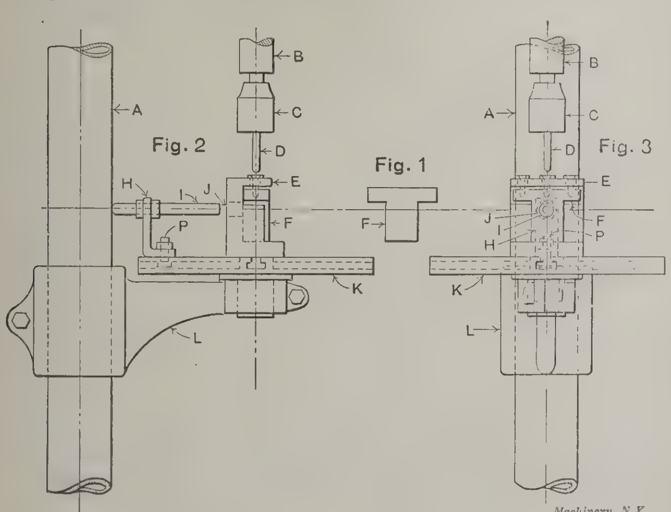


Fig. 1. Forging to be Drilled. Figs. 2 and 3. Front and Side of Drill Press with Knock-out Attached.

Figs. 2 and 3 show the front and the side of the drill press with the fixture for removing the work from the jig. *A* is the drill press column, *L* is the table bracket, and *K* is the table supporting the jig *E*, in which is the drop forging *F*. This forging was clamped in the jig by a clamp, not shown, which encompassed the front of the forging and the back of the jig. A hole, *J*, was drilled in the back of the jig and an angle-piece, *H*, was bolted to the table in which a rod, *I*, was secured by nuts. The hole, *J*, was drilled at such a height that its center was of the same height as the hole in *H* and was made considerably larger than the rod so that there was no trouble in entering it when loosening the forging. To remove the work after removing the clamp the operator takes hold of the jig on each side and shoves it back so that the rod *I* enters the hole in the back of the jig, striking the work and pushing it out. This is much better than dumping the jig on the floor and lifting it back again for each piece.

Philadelphia, Pa. C. W. J.

EXPANDING LATHE MANDREL.

The expanding lathe mandrel shown in section in Fig. 1 is one that was made for turning the shells down in Fig. 3. These, as it will be seen by referring to the dimensions, are very light and thin, the finished thickness or the wall being only 3/16 inch. The body of the mandrel is made of a casting, *A*, which is squared at one end, *G*, for the lathe driver and

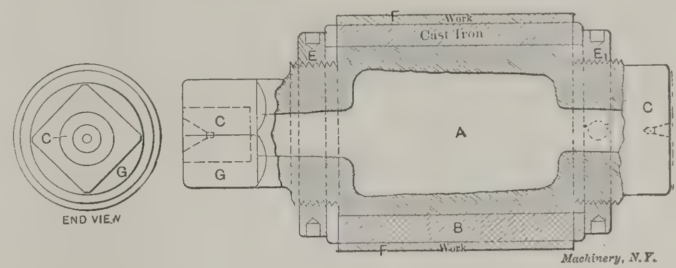

Fig. 1. Expanding Mandrel for Turning Shell.

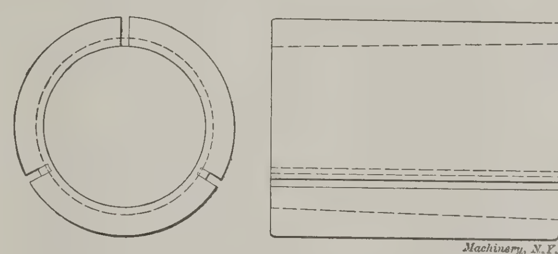

Fig. 2. Bushing Used with the Mandrel.

threaded at each end for the nuts *E* and E_1. The body of the mandrel is turned to a taper of about ¾ inch to the foot, and on this part is fitted the cast iron expanding bushing, *B*. This bushing, shown in Fig. 2, has three longitudinal cuts evenly spaced on the periphery, and one of the cuts goes through to the bore. The ends of the arbor, *A*, are bored out and hardened steel centers, *C*, are fitted therein in which are carefully reamed centers. A spanner is provided for tightening and loosening the nuts *E* and E_1, which is necessary, of course, when putting on and removing the work, *F*. The arbor is driven by the driver shown in Fig. 4. This screws on the lathe spindle and has a square hole cored in the end for the reception of the squared end on the arbor. This arrangement makes a very neat and compact drive and one which, if prop-

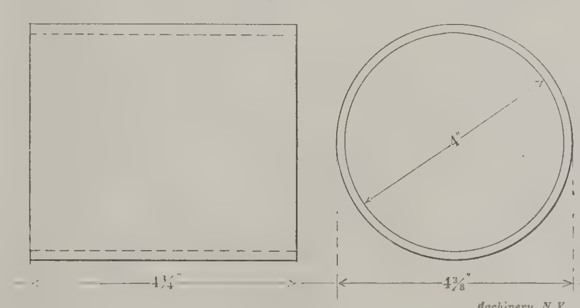

Fig. 3. The Bushing which is to be Turned.

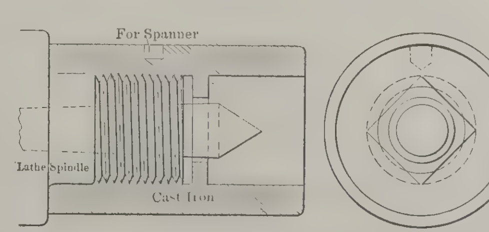

Fig. 4. Driver for the Taper Arbor

erly made, drives the arbor from all four corners of the square and in this manner avoids the tendency to eccentricity which is always present when the work is driven by a single-tail dog.

W. T.

CARD INDEX FOR DRAFTING ROOM.

The card index system has proven a valuable aid in facilitating the drawingroom work, most particularly for keeping track of drawings of varying kinds and descriptions. However, it is apt to become rather voluminous if the business is a growing one, and even though one may add all the card-index guides possible, dividing the index into classes and subdivisions, there will invariably be some sub-divisions that will contain more cards than are convenient to look through every time a drawing is to be found.

For this reason I thought it appropriate to give a sample of a card that will make the index less voluminous, and at the same time permit a saving of time when looking up a drawing. It has been the usual practice to make one card for each drawing indexed. This is, however, not necessary as long as there will always be a certain number of drawings of the same kind of tools or articles that can conveniently be listed on the same card. The card depicted shows plainly the principle employed in regard to using the index guides, having first guides for general classes, and then for subdivisions. On the third

Arrangement of Drawing Card to Save Space.

line of the card is given the general name of the class of articles for which the drawings on this card are made. The remainder of the card can be used for filling out from time to time additional drawings belonging to this same general description. It will be seen that by means of this system the card index can be easily reduced to a fraction of its original volume. As the draftsman is well aware, the average life of a drawing is rather short and still, as superseded drawings have often to be referred to, it is well to systematize the drawing room so that the superseded drawings are kept on file right with the regular ones, but marked "superseded," and with the date the reissue took place. In order to save unnecessary delay in looking up a drawing the date when the drawing was superseded should also be marked on the card in the index. With the exception of these remarks the picture of the card will explain itself, and I hope it may prove a time-saving suggestion to some drawing rooms that work under difficulties with rapidly expanding card-index systems.

Hartford, Conn. ERIK OBERG.

STIFFENING A LONG BORING BAR.

When using a boring bar to take heavy cuts in deep holes, it is impossible to hold the tool with any degree of rigidity by the means ordinarily used. The boring bar is so long that it has tremendous leverage on the comparatively narrow boring surfaces of the compound rest and the main slide rest. The more joints there are in the tool post and slide the worse the conditions become. The accompanying sketch shows an arrangement which may be used to relieve the slide rest bearings of the greater part of the strain, holding a bar very rigidly and doing away with chatter, no matter how heavy a cut is being taken. The device was adopted primarily to avoid the breaking of the dovetail on the tool slide and compound rest.

D is a boring bar held in a tool post *E*, whose construction is clearly shown in Fig. 2, although its exact design is immaterial to the success of the device described. *F* is a stiff

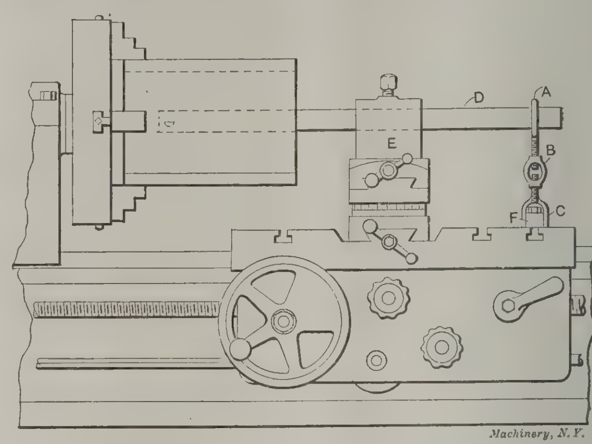

Fig. 1. Stiffening a Long Boring Bar.

steel bar provided with two bolts *G* by which it is fastened in the T-slots of the carriage, as shown in Fig. 1. *A* is an I-bolt, forged of ⅝ stock, which encircles the boring bar. A similar I-bolt *C* is adapted to encircle the bar *F*. These two bolts are connected by turn buckle *B*, and this is screwed up

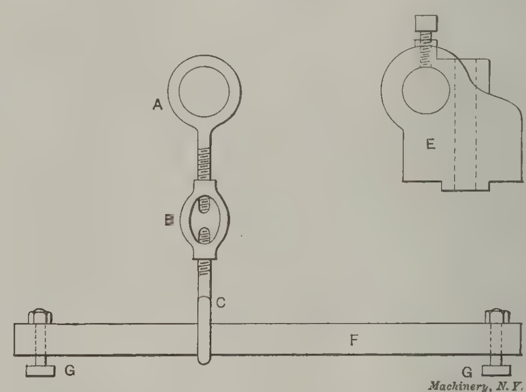

Fig. 2. Details of the Attachment.

until the parts are in tension, thus relieving the bearing surface of the slide rest of the bending strain due to the cut at the front end of the bar. ALBERT ANDREWS.

Chicago, Ill.

FRENCH RULES FOR ABBREVIATIONS OF METRIC SIGNS.

The French minister of public instruction has decided that all teachers throughout France are in future to employ the following distinctive abbreviations for the various weights and measures For denoting length—myriameter, Mm.; kilometer, Km.; hectometer, Hm.; decameter, dam.; meter, m.; decimeter, dm.; centimeter, Cm., and millimeter, mm. For areas—hectare, ha.; are, a, and centiare, ca or m². For measures of bulk (timber, decastere, das; stere, s or m³, and decistere, ds. For measures of mass and weight—tonne, t; quintal metrique, q.; kilogramme, kg.; hectogramme, hg.; decagramme, dag.; gramme, g.; decigramme, dg.; centigramme, cg., and milligramme, mg. For measures of capacity —kiloliter, kl.; hectoliter, hl.; decaliter, dal.; liter, l.; deciliter, dl.; centiliter, cl., and milliliter, ml. The use of capital letters for the three largest denominations of length are intended to prevent confusion, and all the other abbreviations follow on uniform lines. The employment of full stops between the letters is officially abolished, and k. g. for kilogramme and m. m. for millimeter disappear.

* * *

The city of Berlin has a very extensive system of pneumatic tubes for the handling of mail. The total length of the tubes in 1896 was 42 miles; in 1900 this had reached 47 miles, which was increased to 75¾ miles at the end of 1904. Sixty-nine stations are served by this system.

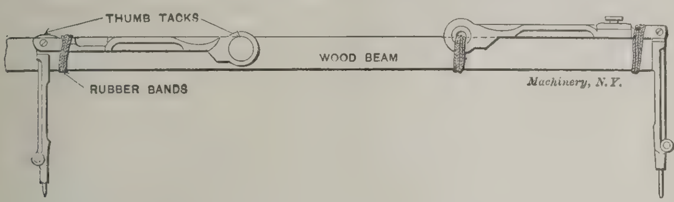
SHOP KINKS.

A DEPARTMENT OF PRACTICAL IDEAS FOR THE SHOP.

Contributions of kinks, devices and methods of doing work are solicited for this column. Write on one side of the paper only and send sketches when necessary.

A SHORT ORDER BEAM COMPASS.

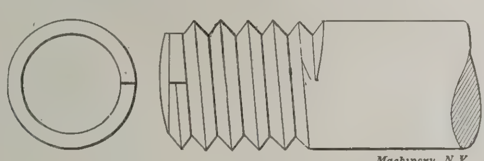
A friend of mine, having need of a beam compass in a land where there was none, hit upon a scheme as illustrated by the sketch. He dismantled the compass belonging to his drawing set and fastened the needle-point end firmly to a stick about one-half inch square, and of the desired length. This fastening was accomplished by first notching one side of the stick to admit the hinge of the compass leg, so it might lie squarely



on top, and tying it with stout cord. The pencil leg was fastened by a thumb-tack through the eye, another on top to prevent "back-lash," and some rubber bands. This part, by the way, was placed at the side and not on top of the beam. The radius was easily adjusted by removing the two thumb-tacks and sliding the pencil leg to the right location. Once constructed, the compass worked as well as an expensive beam compass. BESSEMER.

TO PREVENT "CROSS-THREADING."

I want to tell you of a way to prevent "cross threading." The first turn of a thread on a screw, and in a nut also, begins at nothing, at the bottom of the thread, and increases gradually, for one turn, to a complete thread. Take a file and chisel, and cut away this imperfect beginning of the thread up to where the full thread begins, both in the screw and nut. They will then always "start" right. It is the



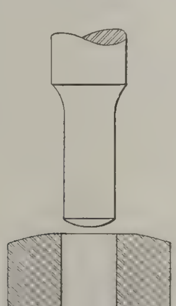
gradual increase at the beginning that allows the thread to get wedged at an angle and the screw and nut to become what is known as "cross-threaded."

Try this on your lathe chucks, etc., where it is an advantage to have the threads start easily, and where "cross-threading" might injure a fine tool; also on pieces of large diameter, with fine threads, which are difficult to start properly, such as unions and other large pipe fittings.

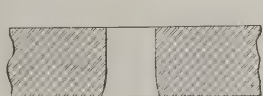
Beverly, Mass. C. E. BURNS.

PUNCHING HOLES THROUGH THICK METAL.

Some very interesting ways of doing work may be seen in agricultural implement factories; for instance, one piece made in such a plant is a piece of steel about 3 feet long, 2 inches



POSITION OF PUNCH AND DIE



SHAPE OF HOLE PUNCHED

wide and ⅜ inch thick at one end gradually increasing to ¾ inch thick at the other end. This piece is punched full of 7/16-inch holes. Most people will tell you that holes cannot of the punch. The tools used on this job are shown in the accompanying cut.

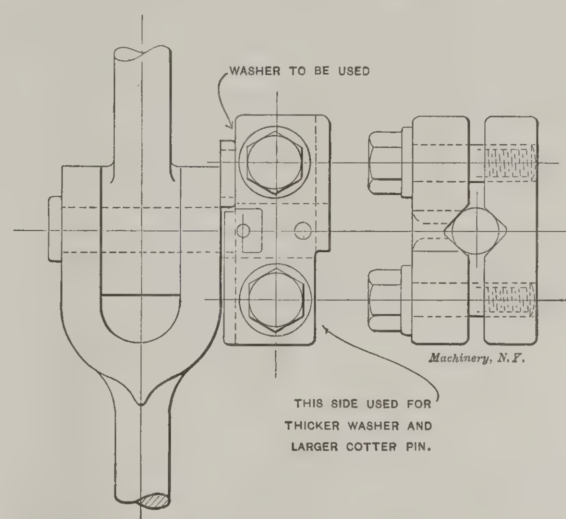
The punch was ground rounding at the end instead of square across and it was not allowed to enter the die by about ⅛ of an inch. For a 7/16-inch punch the hole of the die is made considerably larger, about 31/64 in this case. This makes a hole somewhat bell-shaped, as shown in the cross section.

In one place where I worked the punches were forged, not turned. The operator of the press touches the punches up on the emery wheel after they are tempered and they are then ready for use. My experience has been that a forged punch, especially one made by drop or die forging process, is superior to one which has been turned to shape. The dies are machined in the usual way. A. D. KNAUEL.

Moline, Ill.

JIG FOR DRILLING COTTER-PIN HOLES.

A jig for drilling cotter-pin holes is shown herewith which facilitates the operation as compared with the way it is commonly done. It consists of two pieces of steel forming a clamp, each piece having a V-groove to receive different diameters of studs. The upper one contains two holes which correspond with the size of cotter pins desired. Should more than the two sizes be required, extra top pieces can be used with



the same bottom piece. Part of the upper piece is cut away on each side on a line with the edge of the holes, which allows the washer to be used to be inserted therein and the jig then clamped in position. By this means no scribing or spotting is necessary and a much better job can be done. Although it is shown it is obvious that the male portion of the joint need not be in position when drilling. WINAMAC.

MAKING METAL FILLET.

I had occasion about a month ago to make several metal patterns and, not being able to procure metal fillet that would come up to my requirements, I decided to make it myself. I took some old three square files, ground off the teeth and then ground them to the shape of the fillet that I wanted. I took a piece of good high-grade tool steel and drilled holes just large enough to broach out to the form of the punch. The punch was made slightly tapered and I used one for about three holes, punching each hole a little deeper than the other. The draw plate was then hardened and tempered to a light straw. The fillet made in this way was quite small as I did not require a large size. To make a large fillet in this way would require the use of a draw bench strongly geared. For my use draw tongs and a bench vise did very nicely.

New York. L. I. ROSENTHAL.

* * *

The report of tests made on the cork insert friction surfaces of the brake and clutches made by the National Brake & Clutch Co., Boston, Mass., mentioned in the business notes of the July issue, should also have stated that the average coefficient of iron surfaces is 0.16 and for bronze, 0.14, under the same conditions which gave 0.33 to 0.35 with the cork insert surfaces.

SHOP RECEIPTS AND FORMULAS.

A DEPARTMENT FOR USEFUL MIXTURES.

This page will be used for the publication of shop receipts which the contributors know from experience to be practicable. Nearly all readers of MACHINERY can add something, and it is desired that they use this page as a medium for exchanging useful formulas. It makes no difference if they are old and supposedly well-known, provided they have not already appeared in this department.

228. IMPERMEABLE CEMENT FOR PIPES.

To make an impermeable cement for steam, air and gas pipes mix thoroughly powdered graphite, 6 parts; slaked lime, 3 parts, sulphur, 8 parts, and boiled oil, 7 parts. The mixture must be thoroughly incorporated by protracted kneading until it is perfectly smooth and free from lumps.

Dayton, Ohio. O. E. VORIS.

229. OIL FOR USE IN MICROMETER SCREWS.

To prepare oil for micrometers, fine mechanism, etc., take neatsfoot oil and put into it some lead shavings in order to neutralize the acid contained in the oil; let this stand for a considerable time, the longer the better. Oil thus prepared never corrodes or thickens. JOSEPH M. STABEL.

Rochester, N. Y.

230. SOLDER FOR GOLD.

To make a solder for gold melt together in a charcoal fire 24 grains gold, 9 grains pure silver, 6 grains copper, 3 grains good brass; this makes a solder for gold ranging from 12 to 16 carats fine. For finer gold increase the proportions of gold in the composition. To make it darker in color lessen the proportion of silver and increase that of copper.

Rochester, N. Y. JOSEPH M. STABEL.

231. TO ANNEAL FINISHED COPPER.

To make a mixture for protecting finished copper pieces which require annealing mix to a thick consistency white cold water paint and alcohol and apply to the copper with a brush. Allow the mixture to dry and then heat to a low red by dipping into pure melted lead at the required temperature. Cool in air or water, preferably the latter. L. C. CARR.

Lynn, Mass.

232. FOR GLUING EMERY TO WOOD OR METAL.

The following is a good receipt for gluing emery to wood or metal and I have used it with success where other cements have failed. Melt together equal parts of shellac, white rosin and carbolic acid (in crystals) adding the carbolic acid after the shellac and rosin have been melted. This makes a cement having great holding power. W. T.

233. BELT DRESSING.

I have found the following mixture to answer the purpose of a good belt dressing as well as an excellent anti-slip medium for hard-worked leather driving belts: Russian tallow, 1 ounce; best lard oil, 2 ounces; Venice turpentine, 16 ounces. This dressing is good to use on the belts of belt-driven motor cycles. W. R. BOWERS.

Birmingham, Eng.

234. LUBRICANTS FOR USE IN CUTTING BOLTS AND TAPPING NUTS.

Mineral oils should never be used in thread cutting and tapping, as they do not generally flow freely enough. An excellent solution for this purpose can be prepared by dissolving 1½ pound of sal-soda in 3 gallons of warm water, then adding 1 gallon of pure lard oil. This is known as a soda solution. Pure lard oil is the best for fine, true work.

Urbana, Ill. T. E. O'DONNELL.

235. VARNISHING BLUEPRINTS OR DRAWINGS.

The appearance of varnished blueprints and drawings may be greatly improved and the amount of bleached shellac varnish considerably decreased by the following process: Soak over night a quantity of isinglass in just enough cold water to cover it. Use a perfectly clean glue kettle, in which it is to be heated up, adding whatever amount of water may be needed to make a moderately thin sizing. Apply this warm, *not* hot, to the drawing or blue print. When dry apply one good coat of bleached shellac varnish. The effect will be nearly as good as the best varnished maps. OSCAR E. PERRIGO.

Neponset, Mass.

236. MOLDING MIXTURE FOR RUBBER STAMPS AND PATTERNS.

The following mixture is one which can be used for making molds for rubber stamps, or special shapes of rubber, or for complicated, odd, or queer shaped patterns, of small size, as the working must be done inside of ten minutes, and the surface takes a finish as smooth as glass if well rubbed. If an impression is to be made, the surface of the type or article to be impressed should be rubbed with a solution of kerosene, and graphite. Plaster paris, 5 pounds; French chalk, 2 pounds; china clay, 2 pounds; dextrine, ½ pound. Mix with dextrine water, which is made by dissolving 1 pound of dextrine in one gallon of water. FRANK G. STERLING.

Lowell, Mass.

237. WASHING OILY WASTE.

The following is an excellent method of washing oily waste. The chief objection to most of the common methods employed is that the waste, after being dried, is found to be matted and of a hard, gritty texture. The common method of washing the waste, using sal-soda in solution, is a good one, as far as the cleaning qualities are concerned, but it leaves the waste hard and matted, so that it is difficult to handle. A simple remedy for this is to rinse the waste (after being cleaned in the sal-soda solution), in very hot water, to which has been added a quantity of liquid ammonia. This will render the waste soft and light when dry.

Urbana, Ill. T. E. O'DONNELL.

238. A NICKEL BUFF.

For buffing nickel work, there is nothing that will give a luster equal to Vienna lime composition. It can be made by the user, but it is more satisfactory to buy it of the manufacturer, as when homemade it air-slacks very rapidly; it is put up by the makers in air-tight cans of about one pound each, and this shape will keep until used up. It is also a good buffing composition on brass or other metals where there is not much cutting down to do, as it will cut down and color in one operation. If there is much cutting down, go over the work first with tripoli, then color with rouge or lime. All these compositions are put up in different grades for fast cutting, and also for dry or greasy work. J. L. LUCAS.

Bridgeport, Conn.

239. TO WRITE ON STEEL.

Stamping tools with steel stamps will spring them and throw them out of true. Machinists should write their names on their steel tools using a fluid made of nitric acid 1 part, water 2 parts. Heat the tool gently until some wax that has been put on it melts and spreads thinly over the surface. When cold blacken the wax at a candle; then write on the wax with a steel point deep enough to touch the metal, and cover the writing with the fluid. In about three minutes wash and remove the wax. This fluid, however, will spread more or less and the writing will not be very fine. A better fluid can be made thus: Alcohol 2 parts, nitric acid 1 part, distilled water 15 parts, and nitrate of silver ½ drachm per quart of fluid. Nitric acid, however, produces vapors that are disagreeable and harmful. Chromic acid made by dissolving one part of bichromate of potash in 5 parts of sulphuric acid, for this reason is more desirable as an etching fluid, although much slower in its action. J. M. MENEGUS.

Los Angeles, Cal.

* * *

The unsettled condition of street numbers in San Francisco may be inferred from the following abstract from a letter sent to the Crocker-Wheeler Co. by their San Francisco office: "While it is not absolutely sure whether or not the number will be changed in from six months to a year, we think that our office may be considered as located at 206 First St. We have checked this matter of numbers over as carefully as possible, and we think that the above is as near as we can possibly get until the city authorities get to work and straighten matters out."

HOW AND WHY.

A DEPARTMENT INTENDED TO CONTAIN CORRECT ANSWERS TO PRACTICAL QUESTIONS OF GENERAL INTEREST.

Give all details and name and address. The latter are for our own convenience and will not be published.

22. L. G. V.—Will you please tell me how to make a continuous ringing Faraday type bell; a single-stroke bell? Also please tell me how I can make a direct-current bell work on an alternating current?

Answered by Wm. Baxter, Jr.

Continuous ringing single-stroke bells are generally made by providing a clockwork to ring the bell, and a magnet to throw a catch in or out that stops the clockwork when the bell is not in use. The clockwork is wound up with a key, and will cause the bell to strike several hundred times before it runs down. A single strike bell of the type used for signalling is shown in Fig. 2. This kind of bell will strike once each time the switch is closed. It consists of a horseshoe electromagnet, *A*, which attracts the armature *B*. This armature is held on an arm that is attached to shaft *C*. Another arm on this shaft carries the bell hammer *D*. The spring *E* holds the striker in the position shown, and when the switch is closed, so as to send current through the coils on *A* the armature *B* is attracted and *D* swings down and strikes the gong. If *D* were allowed to swing freely all the way down to the gong, it would rest upon the latter as long as the switch is closed, and this would muffle the sound, hence the arm that carries *D* is made with some spring, and a stop is provided that will hold *D* just clear of the gong; then when *D* is thrown down by the pull of the magnet it will strike the gong and immediately spring back. In some cases the arm that carries

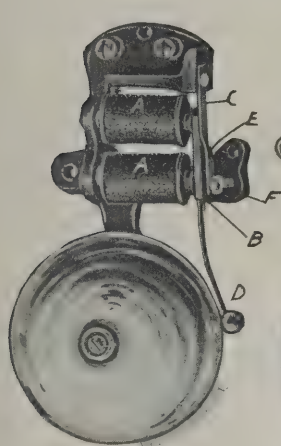


Fig. 1.

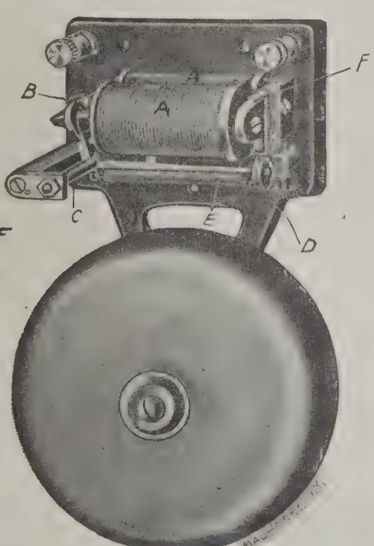

Fig. 2.

D is stiff, and the stop is made to spring. A vibrating bell is shown in Fig. 1. In this the magnet *A* attracts the armature *B*, which is supported by spring *C*, and *D* strikes the gong. The current passes through the spring *E* on the back of *B* to the stop *F* and these points separate when *B* is attracted, thus breaking the circuit and permitting *D* to swing back. The return movement of *B* brings *E* and *F* in contact again so as to close the circuit and send *B* forward once more. This action continues as long as the switch is closed. The rapidity with which *D* strikes depends upon the length from *C* to *D*. The best way to obtain the proportions of these bells is by examining one of the size you desire. They can be found in any railroad station in many designs and sizes. You cannot make a direct-current bell operate with an alternating-current.

Another Answer to Question 20.

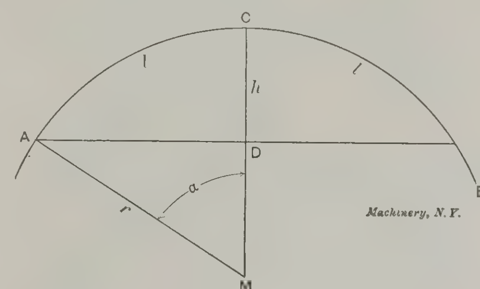
I notice in answering question 20 in the How and Why column of the July issue of Machinery, that you say you know of no method by which the radius of a circular arc can be calculated when only the length of the arc and the height of its middle ordinate are known. Though it is true that there is no formula which allows of a direct solution of this problem, yet it is easily possible to develop formulas which will lead to the desired result, and which can be solved by a method of repeated trials with little trouble and to any desired degree of accuracy.

AC is half the given arc and its length is called l, so that the length of the entire arc is $2l$. The height of the middle ordinate, CD, is called h. We know that $CD = AM \times$ versin α, and that the length of the arc $AC = 2\pi r x \frac{\alpha}{360}$. We thus have:

and

$$h = r \times \text{versin}\ \alpha \qquad (1)$$

$$l = \frac{2\pi r \times \alpha}{360} \qquad (2)$$



In these equations r and α are both unknown. From equation (2) we find by transposing that:

$$r = \frac{360\,l}{2\pi\alpha}. \qquad (3)$$

Substituting this value in (1),

$$h = \frac{360\,l}{2\pi\alpha} \times \text{versin}\ \alpha$$

If we call the value of the fraction $\frac{360\,l}{2\pi} = c$, the equation becomes

$$h = \frac{c}{\alpha} \times \text{versin}\ \alpha \text{ or } h \times \alpha = c \times \text{versin}\ \alpha \qquad (4)$$

This equation offers a solution for α by the method of repeated trial. It may be best to show by an example how this may be done.

Suppose the length of the arc is 30 inches and the middle ordinate is 4 inches; then $l = \frac{30}{2} = 15$ inches and $h = 4$. From this we find

$$c = \frac{360 \times 15}{2 \times 3.1416} = 859.41.$$

Substituting known values in equation (4), we have $4 \times \alpha = 859.41 \times$ versin α, or, simplifying:

$$\alpha = 214.85 \times \text{versin}\ \alpha \qquad (5)$$

Transposing, we find that $\frac{\alpha}{\text{versin}\ \alpha} = 214.85$. For first trial we take any number of degrees, say 30 degrees. The versed sine of 30 degrees $= .13397$, or about $\frac{1}{7\frac{1}{2}}$, so that $\frac{\alpha}{\text{versin}\ \alpha}$ is about $30 \times 7\frac{1}{2} = 225$. This is near enough to 214.85 to try this a little closer.

For this trial we use equation (5). We find that $214.85 \times$ versin $30° = 28.78$, which is not quite 30. As the versed sine increases with the angle, we now try a larger angle, say 31 degrees. We find $214.85 \times$ versin $31° = 30.68$, so that even this angle is not large enough. We try now 31 degrees 30 minutes. $214.85 \times$ versin $31\frac{1}{2}° = 31.66$. This quantity is now larger than the angle, so trying again for 31 degrees 15 minutes, $214.85 \times$ versin $31\frac{1}{4}° = 31.11$. So that 31 degrees 15 minutes is the nearest angle in quarter degrees. Of course, it would have been possible to determine the angle with a greater degree of accuracy, even to seconds by a few more trials; but this is close enough for an example. From equation (3) we find now $r = 27.501$.

A. L. De Leeuw.

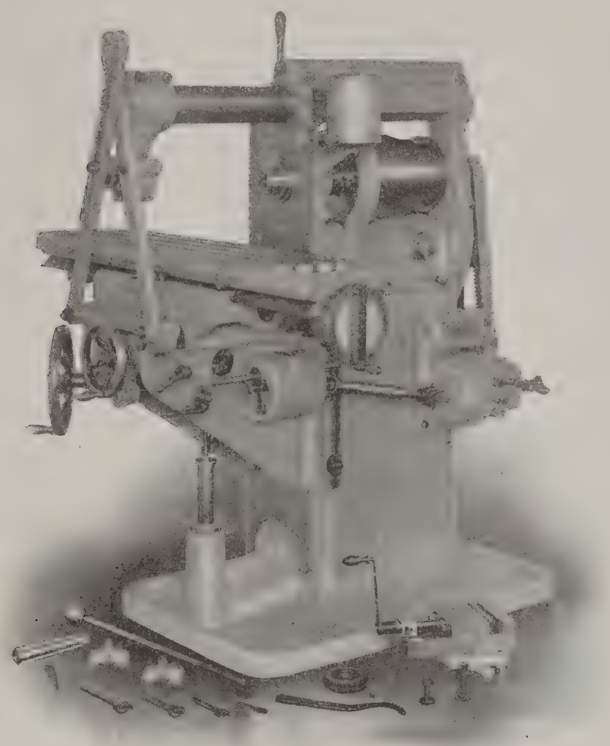
Hamilton, O.

MACHINERY AND TOOLS.

A MONTHLY RECORD OF NEW APPLIANCES FOR THE SHOP.

ADDITIONS TO THE BROWN & SHARPE LINE OF MILLERS.

The Brown & Sharpe Mfg. Co., Providence, R. I., have recently added to their line of milling machines a plain screw feed machine which they call their "No. 2 Heavy." This machine has the same capacity as the regular No. 2: 28-inch longitudinal feed, 8-inch cross feed, 19-inch vertical movement



Brown & Sharpe No. 2 Heavy Plain Milling Machine.

of the knee. A number of changes, however, have been introduced. The knee slide on the front of the column has been extended to the top of the casting, as will be seen in the accompanying halftone. This furnishes a stiff support for the front spindle bearing and permits attachments to be rigidly clamped to the face of the column. The hand wheels for the vertical and cross movements are provided with

Fig. 1. Thompson Grinder Arranged for Surface Grinding.

Fig. 2. Table Reversed and Head in Place for Face Grinding.

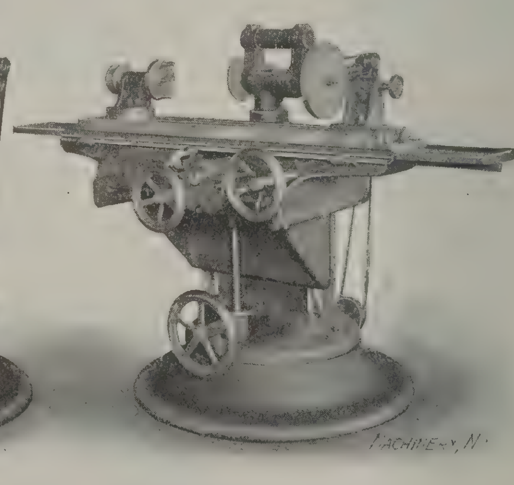


Fig. 3. Machine set up for Grinding between Centers.

clutches which can be disconnected after adjustments are made, thus doing away with the danger of accidental disarrangement of the setting, from pressing upon or hitting the handles of the wheels. The feed drive, which is of the geared variety driven by a chain from the spindle, can be disconnected from the spindle while the machine is running. Besides these changes, the machine has been made about 35 per cent heavier than the regular No. 2 machine. This weight has been so apportioned as to give the maximum amount of stiffness for the heavy service which it is intended the machine shall give.

A four-step cone is used and back gears are provided, these being inclosed in the frame under the cone. The overhanging arm is a solid steel bar, round and true, and it can be pushed back over the table when not in use. It is simply and efficiently clamped at both bearings with one lever at the front of the machine, enabling the operator to make adjustments quickly. The table has an unusual vertical depth, which provides it with a sufficient stiffness against bending strains. It has a quick return operated from the right hand end of the table by an internal gear and pinion; the table feed screw is not splined, an auxiliary shaft being provided for driving the clutch gears. The thread being unbroken, the life of the screw end is greatly prolonged and the original accuracy maintained.

With the double speed countershaft furnished there are sixteen changes of speed in geometrical progression from 13 to 439 revolutions per minute; with eight reverse speeds from 22 to 305 revolutions per minute. The speeds have twenty changes varying from 0.004 inch to 0.2 inch in one revolution of the spindle. There are no loose change gears. The machine is regularly equipped with longitudinal cross and vertical power feeds, but can be provided with hand, cross and vertical feeds when desired. The approximate net weight of the machine is 3,600 pounds. A countershaft, together with vise, wrenches, etc., as shown in the halftone, are furnished with the machine.

A similar machine of a smaller size, the No. 1½, has also been designed. This is a screw feed machine with 24-inch longitudinal feed, 7-inch cross feed, 19-inch vertical feed. This machine likewise is provided with the new features of extended knee slide, clutched hand wheels, and releasing lever for disconnecting the feed chain sprocket from the spindle while the machine is in operation. The net weight of this machine is about 2,600 pounds.

THOMPSON UNIVERSAL GRINDER.

The Thompson Grinder Co. Springfield, Ohio have recently redesigned their universal grinder. The rearrangement of this machine has been effected without altering the principle upon which the machine was originally planned. Inasmuch as the grinding spindle is mounted upon a column that is solid with the base the grinding wheels remain in a fixed position. They do not tilt, or slide up and down, or in and out. A heavy outer casing surrounds the column and carries the grinding table and movable parts. This casing turns upon the base

and neck of the column through an angle of slightly more than 180 deg. and can be clamped rigidly to the base below and the neck of the column above at any position, thus bringing the grinding table to any desired relative position to the wheel at either end of spindle. The photos herewith, were all taken without moving the camera, the different positions shown being entirely due to the turning of the casing and table about the column.

A great advantage is claimed for this principle from the fact that the work is always brought to the wheel, instead of the wheel being made adjustable in relation to the work; thus but few attachments are needed to effect the various grinding operations.

It is claimed by the makers that this machine has a larger capacity, and will do a greater range of work than any other universal grinder yet produced. The main dimensions of work that may be handled on this machine are are as follows: Knife grinding to the full length of table, 48 inches; surface grinding, 7 inches by 36 inches, is easily accomplished (see Fig. 1); cylindrical and taper grinding, 10 inches diameter by 36 inches long, on small head and tail stock (see Fig. 3); internal grinding by use of a high speed spindle, the fixture of which is clamped in the head of machine (but not shown in the cut), extends from the smallest diameter desired up to the swing of head stock, which is 10 inches; large shallow internal grinding up to 30 inches diameter by 3 inches deep, may be done by using a special headstock and allowing the work to hang over the edge of table (see Fig. 2). This last feature adapts this grinder to the use of die making and maintenance.

Strong claims are made for this machine upon the point of large capacity for every form of grinding operation. At the same time, all kinds of cutter grinding can be done quickly and conveniently as on any small machine designed especially for cutter grinding. This latest pattern is the result of constant use and severe tests for several years past.

GARVIN DUPLEX MILLING MACHINE.

The Garvin Machine Co., Spring and Varick Streets, New York, have recently built a duplex milling machine, which presents a number of noteworthy features. The most noticeable departure from the usual practice, as will be seen from the cuts shown herewith, is the method adopted for driving

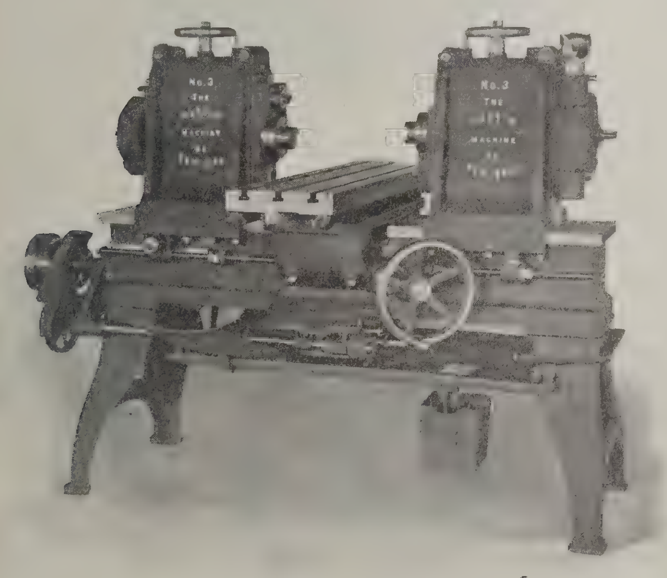

Fig. 1. Garvin Duplex Milling Machine.

the spindles, which receive their motion, not through belts as is the usual practice, but from vertical shafts with universal joints, leading from the overhead works. Another innovation is the provision of center supports for arbors for each of the two spindles, used when they are adjusted at different heights.

The line cut, Fig. 2, indicates the arrangement of the driving mechanism. The countershaft is driven by a friction clutch working within the cone pulley, which is in turn loose on the countershaft and directly belted to a corresponding cone on the main line. Two sets of spiral gears, one in each hanger, drive a pair of vertical telescopic shafts, which are below connected to steep pitch worms, running in oil, and meshing with worm wheels on the spindles. This arrangement gives a strong, positive drive, allows perfect freedom for adjustment, and avoids all belts, idlers, and tighteners.

The spindles have taper bearings and run in bronze boxes. They are carried in strongly constructed slides which have a

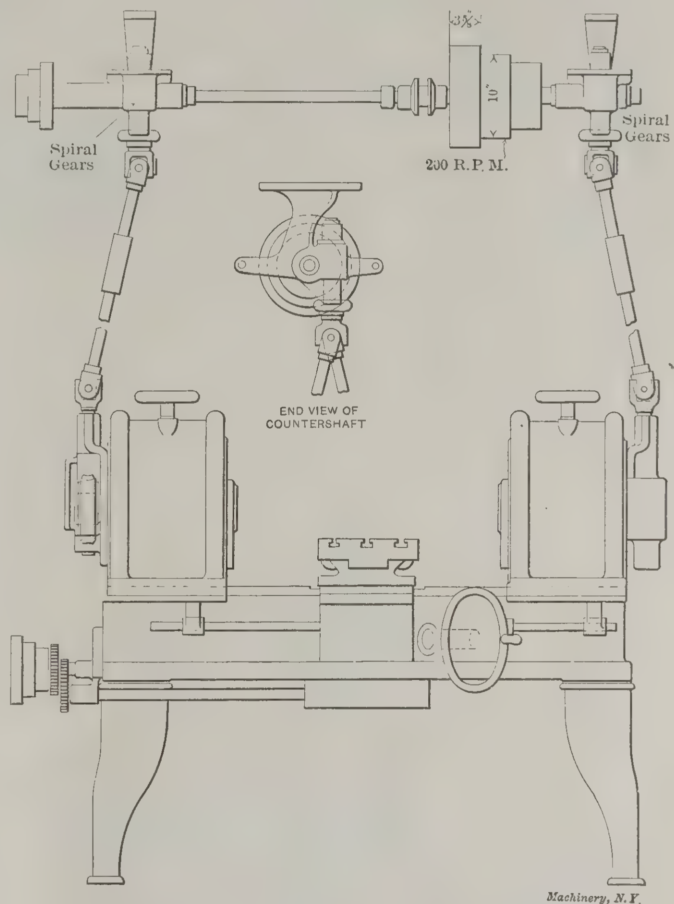

Fig. 2. Diagram showing Driving Mechanism.

vertical micrometer adjustment in the heads which carry them. Both of these heads have a micrometer adjustment along the bed, and one of them has, besides, a quick movement for running back to insert new cutters and arbors. Above the nose of the left-hand spindle, and below that of the right-hand one, will be seen in the halftone centers for the support of the outer ends of the two cutter arbors. These are adjustable within certain limits to permit a variation in the center distance between the two spindles. This arrangement permits the taking of cuts simultaneously on the top and bottom of a piece of work in cases where this is possible. Heavy cuts in steel can be taken in this way, feeding the work in between the upper and lower cutters.

The feed for the table is taken from a cone on the countershaft. The cone and the change gears furnished give twelve changes of feed. An automatic trip and reverse is provided, as well as a quick movement operated through a rack and pinion by the large hand wheel on the side. The length of feed is 42 inches; maximum distance between spindles is 5 inches; and the net weight of the machine about 3,120 pounds.

NEW HAVEN HORIZONTAL BORING MACHINE.

The New Haven Mfg. Co., of New Haven, Conn., build the horizontal boring machine shown in Figs. 1 and 2. On the bed is mounted a carriage with feeding and controlling mechanism similar to that of the lathe. At either side of the machine are mounted standards carrying the spindle heads, whose height can be adjusted to suit the position of the hole which is being bored. Between the centers of these two heads the boring bar is mounted.

This machine has a "swing" of 84 inches over the table. It takes 9 feet between the centers, although a bed 20 feet longer

can be furnished if desired, and it has a clamping surface on the table 48 inches long by 64 inches wide. The hand cross feed of the table is 52 inches. The head spindle, which has a diameter of 5½ inches, is driven by planed bevel gears. The centers for both head and tail spindles have No. 6 Morse taper. Both heads have a vertical adjustment by hand, but they can also be raised and lowered by power. A special feature of the tail spindle, shown quite clearly in Fig. 2, is that by loosening the lower bolts the spindle can be swung up out of line with the boring bar, thus allowing the bar to be removed without loosening the adjustment of the center or changing the position of the table. This is done by the hinge construction as shown. Both heads are counterbalanced. The screw cutting range is from 1 to 12 threads per inch, with feeds from 1/100 to ⅛ inch per revolution With a 16-foot bed the weight of the machine is about 30,000 pounds.

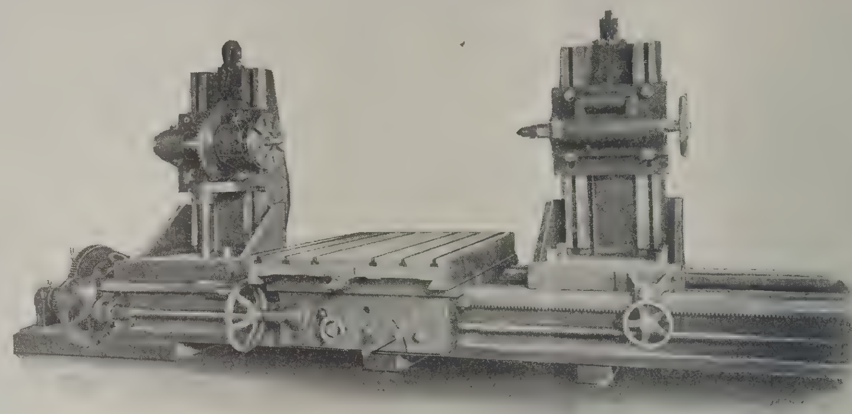

Fig. 1. New Haven 84-inch Boring Machine.

THE LATSHAW PRESSED STEEL PULLEY.

Two examples from a new line of pressed steel pulleys are shown in Figs. 1 and 2. The first halftone shows a six-arm pulley with reducing bushings removed from the hub;

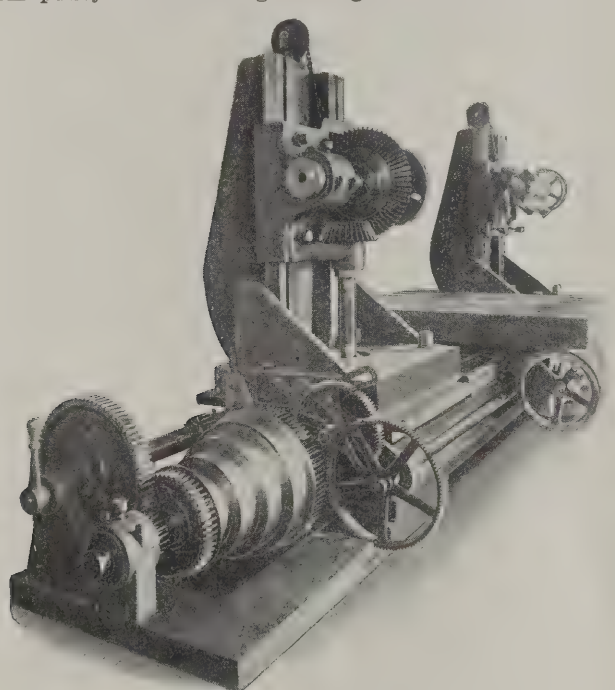

Fig. 2. Driving Mechanism of New Haven Boring Machine.

the second cut shows the double six-arm type used on the wider sizes. Larger diameters are provided with eight arms instead of six.

The pulley is of unusually simple construction. The rim

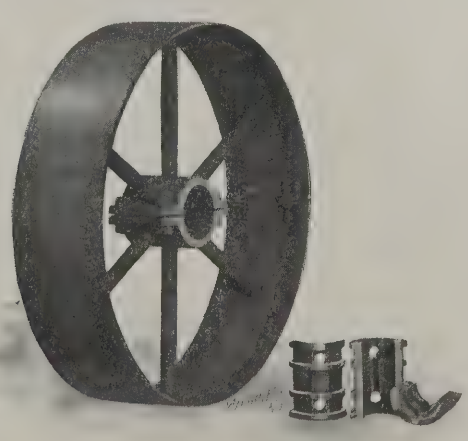

Fig. 1. Six-arm Single Latshaw Steel Pulley.

is formed of two curved sheets, bent for a straight or crowned face, as may be required, clamped together by riveted and bolted ears on the inner surface, and punched with suitable holes for the arms. The hubs are drop forgings, made by an improved process developed by the builders, which brings them so closely to size and finishes them so smoothly that no machining whatever is needed on them. These hubs are also punched for the arms, which are solid steel rods, reduced to a shoulder at the ends where they enter the rim and the hub. After being assembled with these parts, the ends of the spokes or arms are upset, and the pulley is completed.

It is claimed for this pulley by its makers, the Latshaw

Fig. 2. Six-arm Double Pulley, with Bushings in Place.

Pressed Steel and Pulley Co., Pittsburg, Pa., that this design is the simplest and strongest of any yet manufactured. The parts are few and simple, the hub is sufficiently strong to resist severe clamping strains, and has a thick enough section to be tapped for setscrews. It is furnished in all standard sizes from 12 inches to 50 inches diameter, and in all widths from 3 inches to 24 inches, crowned or straight. All pulleys over 14 inches wide have double arms, thus strengthening the rim against collapse from excessive belt pressure.

THE WIDE RANGE DRILL CHUCK.

The Wide Range Drill Chuck and Tool Co., Muncie, Ind., have brought out a drill chuck which presents a number of novel features. The design of the tool will be readily understood from the accompanying cut. Fig. 1 shows a front view of the chuck, Fig. 2 a side view, Fig. 3 is a detail of the jaw guide, Fig. 4 is a longitudinal section, and Fig. 5 is a detail of the jaws. The same reference letters are used throughout.

To the shank *A*, which is fitted to the machine spindle in the usual way, is attached the base of the chuck *B*. Two filister head screws unite this part solidly with the jaw guide *C*, which is shown in Figs. 3 and 4 in two positions, being rotated in one case 90 degrees about the center line from the position shown in the other view. This part is milled out to form seats for two jaws, *D* and D_1, which work at right angles to each other, the one in the front face and the other

in the rear face of jaw guide *C*. Setscrews, *E*, in the jaws are tightened by a square end key, onto the tool being held, which is thus clamped in the V-shaped side of the openings in the jaws. Springs *F* keep the setscrews pressed against the outer shell *G*.

The action of the device is as follows: The parts being in the position shown in the cut, screw *E* is tightened down upon the tool, which is thus centered horizontally in the V

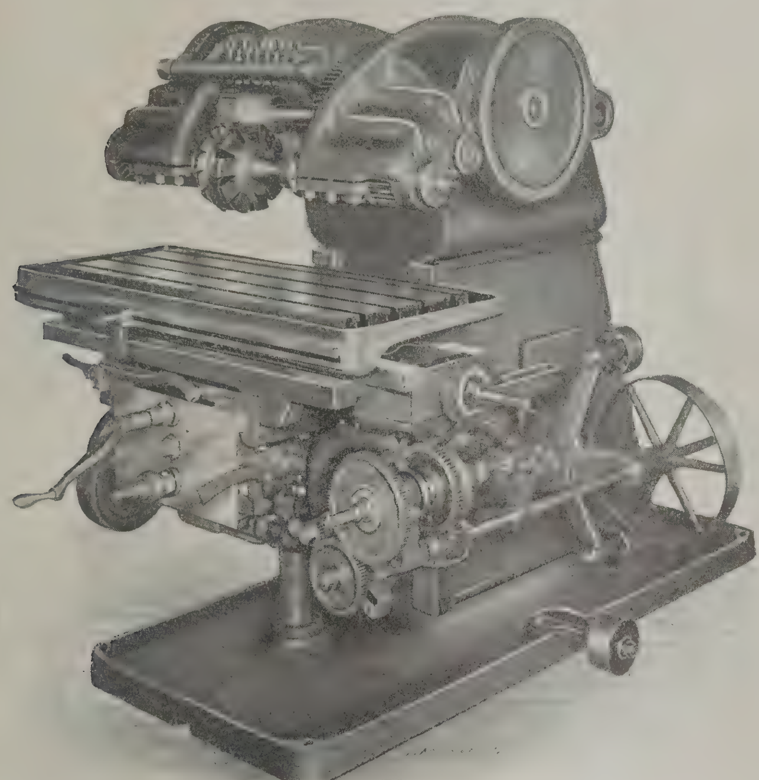

Fig. 1. Walcott Automatic Rack Cutter.

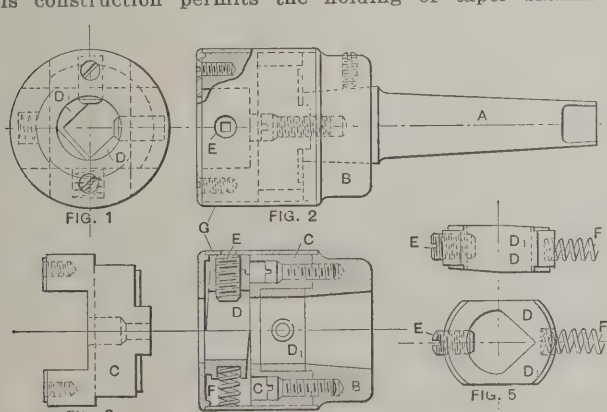
groove of the first jaw *D*. The setscrew in the jaw D_1 (which is identically similar to *D*, although located at right angles to it) is next tightened, which centers the tool vertically. The movement necessary for this last centering is permitted to the tool because, while it is tightly held in jaw *D*, this jaw itself is free to move vertically, against no other resistance than that of spring *F*; when the two screws are tightened the tool is centered and securely held. Since the two jaws are similarly placed, either of them may be tighened first. It will be noted that jaws *D* and D_1 are slightly beveled on the opposite faces, from the center line to the opposite ends. This construction permits the holding of taper shanks as



The Wide Range Drill Chuck.

rigidly and truly as straight ones are ordinarily held, the beveling of the dog permitting it to tip to one side enough to line up with the taper.

The makers have called this chuck the "Wide Range," both on account of the large tools it will take in comparison with its diameter, and on account of the fact that it will hold and center accurately any kind of a shank, straight, taper, square, a taper square, with tangs on or twisted off. It is built of steel throughout, and is made in four sizes, covering a range of from a No. 60 drill up to a 1-inch drill, or, with a No. 3 taper shank, up to 1¼ inch.

WALCOTT AUTOMATIC RACK CUTTER.

The machine illustrated in the accompanying cuts, Figs. 1, 2 and 3, is built by Geo. D. Walcott & Son, Jackson, Mich., and is an outgrowth of their "half automatic" rack cutter, which was illustrated and described in the April, 1905, issue of MACHINERY. The changes which have been introduced include the addition of automatic feeding and automatic indexing mechanisms, and a change in the method of holding the cutters. A countershaft stop has also been added, which throws off the power as soon as the required number of teeth in the work has been cut. The machine has a range of feeds from ½ inch per minute to about 5½ inches per minute, giving a suitable range for either fine or coarse pitch cutters. Since there are 10 inches of cutter space on the spindle, it is well adapted to the use of gang or multiple cutters.

The spindle is driven through a three-step cone at the rear of the top housing. This cone does not appear in either of the photographs. It is mounted on the transverse shaft which shows the farthest to the rear of those whose bearings are seen on either side of the housing. From here the motion is transferred to the right and left-hand spindles at the front of the housing by a train of gearing which can be easily traced in the halftones and the line cut. As may be seen in Figs. 1 and 3, the left-hand, or main spindle, is driven by a herringbone train, while the other is similarly driven by spur gears, the main burden of the driving being imposed on the left-hand train, as will be seen by examining the arbor driving mechanism. The cutter arbor is provided with tongues at either end, which fit in the corresponding grooves in the two cutter spindles. Bolts passing through the cutter spindles enter holes tapped in the end of the arbor. When these bolts are drawn up the two spindles and the arbor form a solid continuous spindle. This construction may be understood by studying Fig. 2 and the two halftones. In removing the arbor the bolts are loosened and the arbor is drawn out toward the front. All of the gears shown are provided with guards which have been removed in taking the photograph in order that the drive may be more easily understood.

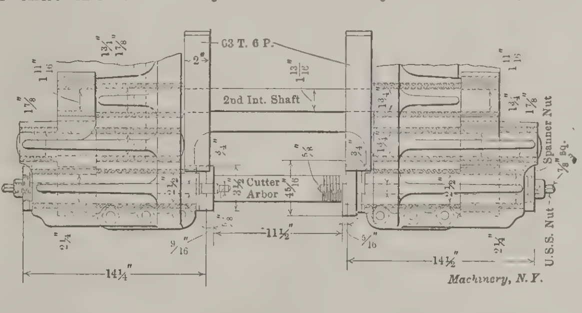


Fig. 2. Spindle Driving Mechanism of the Walcott RackCutter.

As shown in Fig. 3, the feeding mechanism is driven by a pair of four-step cones, of which the driver is connected by a swinging train of gears to a shaft in the spindle driving train. A reach rod whose length is adjustable by means of a turnbolt is provided to keep the belt tight. The push pin shown at the left of the cone in the knee controls a change of feed so that, with the cones, eight different rates are provided in all. Suitable clutches and gearing located within the knee and operated by adjustable dogs provide for a slow forward feed and a quick return after the cutting has been completed. As the forward feed again commences, the work is indexed, thus being automatic in all its actions. The indexing mechanism is driven by a separate quarter turned belt from the countershaft; the driving pulley is shown near the base of the machine in Fig. 1. Two sets of change gears are provid-

ed; the one on the longitudinal feed screw of the table is changed to suit the pitch of the rack being cut, while another set mounted at the front of the mechanism is changed to agree with the number of teeth being cut at one time. If, for instance, four 6-pitch teeth are being cut at one time the gears at the front will be set for four teeth while those on the screw will be set for 6-pitch. The indexing mechanism is operated entirely by positive clutches and gears, there being no friction slip to get out of adjustment and consumed power. For centering a cutter in a tooth space already cut, the index gear on the longitudinal screw is mounted on a friction bearing, which can be tightened by means of the nut shown. With the nut loosened the table may be set at any required point to bring the cutter and tooth studs to the proper position. The gear is then tightened and the indexing proceeds.

A dog at the front of the table operates a lever which trips a chain on the left side of the machine, not plainly shown in the cuts. This chain is connected with the countershaft, as was before mentioned, and stops the machine when any desired position on the rack has been reached by the cutter. The base of the machine is formed to act as an oil tank and is provided with an oil pump. Suitable arrangements are provided for distributing the oil over the cutters and for returning it to the tank. The net weight of the machine is a little over 5,000 pounds.

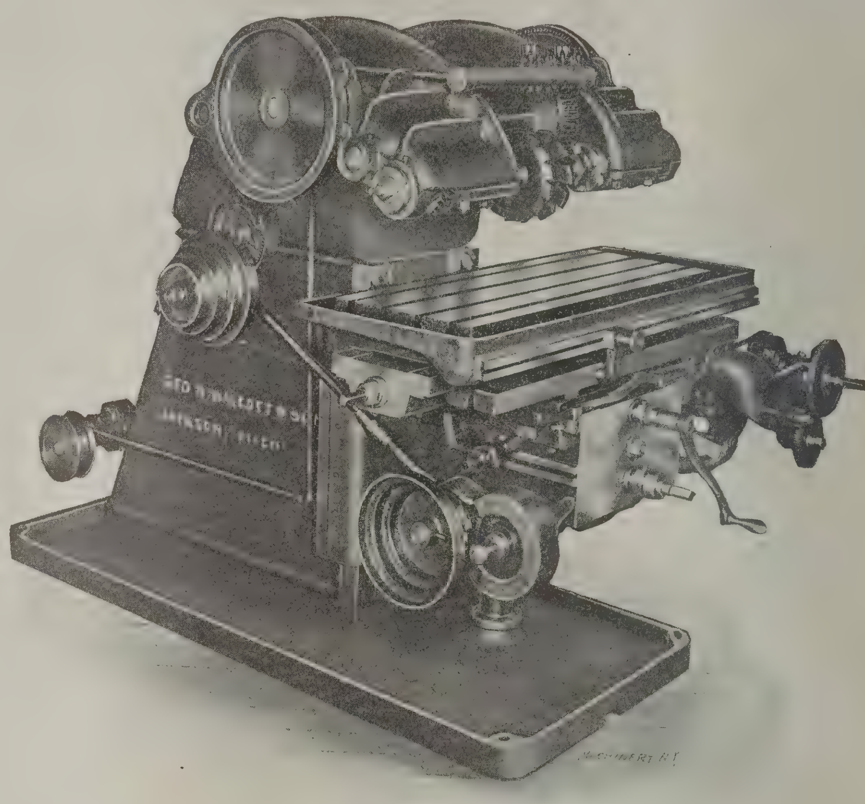

Fig. 3. Left Side View of Walcott Rack Cutter.

OBITUARY.

Dwight Slate, president of the Dwight Slate Machine Company, Hartford, Conn., died July 31 at his home in that city. He was born May 29, 1816. Mr. Slate was the inventor of the lathe taper attachment and the sensitive drill press and other improvements of machine tools. An extended biographical sketch of Mr. Slate, with portrait, appeared in the July issue.

Daniel B. Wesson, of the well-known firm of revolver manufacturers, Smith & Wesson, died at his home in Springfield, Mass., August 4. Mr. Wesson was born in Worcester, Mass., in 1825. He was closely identified with the early improvement of firearms and is credited with the invention of the metallic case ammunition now universally used in all breechloading small arms, but this is disputed, the invention being claimed by some as that of C. D. Leet of Springfield, Mass. The firm of Smith & Wesson had its inception in 1852 at Norwich, Conn., but the manufacture of revolvers did not begin in Springfield until 1857. The outbreak of the Civil War gave a great impetus to the business and it became very successful.

* * *

PERSONAL.

Frederick Hitchcock, of Meriden, Conn., has been made principal of the Manual Training School of New London, Conn.

Redfield Allen, for the past five years chief draftsman of the engineering department of the Fore River Shipbuilding Co., has resigned.

John W. Pilling, formerly of Waterbury, Conn., has been appointed assistant superintendent of the mill department of the Seymour Mfg. Co., Seymour, Conn.

H. J. Bachmann, a frequent contributor to MACHINERY, has severed his connection with the Mergenthaler Linotype Co. and has accepted a position as superintendent of the Alton Mfg. Co., of New York City.

H. A. Sedgewick, for several years superintendent of Gay & Ward, Inc., Athol, Mass., and later connected with the Union Twist Drill Co., successor of the above firm, has resigned his position to become superintendent of Madison-Kipp Lubricator Co., Madison, Wis.

FRESH FROM THE PRESS.

THE ANALYSIS AND SOFTENING OF BOILER FEED-WATER. By Edmund and Fritz Wehrenfennig. Translated from the German by D. W. Patterson. 290 pages, 6 by 9 inches, and 171 cuts. Published by John Wiley & Sons, New York. Price $4.00.

This book in review is of the second edition, and is, perhaps, the most valuable treatise on the subject of boiler feed water analysis and softening now available in England—thanks to Mr. Patterson, the translator, who had found it invaluable in his work. Of the Wehrenfennigs, the first named is chief inspector of the Austrian Northwestern Railway in Vienna, and the second is an analytical chemist and director of factories in Eggenburg. By chapters the topics are as follows: Impurities in Feed-water; The Analysis of Water; Preparation of the Necessary Chemicals for Water Analysis; The Improvement of Water; Determination of the Amount of Reagents; Testing the Softening; The Removal of Precipitate from the Treated Water; The Accomplishment of Water Purification and the Separate Arrangements Therefor; Review of the Development of Water-purifying Plants; Critical Examination of Water-purifying Plants; Study Concerning the Installation of Water-purifying Plants; Report on Water-softening by the Society of German Railway Managers; Method of Tabulating Data. The book is of special value to railway chemists and others having to do with purification of feed-water for locomotives. This subject is becoming a most important one in railway management, and we shall expect to see a great improvement in present American railway practice in the near future. The book is cordially recommended to all interested.

NEW TRADE LITERATURE.

NATIONAL MCH. TOOL CO., 208 Lawrence Street, Cincinnati, O. Latest pamphlets issued are The Verdict, being made up of letters of commendation of their key-seating tools; and Improved Speed Changers, devoted to description of the new and distinctive features in the design of speed changers.

WHITCOMB-BLAISDELL MCH. TOOL CO., 134 Gold Street, Worcester, Mass. Catalogues of Patent Geared Head Lathes and Whitcomb Planers. The catalogues are arranged with a general description in the front, followed by alternate pages of description and illustration of the various types.

THE AMERICAN LOCOMOTIVE CO., 111 Broadway, New York. Pamphlet reproducing a paper "Large Steam and Electric Locomotives" read before the New York Railroad Club by Mr. J. E. Muhlfeld, general superintendent of motive power of the Baltimore & Ohio Railroad; together with abstracts from transactions by the members. The paper is a discussion of the relative merits of large steam and electric locomotives, comparing the performances of the Mallet type articulated compound No. 2,400, built by the American Locomotive Co. for the Baltimore & Ohio Railroad, and the electric locomotive No. 7-8 built by the General Electric Co. for that road. Mr. Muhlfeld says that the results obtained by the articulated type of locomotive cannot be duplicated by other single units of steam, electric or internal combustion locomotives in use on American railroads to-day.

MANUFACTURERS' NOTES.

THE BATES FORGE CO., Indianapolis, Ind., are making a large addition to their plant that will double their capacity. Most of the new machinery has been contracted for.

THE LINK BELT MACHINERY CO., Chicago, Ill., under its new name, the Link Belt Co., has purchased the plants and all other assets of its associate companies—the Link Belt Engineering Co., Philadelphia, Pa., and the Ewart Mfg. Co., Indianapolis, Ind. It will maintain the offices and operate the plants as now established.

MR. ARTHUR APPLETON has been made resident manager of the New York office, at 45 Broadway, of Pawling & Harnischfeger, Milwaukee, Wis., builders of traveling cranes, and will represent this firm's interests in and about New York City, the New England States and Eastern Canada. Mr. Appleton was formerly associated with William Sellers & Co., Philadelphia, for many years as traveling salesman.

RAILWAY MACHINERY.

A special edition of MACHINERY devoted to Locomotive and Car Equipment and Mechanics.

October, 1906.

ADRIATIC TYPE FOUR-CYLINDER BALANCED COMPOUND LOCOMOTIVE OF THE ITALIAN STATE RAILWAYS.

ITS OBJECTS, CONSTRUCTION, OPERATION AND ECONOMICAL RESULTS.

CHARLES R KING.

The Adriatic or Meridionli Railways of Italy have ceded to the State all their locomotives and plans for new types of machines—the whole of which will henceforth become the standard practice of the Italian State Railways. In the future all the high-powered locomotives of the Italian State Railways will be modeled after the very interesting engine described

Fig. 1. The Adriatic Type Four-cylinder Balanced Compound Locomotive.

in this article. The Adriatic four-cylinder balanced compound locomotive will be perpetuated in all the large machines planned or in construction for various services—express, passenger, fast freight, mountain and ordinary freight, with but slight variations affecting the machine as a whole—*i. e.*, the extensive adoption of single-bearing axles in place of four-wheeled trucks.

The principal feature of these locomotives is the dissymmetric arrangement of the four cylinders, the high-pressure being all to one side, with a single piston-valve, and the low-

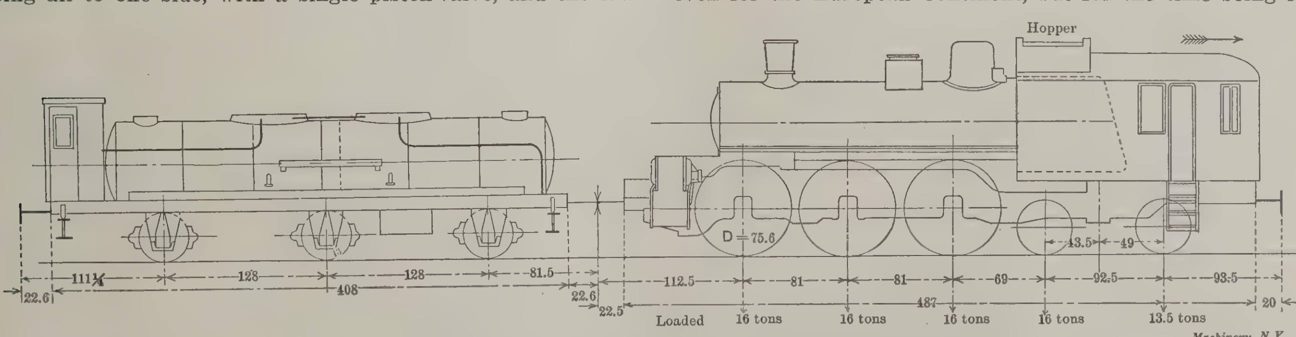

Fig. 2. Diagram of Engine and Water Tank, Adriatic Type Engine.

pressure all to the other side, with a single piston-valve. This arrangement permits any desired difference in the travel or timing of the two valves, and is equal, practically, to many engine designs with four valves and four valve mechanisms. The most evident peculiarity of the present locomotives is the reversal of the boiler on the frames. This was done in order to permit the use of a deep and wide firebox together with six connected wheels. Any other arrangement would have required the firebox to be lifted up over the top of the driving wheels and this, with the restricted constructive gage of Italy, would have been impracticable. An incidental advantage was the placing of the footplate over the pilot truck where the view of the road is as perfect as from the cab of an electric locomotive, and this is, consequently, a great boon to the engineer in sighting signals at all times from any position on the footplate, even when traversing certain curves which with the ordinary arrangement would cause the boiler to block out the view of the road on his side of the engine. With this arrangement any boiler whatever might have a flat-topped firebox completely filling the constructive gage to its utmost limits and entirely blocking out all view over and around it without in the least affecting the engineer's convenience.

From Fig. 2 it will be seen that the engine is quite small even for the European Continent, but for the time being it is impossible to increase the size of the boiler, for the reason that the extreme limit weight per axle has already been reached, *i. e.*, 16 tons. It is, however, a remarkable engine not only for its unprecedented economy but also for its power. Take the engine and tender together with half the full load of fuel and water (99 tons), and compare this with the maximum load which it pulls in a very difficult express accommodation service (called "direct" trains in Italy), which is 490 tons, and we will find that one ton of engine

pulls five tons of train at speeds of up to 54 miles per hour. It is very difficult to find authenticated cases of a similar proportion of 1 to 5. This figure might be touched by single expansion engines by reason of the lighter weight of these latter, but then the fuel consumption will differ widely, and therefore the comparison would not be just.

The engine has one high-pressure and one low-pressure cylinder inside the frame and one high-pressure and one low-pressure outside of the frame. Inside they are slightly in-

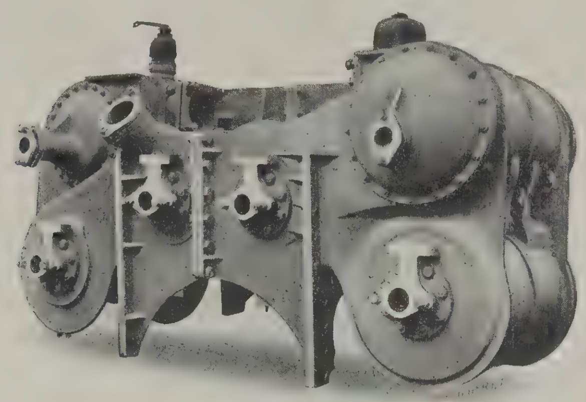

Fig. 3. Cylinders and Valves, Adriatic Type Engine.

clined (7 degrees), outside they are horizontal. The single piston-valve for each group of two cylinders is placed outside in the same vertical axis as the outside cylinder on either side, and both valves have a horizontal alignment. The whole of the cylinders and valves are cast in two pieces bolted together a little out of the center line of the machine, this being in order to give the low-pressure inside cylinder a little more room.

The high-pressure cylinders are connected with the low-pressure cylinders as follows: The receiver, a transversal pipe (*R*, Fig. 4), joins the middle of the high-pressure valve

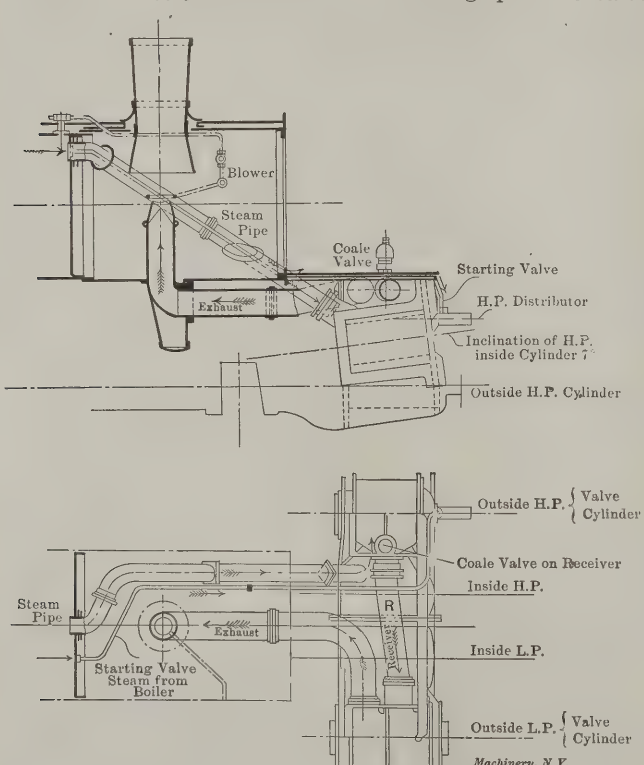

Fig. 4. Diagrams of Cylinders, Adriatic Type Engine.

chest with the back end of the low-pressure valve chest. (In this description the locomotive is always considered as advancing with the firebox in front and the cylinders behind.) This receiver is protected against condensation by means of an enveloping pipe. The connection to the two high-pressure cylinders is by direct steam ports to the inside cylinders, as shown in Fig. 5, and by crossed steam passages to the outside cylinder, as shown in Fig. 6. The opposite end of each cylinder is, it will be seen, in constant communication with that of its fellow, and the pressure operating against their two pistons must, as a consequence, be precisely the same.

For constructional reasons it was desirable to avoid crossed passages on the low-pressure side. Double-ported valves with double type piston-valves are employed, as shown in Fig. 7. The exhaust passes around the body of the valve which it serves to protect against condensation. The spaces *A* are all open to the exhaust to the smokestack. The action of the valve is plainly indicated on the cut. The connection by which the opposite ends of the cylinders are maintained in constant communication with that end of the valve chest from which the fellow cylinder is served, is a small tube fitted outside the cylinder and beneath the clothing. The two tubes are not visible in any of the cuts. Through them the steam pressure at the opposite ends of the cylinders is assured equality at all times.

The cylinders of these engines have a ratio of volume high-pressure and low-pressure of only 1:2.7, or, inversely, the high-pressure cylinder volume is 37 per cent of that of the low-pressure, which is somewhat higher than the 34 and even 33 per cent common in the most recent continental practice (*i. e.*,

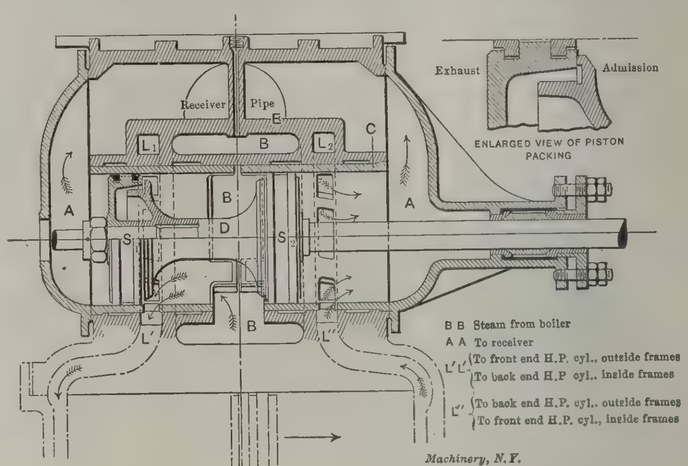

Fig. 5. Section of High-pressure Valve, Adriatic Type Engine.

1:2.9 and 1:3). In the Adriatic engines the working pressure is, however, only 201.3 pounds. As usual where the ratio of cylinder volumes is somewhat low, the low-pressure valve motion is set to give a cut-off 20 per cent larger than the degree of admission allowed by the high-pressure valve motion.

As a general rule, for high speeds the minimum cut-off advisable is fixed at 35 per cent for the high-pressure and corresponding to about 42 per cent for the low-pressure cylinders. For reducing the work of the machine, rather than reducing the valve travel below 35 per cent of piston stroke, it is preferred to operate with the throttle. This refers to the most recent practice. In the earlier engines of his type, before the engineman had been thoroughly broken to compound workings, it was usual to haul the heaviest trains with 15 per cent admission on the level, and from 25 per cent up to 30 per cent admission on heavy grades. Many hundreds of miles on various railway sections were traveled by the writer with the engines working in this manner, disapproved by the traveling inspectors, and yet the locomotives in every case proved remarkably economical and to possess an extraordinary capacity for hauling heavy loads at speed. The medium admission of 20 per cent (+ 24 per cent in the low pressure) corresponded to an expansion at the point of release nearly 21 times the initial volume, and this excessive lamination undoubtedly militated against the best efficiency of the machines. This practice has now been changed. At present, with a train-load behind the tender of 450 metric tons (say 490 U. S. tons) and at full speed, the rule is to work between the extreme limits of 35 per cent and 50 per cent according to the grade. On the level in ascending light grades, 40 per cent is now customary. This, with 48 per cent in the low-pressure valves, corresponds to a total admission for the two cylinders of about one-fifth, or, 40 per cent × 48 per cent

= 19.2 per cent, say, 20 per cent. On heavy gradients the 50 per cent (high pressure) admission equals 50 per cent × 60 per cent (low pressure) = 30 per cent, or an admission of 11-10, and an expansion of 9-10 of the total volume of the two cylinders.

After tentative trials the clearance-volumes allowed in the cylinders have been fixed as follows: 15 per cent for the high pressure and 8 per cent for the low pressure. Both piston valves are 10.4 inches diameter and have a steam lap of high pressure, 1.34 inch; low pressure, 0.9 inch, and a lead to exhaust of high pressure, 0.078 inch, and low pressure, 0.118 inch. Here it should be mentioned that the engines are designed for maximum speeds of 60 miles per hour and for loads of 460 tons in express service, 490 tons in fast freight service and 930 tons for special freight service; in all cases exclusive of the engine's weight. The maximum tractive effort (theoretical) is 7.2 tons and the load under each driving tire 16 tons, or 0.6 tons in excess of the regular limit allowed for the light Italian tracks. Sand has to be used liberally in starting trains.

All the effort of the four cylinders is concentrated on one (the middle) connected axle which is of the Z crank-axle type and hollow. The inside cranks are arranged, as usual, in balanced compounds, at an angle of 90 degrees, the crankpins outside forming an angle of almost 180 degrees with the nearest crank inside. As the inside cylinders (high pressure and low pressure) are inclined 7 degrees in order to allow the pistons to clear the rear axle, this angle is compensated by keying each outside pin so as to precede the two inside cranks by an advance (in the normal direction of running) of 173 degrees, as shown in the diagram, Fig. 8.

As the machine always works compound, means are provided for supplementing the steam in the receiver to enable the low-pressure cylinders to start the train whenever the two high-pressure cranks would be near dead center—a matter of importance with the Adriatic system, as will be seen by a glance at the diagram Fig. 8. It is for this reason that the starting valve has in this machine been made a constituent part of the throttle, and in such a way that a momentary admission of live steam to the receiver always takes place in starting the locomotive. Briefly described, this consists of a small double supplementary throttle valve on the back of the main throttle valve, and which, when the engineer pulls his lever, uncovers a port in the latter through which steam passes into a special conduit in the valve seating which is in direct connection with the receiver. But the continued pull on the handle then raises the main valve and at once interrupts the supplementary admission to the receiver, which cannot take place again until the throttle is once more opened from its fully closed position.

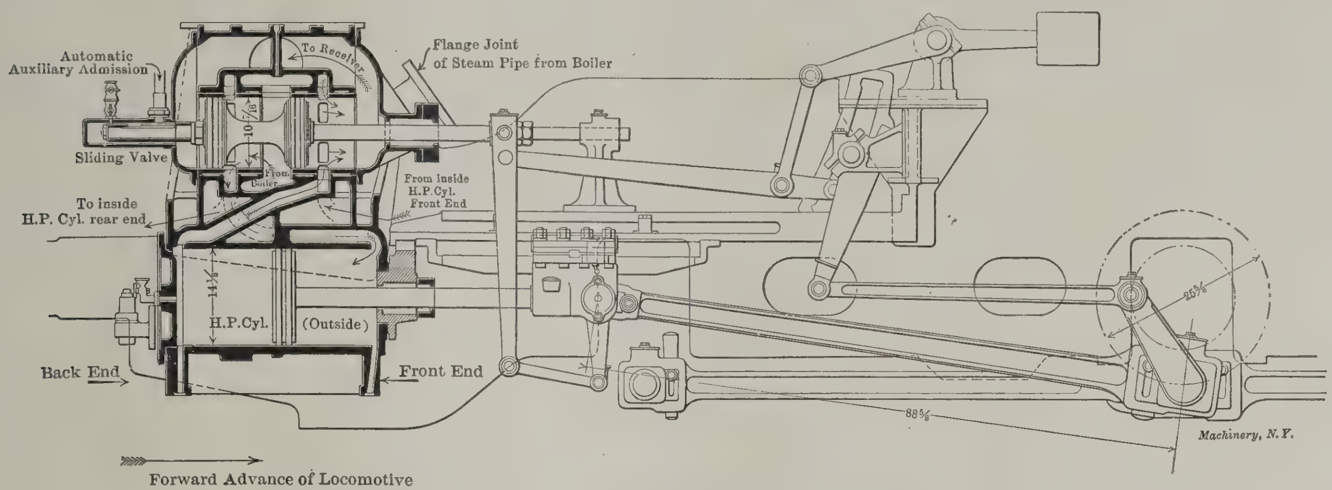

Fig. 6. Section of Outside High-pressure Cylinder and Valve, Adriatic Type Engine.

An interesting addition to these locomotives is the pivoting axle box, shown in Fig. 9. The object of the pivoting liner between the axle box and the frame guides is to permit the axle to oscillate freely about a theoretical longitudinal axis. With ordinary rigid flanges or cheeks to the axle boxes the unequal vertical displacements are absolutely opposed by the parallelism of all the parts effected. The axle seeks to describe a circle, but the frame guides oppose this. The compromise between the two results is diagonal wear on the upper and lower surfaces of the axle box flanges; grooving of the extremities of the journals and their bearings; frequent breakages of the brass bearing flanges, of the horn blocks or axle box guides, and also of the frame plates. The steady augmentation of these troubles is attributable to the greater weight of engines calling for increased dimensions in the length of journals and also in the width between the horn block faces, to the greater thickness of the frames and to the methods employed for increasing the rigidity of the frames, and also to the higher center of gravity now common, accompanied by the higher speeds of running. The usual remedy for these inconveniences has been a resort to greatly increased dimensions, thus abating the frequency of breakage,

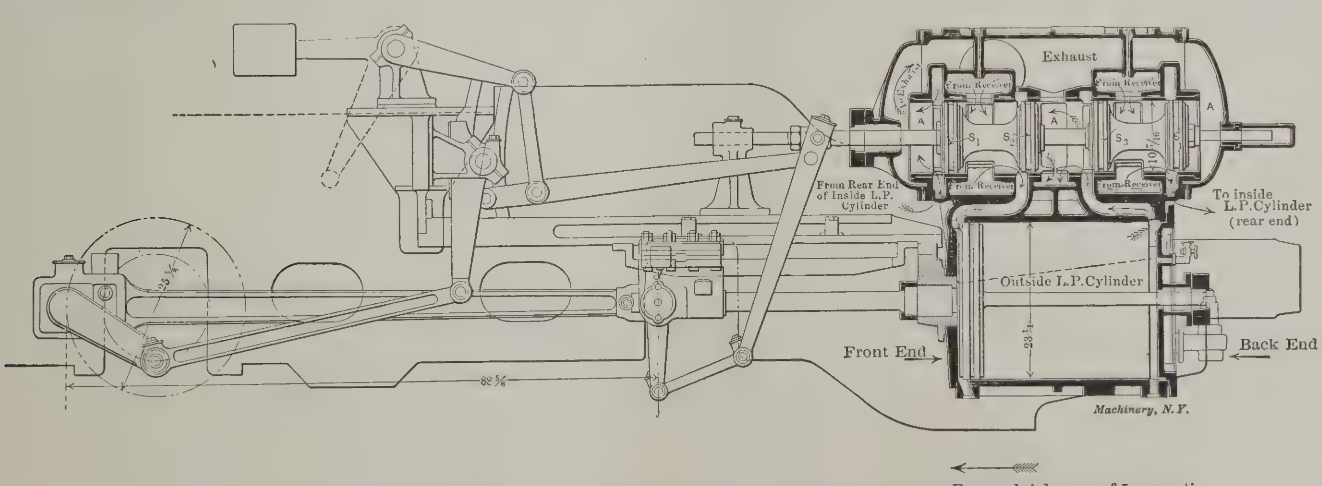

Fig. 7. Section of Outside Low-pressure Cylinder and Valve, Adriatic Type Engine.

but not eliminating it entirely. The obvious practical solution is a hinge, just as we find in side rods. This hinge or pivot is very simply effected by means of liners interposed between the forward and rearward faces of the axle box. These liners are parallel in width, except at mid-length, where there is a flat circular portion which fits into a corresponding flat circular recess in the axle-box face. The recesses in the axle box which correspond to the parallel portion of the liner are fan-shaped, thus allowing the latter free play to revolve within certain limits. The liners carry the flanges embracing the horn blocks or guides, and they merely take the place of

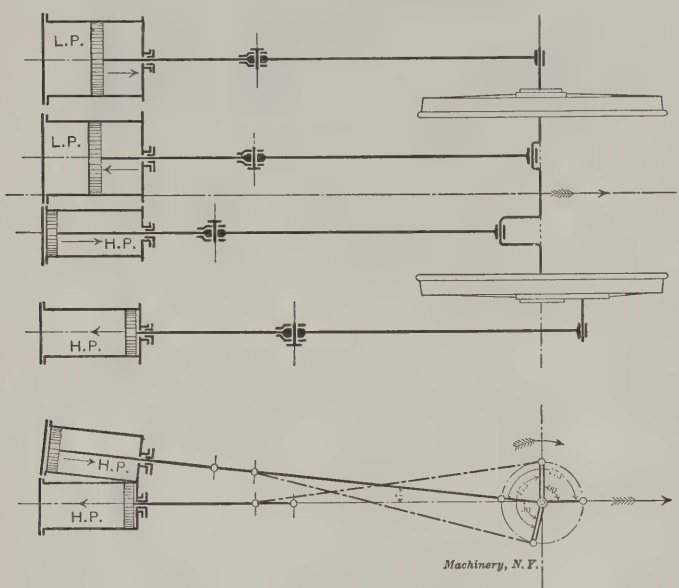

Fig. 8. Diagram of Cylinders and Piston Action, Adriatic Type Engine.

the liners or rubbing blocks that are used on many railways in place of the usual screw wedges for taking up the wear between the axle boxes and their guides. The arrangement eliminates all strain, stress and the wear due to non-parallel movement of the axle even on curves of the shortest radius at fast speed, or on poorly maintained track inducing transverse rolling, while a closer and more regular contact of all parts is maintained through the elimination of wear and the play caused thereby. The shocks upon entering curves are reduced while the speed may be increased rather above the usual limits at such parts of the road, and on the other hand heating of axle boxes is decreased in very many instances. About 2,000 such boxes are now in use.

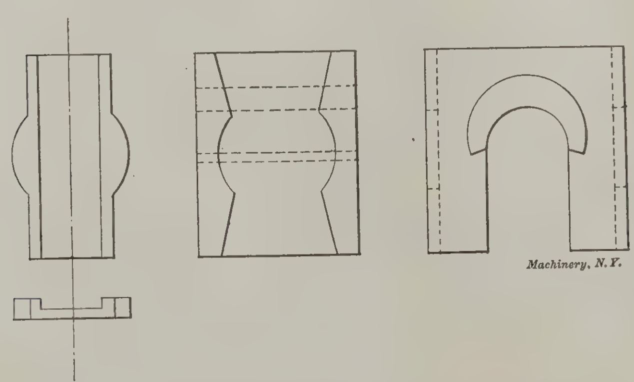

Fig. 9. Pivoting Liner and Axle Box, Adriatic Type Engine.

The boiler construction of this locomotive presents few details that will interest American engineers. Its reversal, end-for-end, introduces no novelty of operation that has not been already common to thousands of suburban locomotives running with the firebox in front. Tank locomotives, 4-6-4, running firebox in front, differ very little in operation from the Italian express locomotives here described. The same ordinary care is required in both with regard to the lowered level of water over the firebox crown in ascending gradients, but this is a matter of habit. Likewise the same attention is required to avoid cold air currents on the flue sheet either from a thin fire immediately against it, or from a prolonged opening of the firebox. These locomotives are provided with fire-hole deflectors directing the air current downwards below the brick arch, and the introduction of air on top of the fire by means of slightly opening the door is recommended for a few minutes' interval after firing, in order to consume the smoke. This is only allowable with a fairly well filled grate. The grate is flat and the coal is laid on in the form of a saucer, tilting slightly downward beneath the brick arch.

With these ordinary precautions the reversed boiler for express service has proved itself to be much superior as a generator to the normal type of locomotive boiler working on the same roads. The coal bunker of three tons' capacity is situated on the right-hand side, advancing. It occupies the space above that same side of the boiler in order to concentrate the weight at the center line or axis, and most of the space on that side of the cab is also occupied by the descending fuel. There is also a small bunker for one ton of briquettes under the front windows, also on the same side of the cab. Had the limit to the wheel loads been of as little importance, as in America, the entire bunker could have been located beneath the forward windows, just as is usual with tank locomotives.

Non-conducting substances, asbestos, etc., are not often used in Continental practice beneath the boiler clothing, but asbestos is employed here, around the firebox only, to prevent radiation of heat. The cylinder water tank is always coupled behind the locomotive, which normally runs cab first. But to enable the engine to run chimney first in local work, switching, etc., and at speeds not exceeding 40 miles per hour, the injector feed pipes from the tender are carried the whole length of the engine, one pair on either side, and each pair in connection with flexible couplings both at the back and at the front end of the locomotive. In switching the engine is uncoupled from its tender, and in coupling up again either end of the engine may become the front end.

The injectors in connection with the feed pipes are located beneath the cab. In the cab the arrangements are as follows: In the front left hand corner grouped about the engineer's seat: Horizontal reversing wheel; vertical scale of the expansion-gear fixed on front wall of cab; throttle lever over reversing wheel for engineer's left hand grasp; whistle-pull, next to throttle lever; under engineer's left hand, forward of the reversing wheel, two triple valves operating Westinghouse brakes on all the wheels of engine and tender. As there are two separate air reservoirs for the two brake cylinders, one for the driving wheels and one for the truck, there are cut-off cocks placed in the connecting pipes so that either set may be worked independently. The brake cylinders are both shown in Fig. 10. In addition there is a hand brake (fireman's) on the six connected wheels. On the bracket carrying the vertical reversing screw is placed the handle which operates the compressed-air sander, and the same bracket carries the sliding shield which cuts off the rays of light from the open firebox at night time. The lever operating the purge-cocks of the cylinders is placed conveniently near; the regular purging of four cylinder compounds with piston valves is of first importance. Previously this operation would sometimes be interrupted by careful engineers in order to avoid scalding linemen, therefore the purge cocks now discharge into perforated mufflers, and save enginemen any concern in this score. To reduce the amount of condensation which occurs after the engine has been standing long in the stations, and which during the very severe cold of the Italian winter is necessarily considerable, the engineer simply sets his throttle over the starting valve port, thus passing steam for heating direct to the receiver and low pressure valves. The engineer can feel, by touch of the lever, the place of his throttle over the opening. This warming up and subsequent purging might be made automatic by suitable connections with the throttle and reversing screw, but it has not, so far, been done with the engines of this class.

The boilers steam best with water maintained at medium level, whether on the level or in mounting steep grades when, of course, the level falls rather rapidly aided by the upward inclination of the firebox. A very considerable control of the fire is exercised by means of the variable blast nozzle of double wing pattern, but in these engines its influence may

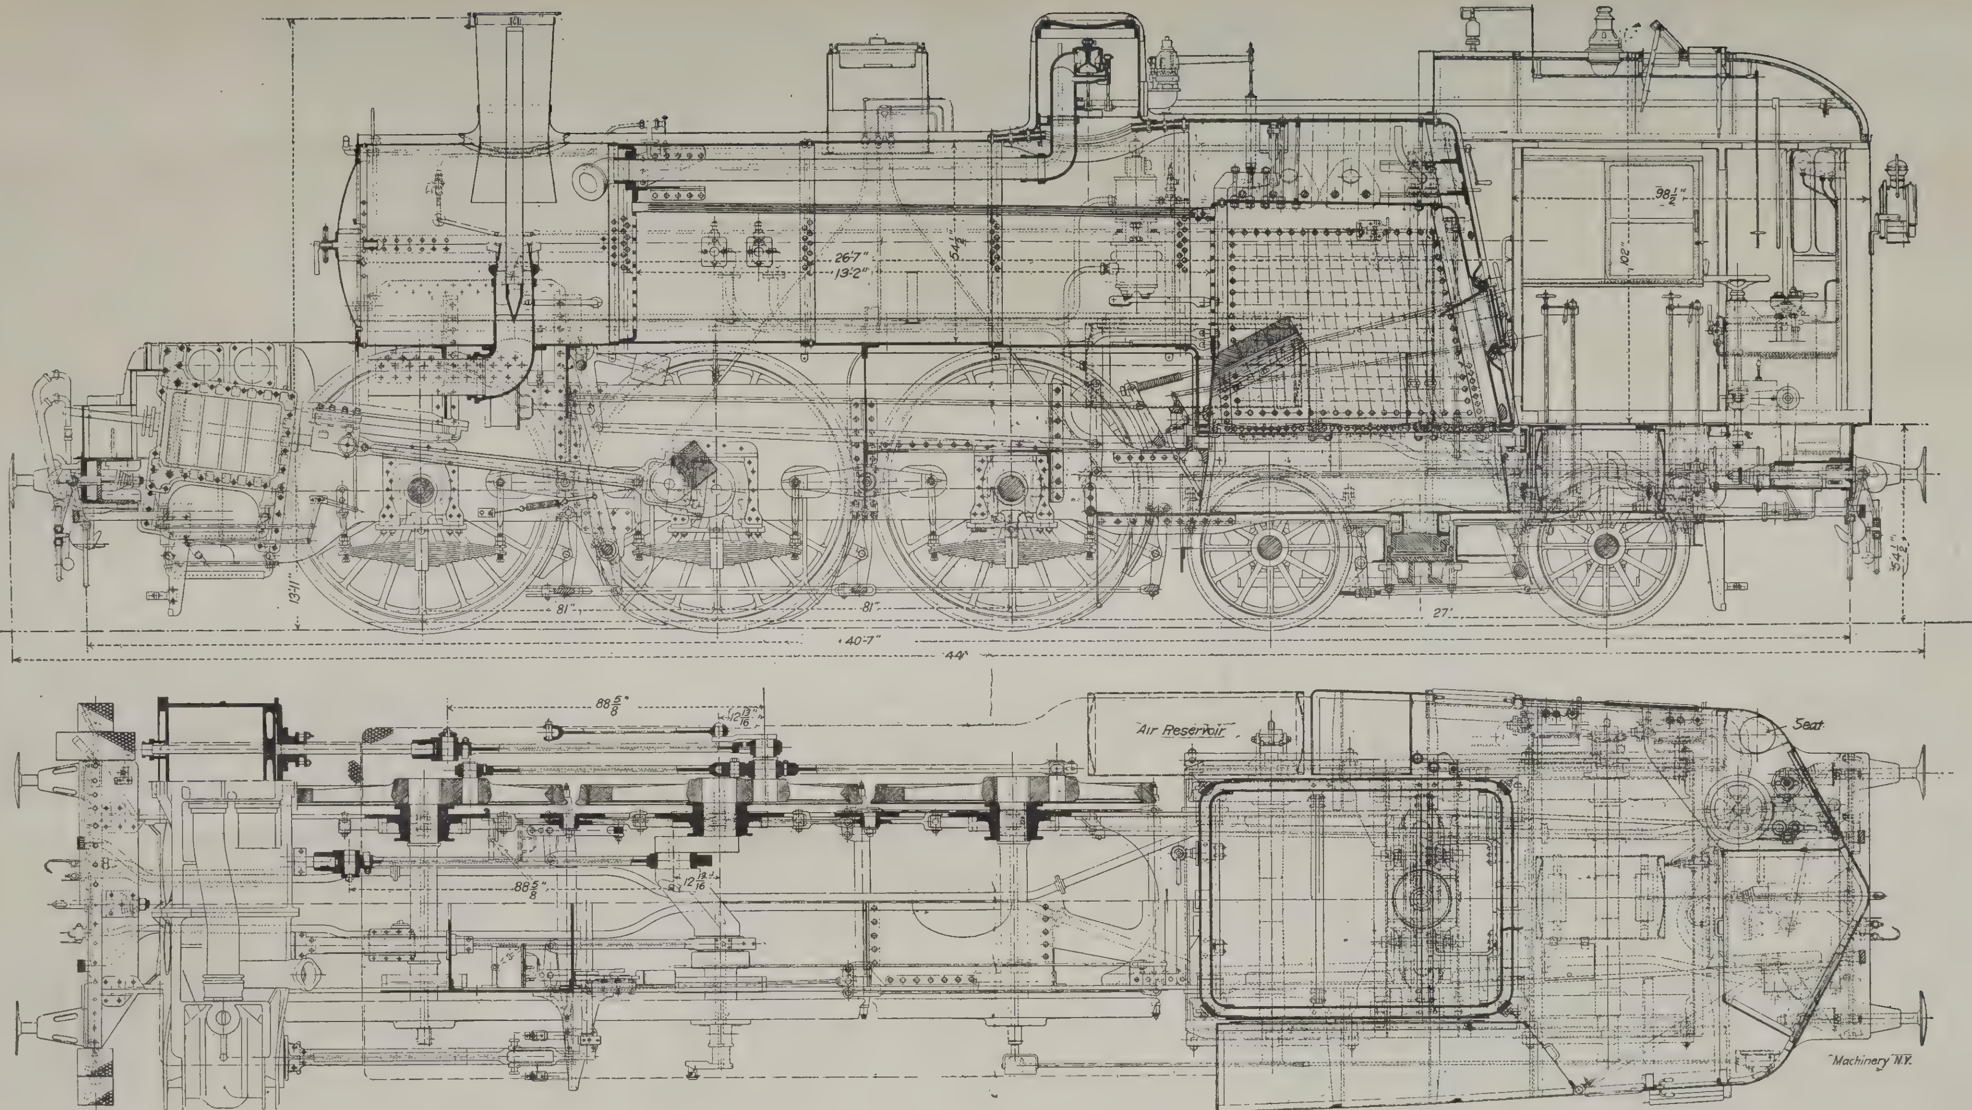

Fig. 10. Plan and Elevation of Adriatic Type Engine.

be very detrimental, hence the enginemen are advised only to decrease the area of the nozzle when all other means fail. The blower is recommended in preference to increasing back pressure on the low-pressure pistons. When running with closed throttle the reversing gear is always set full forward. The engine has no apparatus for running against reversed steam, as is now rather common with such machines, and therefore reversing the engines against steam is only allowed for brief intervals, and in case of break failure. The engine, like all Italian express engines, is fitted with the Hausshaeltor speed indicator and recorder, the dial of which is at all times plainly visible to the engineer. There are at present about 43 of these machines built or in construction. Of the newest types it is not, so far, possible to give details of coal consumption, which will, very possibly, have been reduced to a yet lower figure. Already the coal consumption with the earlier machines of this type has been remarkably low, lower in fact than any which can be traced relating to the averages of other engines for an equally long period of service. In a period of three months' rather light service, not conducive to coal economy in compounds, seventeen engines ran 184,390

miles on a consumption, including lighting up and standing about, of 42.2 pounds per mile or of 40.4 pounds per hour actually consumed in working and while pulling an average net load of only 266 tons as compared with the 400 tons, which is the most economical load for these machines. Reducing the real miles to virtual miles (grade and curve duly computed), this consumption amounted to 144.2 pounds for each thousand ton-miles (the ton weight being that of the useful load hauled by the locomotive and which varies from 170 to 420 tons), and calculations based upon these averages, and according to the various formulas of Barbier, Van Borries and Aspenall, show the consumption to be 2.92 pounds per H. P. hour at the driving wheels, and 2.67 pounds per indicated H. P. hour. Expressed thus merely in pounds of coal, the result may be without value unless the more important factor of coal value is given, consequently, the consumption accurately expressed was 21,000 B. T. U. per I. H. P. hour. The coal (Curdiff) has a thermal value averaging 7,900 B. T. U. per pound. In ordinary boilers it produced up to 7

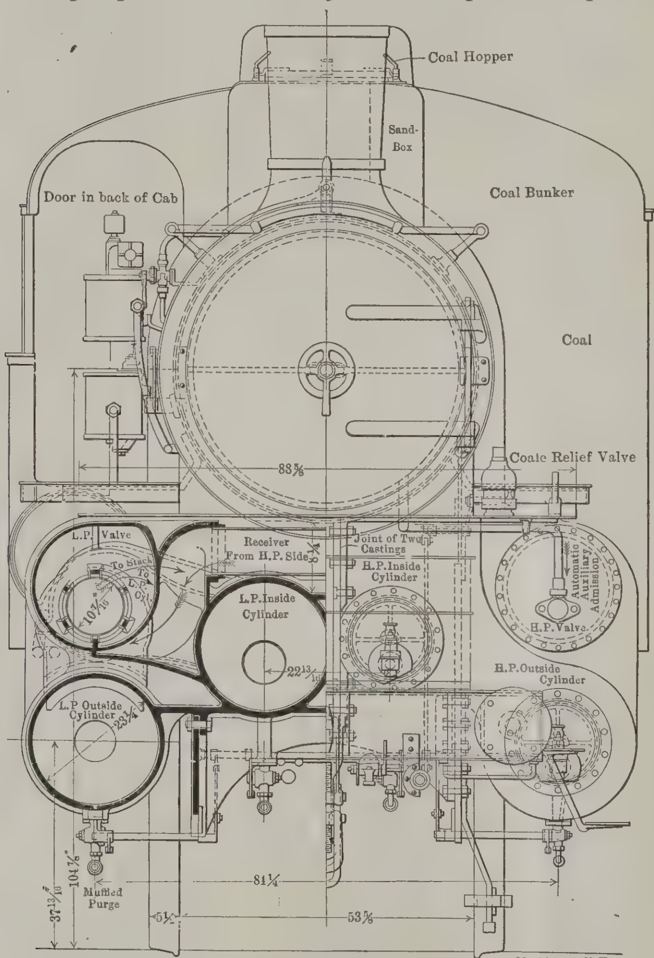

Fig 11. End View, and Section through Low-pressure Cylinders Adriatic Type Engine.

pounds of steam and in the reverse boilers up to 9 pounds of steam per pound of fuel. In the foregoing only the figures relating to a long period of regular service are given. In individual runs in the course of daily work (and not to be cited by the side of special trials where selected coal and all other conditions are arranged to favor the utmost efficiency) the writer has noticed a consumption of 45 pounds per real mile with a train behind tender varying from 400 to 413 tons, or 115 pounds per thousand virtual ton miles, a result 20 per cent more economical than those previously cited and upon which the horse-power fuel consumption is based. Under favorable conditions one H. P. hour, indicated, for 2.35 pounds (18,560 B. T. U.) is probably often realized in the older and less perfect locomotives of the type described. It is true 2.11 pounds was realized with a Woolf-Mallet tandem compound (No. 101) on the South Eastern Railways of Russia in May, 1892, but then that was during special trials.

PRINCIPAL DIMENSIONS.

High-pressure cylinders, diameter	14¼ in.
Low-pressure cylinders, diameter	23¼ in.
Piston stroke	25½ in.
Wheels (drivers), diameter	6 ft. 3⅝ in.
Boiler pressure (working)	201 lbs.
Heating surface (inside), firebox	120.8 sq. ft.
Heating surface (inside), tubes	2149.5 sq. ft.
Heating surface (inside), total	2270.3 sq. ft.
Grate area	32.25 sq. ft.
Weight under driving wheels (loaded)	48 tons
Total weight (loaded)	77.5 tons
Total weight (empty)	67.5 tons
Bunker capacity on locomotive	4.4 tons
Tender weight (empty)	17.5 tons
Water capacity	22 tons
Tender weight (loaded)	39.5 tons
Engine and tender weight (loaded)	117 tons

* * *

THE WALSCHAERTS VS. THE SPEPHENSON VALVE GEAR.

The paper, "The Walschaerts Valve Gear as Applied to Locomotives," read by Mr. James Kennedy before the September 21 meeting of the New York Railroad Club was productive of an interesting discussion. The mechanical engineers of this country's railways are apparently by no means ready to give up the Stephenson valve gear in favor of the Walschaerts, although it has certain conceded advantages. These are lightness, absence of large eccentrics, better frame bracings and, principally, accessibility, the whole gear being located outside of the driving wheels. Some of the speakers deplored the attacks on the Stephenson gear in the paper; they pointed out that it had done yeoman service for American transportation and is still capable of handling a large part of our transportation work; no doubt it will continue to do so for a long time, notwithstanding the present agitation in favor of the Walschaerts gear.

Mr. A. W. Gibbs submitted a written discussion which was enthusiastically in favor of the Walschaerts gear. Its introduction on the Pennsylvania R. R. dates from the importation of the DeGlehn balanced compound, imported from France and exhibited at the Louisiana Purchase Exposition. The Pennsylvania R. R. now has over 400 locomotives built or in process of construction with a Walschaerts gear, and the general sentiment of both the mechanical engineering department and the engine runners is very much in favor of the new gear. This last speaks volumes, for the natural conservatism of locomotive runners is well-known, and unless the new gear is as good or better than the old form they would be likely to condemn it, being unfamiliar with it. So far as steam distribution is concerned Mr. Gibbs stated that it has no advantage over the Stephenson gear and that all its advantages are purely mechanical, being principally those of accessibility and avoidance of large eccentrics between the wheels.

Mr. Angus Sinclair referred to the fact that the Pennsylvania R. R. a number of years ago built a locomotive with the Joy gear, and he asked the question of Mr. Gibbs why it was that this gear had not been developed, in this country, believing as he did, that it has proven to be a very serviceable gear in Great Britain, and is even simpler than the Walschaerts. Mr. Gibbs replied that his experience with this valve gear was quite unfortunate. It was found that the vertical deflection of the connecting-rod when running at high speeds seriously distorted the action, the excess movement of link block being very pronounced, and the wear of the link and block was excessive. Again when rounding curves the irregular action of the gear was serious on account of one side of the locomotive being elevated more than the other relative to the wheels. This action is not particularly noticeable with the English type of locomotive, having, as a rule, inside cylinders which throw the valve gear near the center line of the engine; this reduces the distortion due to rounding curves and swaying generally.

The amount of lead allowed by the Pennsylvania R. R. so far on the Walschaerts type is approximately 5/16 inch, and this, of course, is constant in all positions of cut-off. This feature of constant lead was attacked by Mr. Quereau, who declared that it is a most serious matter for a locomotive which has to haul heavy trains at slow speeds at one time and run at high rates of speed at another to be deprived of the advantages of variable lead. It is obvious that at slow speeds constant lead means pre-admission of steam to the

cylinder, and consequent high back-pressure. With the Stephenson gear the valves may be set so that there is no lead or even a negative lead in long cut-offs, and in the shorter cut-offs, used in running at higher speeds, ample lead is provided for the necessary cushioning effect. Not so with the Walschaerts gear; the lead must be selected for the average speed and any variation above or below is not as well taken care of as with the Stephenson gear. Another drawback to the use of the Walschaerts gear at the present time is the matter of cost; it was alleged by Mr. Quereau that the builders demand about $1,000 more for this gear than for the regular equipment.

Total weight, engine and tender..	503,000 pounds.
Cylinder diameters	21½ and 33 inches.
Piston stroke	32 inches.
Steam pressure	200 pounds.
Driving wheels, diameter	55 inches.

Wheel base of each driver section, 10 feet; total wheel base of engine, 44 feet 10 inches; engine and tender, 73 feet 2¼ inches.

Tubes, number, 441; diameter, 2¼ inches; length, 21 feet.

Heating surface, firebox, 225 square feet; tubes, 5,433 square feet; total, 5,658 square feet; grate area, 78 square feet.

Tractive power, 71,600 pounds.

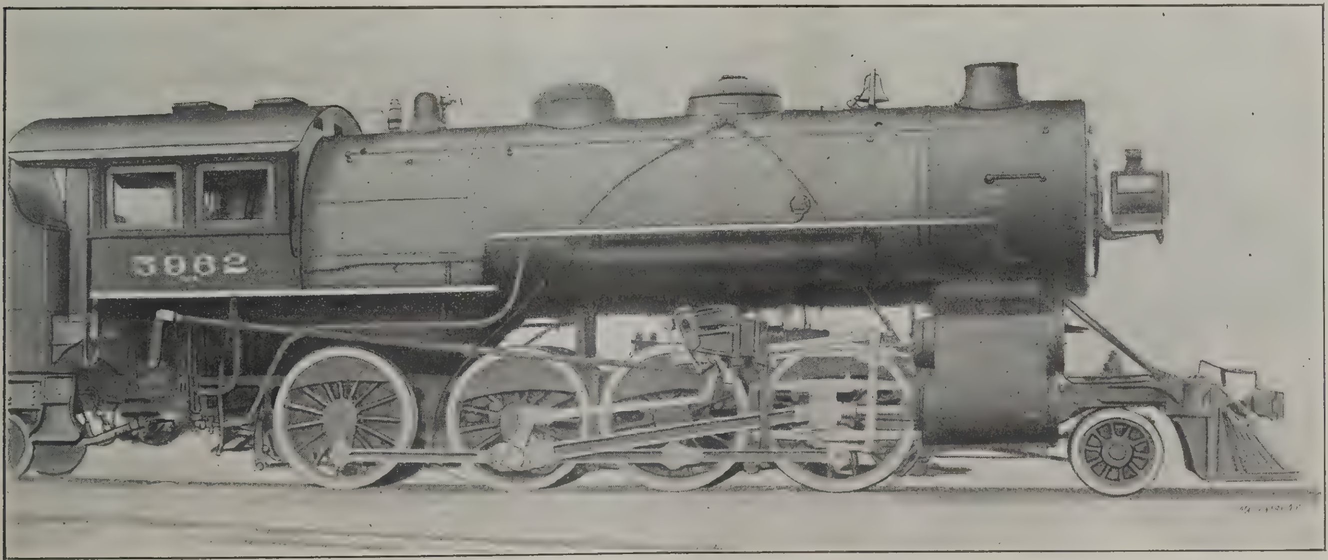
The engines are designed to pass a 10-degree curve.

Great Northern Railway Mallet Compound Locomotive.

GREAT NORTHERN RAILWAY MALLET COMPOUND LOCOMOTIVE.

The Mallet 12-driver articulated compound locomotive shown in the accompanying cut is one of five recently built by the Baldwin Locomotive Works for the Great Northern Railway. It differs from the Baltimore & Ohio articulated compound locomotive described in RAILWAY MACHINERY, July, 1904, in that two-wheel leading and trailing trucks are provided, thus the weight is not carried entirely on the drivers, 41,000 pounds being distributed on the trucks. Its nomenclature by the Whyte system in 2—6—6—2. Balanced slide valves are used on both the high- and low-pressure cylinders; the valve gear is the Walschaerts. The tender carries 13 tons coal and 8,000 gallons water. Following are some of the principal dimensions:

Weight on drivers...............	316,000 pounds.
Weight on front truck...........	19,000 pounds.
Weight on trailing truck.........	22,000 pounds.
Total weight	357,000 pounds.



New York Central Lines Consolidation Locomotive.

NEW YORK CENTRAL LINES CONSOLIDATION LOCOMOTIVE.

The accompanying half-tone shows one of twenty-five consolidation locomotives recently built by the Brooks Works of the American Locomotive Co. for the New York Central Lines. Its design is substantially the same as that of the previous locomotives of this type built for the New York Central, Lake Shore & Michigan Southern, Big Four, and Indiana Harbor lines. The total weight of the engine, however, is somewhat greater than those previously built, due to slight changes in the construction, such as the use of cast-steel bumpers, etc. The design is of interest inasmuch as it illustrates what is now practically the standard 2—8—0 class adopted by the New York Central lines and represents a very large number of locomotives. This order was equipped with the latest type of Walschaerts valve gear, which embodies some improvements, being the result of recent experiences with this gear as applied to large locomotives. The following are the principal dimensions, etc.:

General Specifications, New York Central Lines Consolidation Locomotive 2–8–0.

Cylinder: Type, simple piston valve; diameter, 23 inches; stroke, 32 inches; piston rod diameter, 4 inches; piston packing, Dunbar; valves; type, piston; diameter, 14 inches; travel, 5½ inches; steam lap, 1⅛ inch; clearance, 0 inches; setting, 17-64 inch lead.

Gage, 4 feet 8½ inches, wheel base, driving 17 feet 6 inches; rigid, 17 feet 6 inches; total, 26 feet 5 inches; total engine and tender, 60 feet 9½ inches.

Weight in working order, 232,500 pounds; on drivers, 207,000 pounds; engine and tender, 382,100 pounds; tractive power, 45,677 pounds.

Axles, driving journals, main 10 x 12 inches; others, 9½ x 12 inches; engine truck journals, diameter 6 inches, length 12 inches; tender truck journals, diameter 5½ inches, length 10 inches.

Boxes, driving, cast steel; others, cast steel.

Boiler, type, radial-stayed straight top; outside diameter first ring, 81⅝ inches; working pressure, 200 pounds; fuel, bituminous coal.

Heating surface, tubes, 3,492.18 square feet; firebox, 185.64 square feet; arch tubes, 27.41 square feet; total, 3,705.23 square feet.

Firebox, type, wide; length, 108⅛ inches; width, 75¼ inches.

Grate area, 56.5 square feet; style grate, rocking.

Thickness of crown, ⅜ inch; tube sheets, ½ inch; sides, ⅜ inch; back, ⅜ inch.

Water space, front, 4½ inches; sides, 4½ inches; back, 4½ inches.

Crown staying, radial 1⅛ inch.

Tubes, material, steel to New York Central specifications; number, 446; diameter, 2 inches; length, 15 feet ½ inch; gage, 11 B. W. G.

Exhaust pipe, single.

Smokestack, diameter, 20 inches; top above rail 14 feet 9½ inches.

Brake, driver, Westinghouse-American; tender, Westinghouse; air signal, Westinghouse; air pump, 11-inch Westinghouse; reservoir, 18½ x 120 inches.

Tender, frame, 13-inch channel steel; style, water bottom; capacity, 7,500 gallons; fuel capacity, 12 tons.

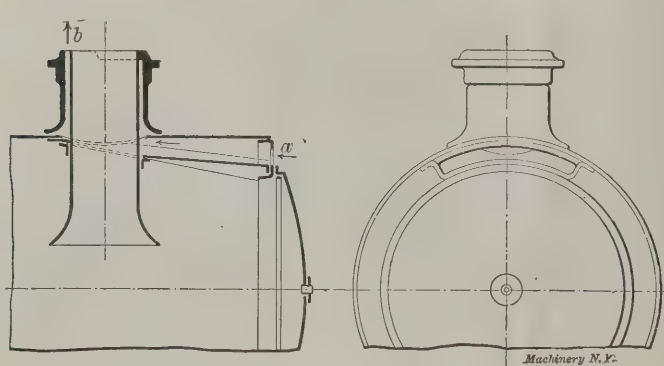
Wheels, driving, diameter outside tire, 63 inches; wheel center diameter, 56 inches; material, cast steel; engine truck diameter, 33 inches; kind, National No. 3; tender brake wheels, diameter, 33 inches; kind Paige plate steel tired.

Engine truck, two-wheeled three-point suspension.

* * *

LOCOMOTIVE EXHAUST DEFLECTOR.

The accompanying cut shows the principle of a new invention, the object of which is to prevent smoke and steam from the chimney of a locomotive settling on the cab windows,

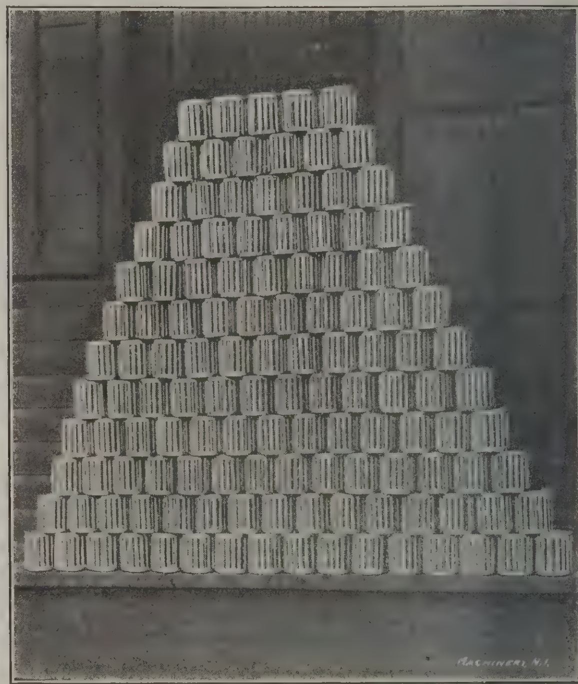


Locomotive Exhaust Deflector.

thus obstructing the view of the engineer. An opening is provided at *a* through which the air will be pressed in with great force when the locomotive is in motion; the air passes around the chimney and up at the rear side at *b* where it will force the smoke and steam upward. According to the *Railroad Gazette*, from which the cut is taken, the device has been applied to locomotives on the Great Northern Railway of England.

CAR AXLE ROLLER BEARINGS.

The accompanying photograph shows a pile of 126 railway roller bearings for 3½ x 5-inch car axles. These were made by the Bantam Anti-Friction Co., Bantam, Conn., and are mostly used upon plantation and industrial railways, especially in Cuba and the South. The present status of railway bearings for car axles is in a rather unsatisfactory condition,



Car Axle Roller Bearings.

as the design of the M. C. B. car box, truck, pedestal jaws, etc., forbid the use of any practicable type of roller axle bearings. Until something can be done to modify the present standard designs the use of roller bearings for railway cars will probably in general be limited to use on private equipment.

* * *

The growth of the use of the Pullman sleeping car is one of those developments which scarcely could have been predicted by any one who was in a position, say forty years ago, to know something of the probable improvement in railroad transportation. In the early days the sleeping car was regarded as a pure luxury to be patronized only by the very wealthy or the recklessly improvident. Now the use of the Pullman sleeping car by the business man is a matter of economy, inasmuch as it is a great saver of time. It enables him to travel say 400 or 500 miles in a night and arrive at his destination in fairly good shape for a day's business. The following night he can return to his home and take up his duties with the interruption of only one business day and without the tiresome monotony of riding in day coaches and practically wasting two or three days extra time, besides the expense of hotel bills. This, of course, is telling what is already well known to every one conversant with common business practice, but it is a very good example of the surprising changes wrought by what are at first regarded as luxuries, and which become business necessities. In other words many of the luxuries of one generation become the necessities of the next.

* * *

According to an article in a recent issue of the *Railroad Gazette*, the Pennsylvania Railroad was probably the last American railroad to adopt the Stephenson link motion. This slowness to adopt an improved valve motion is attributed to the well-known opposition of M. W. Baldwin, who was not favorable to this form of valve gear. Consequently the Pennsylvania Railroad experimented with a great many varieties of gears, fifteen of which are illustrated and described and none of which at all compare with the Stephenson gear in simplicity and effectiveness.

A SOUTHERN MACHINE REPAIR SHOP.

A country machine repair shop is generally of interest to the mechanic; it is a place where ingenuity, enterprise and resource are commonly developed to an extent seldom met with in much more pretentious manufacturing shops. The work that comes to it is generally of an emergency nature requiring instant decision and quick action. Its motto is, or should be, "get there, and do it quick." Instructions from owners are usually indefinite and vague, their principal consideration being limiting the cost and the time. Usually there is no precedent, but if the work is not satisfactory there will always be a hereafter. An engine, for example, must be made to run a few weeks longer; it needs a thorough overhauling, or what is more likely, relegation to the scrap heap, but the proprietor can spare neither the time nor money at the present for thorough repair or replacement. The present machine must be made to run somehow, and that somehow is up to the repair man. Long hours and undesirable work are the rule, but the work nevertheless has its compensations to those who love it.

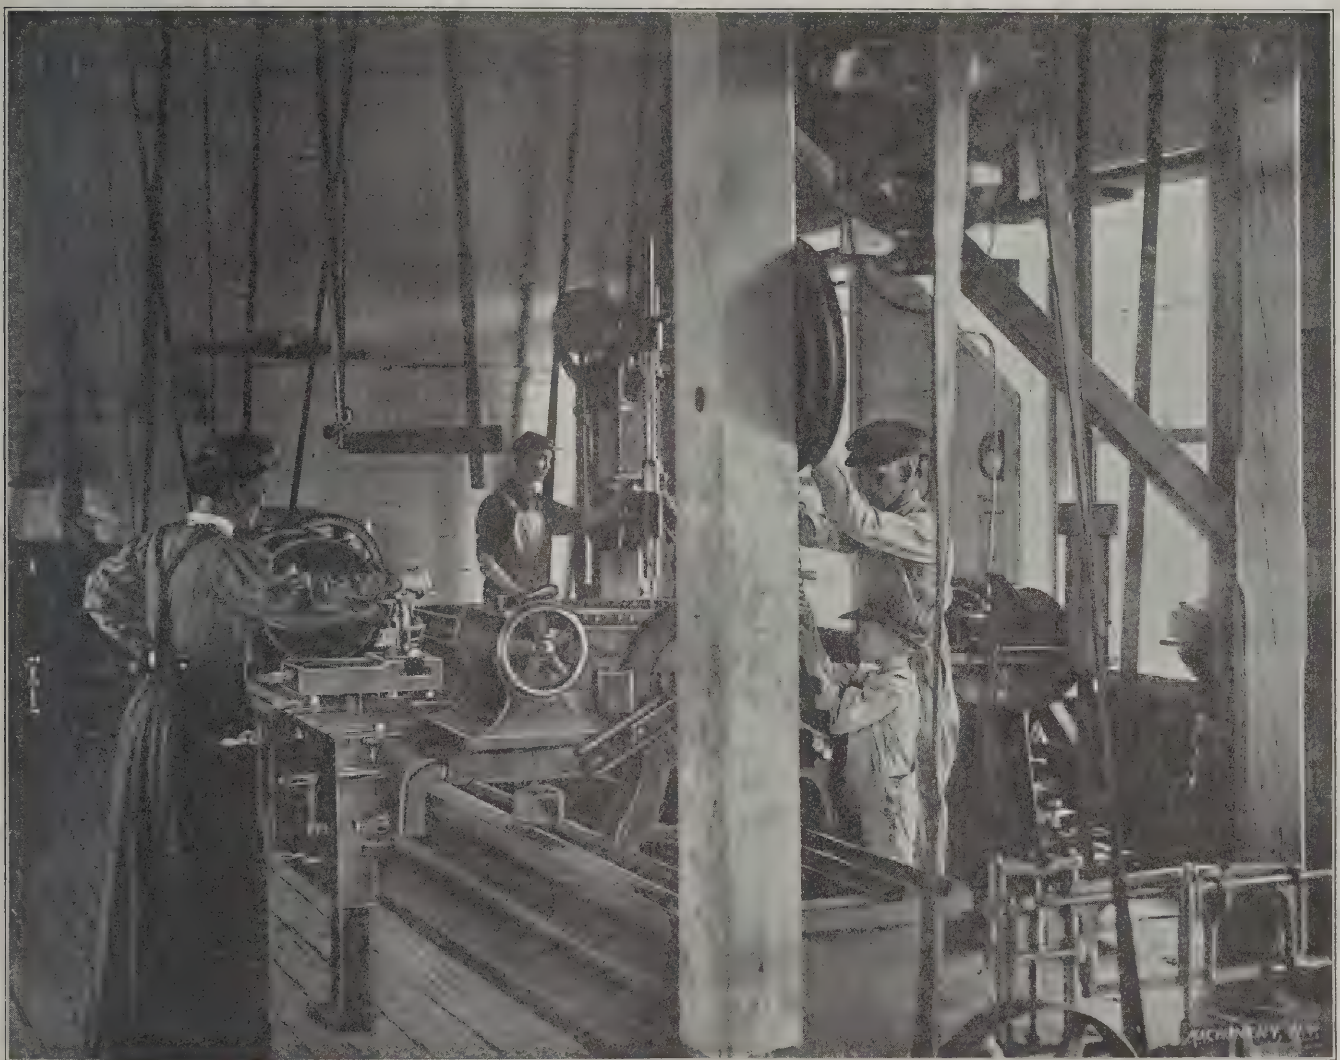


Fig. 1. A Southern Machine Shop; All Hands at Work; Mrs. Parkins Turning a Piston Rod

Down South in Dickey, Ga., is one of these repair shops, typical in meeting all the demands of the country round about, having the reputation for first-class work and unique in having for one of its principal all-around mechanics a woman of resource and mechanical ability equal to almost any emergency. The shop is that of Mr. Eugene P. Parkins, and his wife is his principal helper. Mr. Parkins was born in Champaign, Ill., forty years ago; his father moved to Atlanta, Ga., when he was but a lad. In 1879 his father bought a plantation in the southwestern part of the State, and moved there with his family. Among other improvements which he made was the installation of a cotton gin, driven by a small engine and boiler. In 1883 the son left the farm, for he was never satisfied there except when the engine and boiler were in operation. He entered the repair shops of the Western & Atlantic R. R. as an apprentice and stayed there five years. Then with his savings he equipped his first machine shop, which was built back on the old home farm, adjoining the gin house. The boiler and engine which used to run the gin furnished the power to run the shop. The first tool equipment consisted of of a 16-inch by 8-foot bed Perkins lathe, and a 10-inch crank shaper, a small drill press, a grindstone, together with such small tools as he could afford to buy, including stocks and dies for threading pipe, screw plate, taps and dies, etc.

The building of a shop in the heart of the "piney woods" fourteen miles from a railroad was "a seven-day wonder" and everyone, without exception, predicted failure, but the proprietor was not ambitious beyond what he could clearly see, and he saw the chance to build up a good business with perseverance and first-class work. This has always been his hobby—the turning out of first-class work. When the shop was first built the people in this section of the country had to send their work to Macon, over 100 miles distant, or to Montgomery, equally as far. Hence the shop was a great boon to the locality. There were innumerable cotton gins and saw mills in the locality and the owners of these soon learned the road "to Parkins."

As time passed Mr. Parkins saw the need of more tools and larger machinery, which were added from time to time as his business warranted the expenditure. The shop really built and equipped itself from the very start, all the machinery having been purchased from the earnings. In 1891 Mr. Parkins married a young lady in Washington, D. C., who at that time was stenographer, typewriter, bookkeeper, etc., to one of the prominent business men of that city, a man who afterward was one of the commissioners of the District of Columbia. Soon after his marriage, Mr. Parkins built a new

and larger shop and his dwelling house was attached. In fact, the shop and home are under one roof. This proved to be a most satisfactory arrangement, because Mrs. Parkins now spends a large part of her time in the shop as a general all-around helper to her husband. At first she would take her sewing to the shop for "company's sake." Then, having a natural taste for the intricacies of machinery, she became interested in the work and would often take hold and do some simple job. Now she is a full-fledged machinist and carries on the work in her husband's absence. In fact, last summer she ran the shop every day for three months, doing all the work as it was brought, with the assistance of an apprentice and her son, and she has never had to turn away a piece of work yet because she did not know how to do it. The general class of work which comes to the shop is principally engine repairs. The work in which she particularly excels is the reboring of cylinders, making new pistons complete, including head rod and rings, planing and fitting rod brasses, planing valve seats, repairing injectors, etc. Many of these jobs are done from start to finish without any assistance whatever from Mr. Parkins, and, in fact, many of them he never sees from the time they come into the shop until they

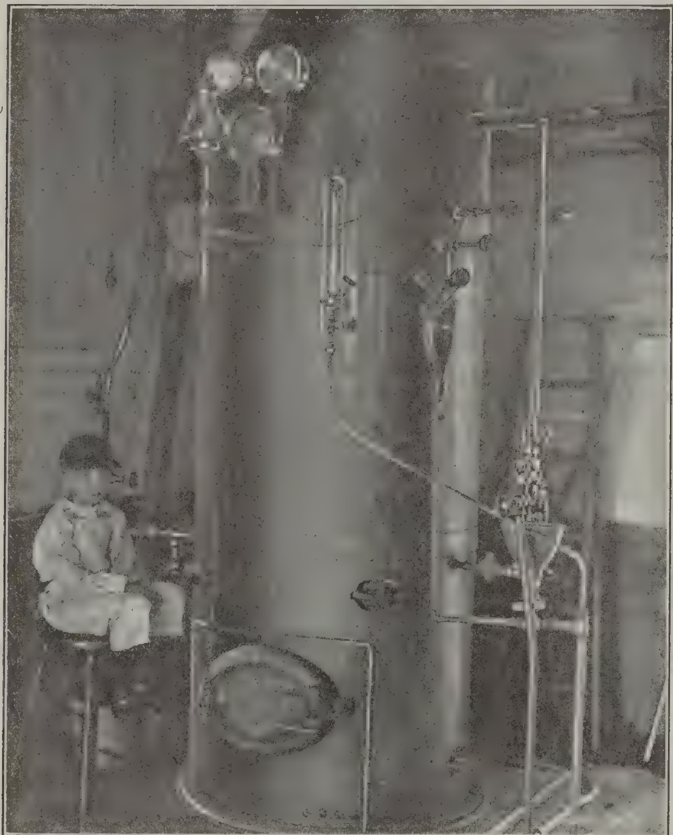

Fig. 2. The Boiler and the "Fireman."

leave, ready for business. The normal shop force consists of Mr. and Mrs. Parkins, a 16-year-old apprentice, and her seven-year-old son, who is the fireman.

After Mr. Parkins had been in business a year or two he found that he must learn boilermaking as an extra trade, for he was frequently called upon to repair boilers as well as engines. At first he would send to Macon for a regular boilermaker to do the work, but by watching the work and helping under directions he soon "caught on" to the principles involved, and then it was only experience and practice that were required. To-day he is a competent boilermaker, able to do all the repair work of this kind that comes his way. He keeps in stock boiler steel for patches, patch bolts, all sizes of rivets, and all boiler tools, such as flue expanders, staybolt taps, patch-bolt taps, and, in fact, any tool or chisel necessary for turning out a first-class job.

The present equipment of the shop consists of a Hamilton lathe, 26-inch swing by 16-foot bed, with quick-change gear screw cutting attachment; the small Perkins lathe before mentioned, which "built the shop"; a 32-inch Steptoe gear shaper; a 30-inch drill press, with power feed; emery grinder with two wheels, wet and dry; and a power hack-saw. Besides, there is a splendid equipment of all small tools necessary to turn out strictly first-class work, such as drills, reamers, taps, screw-plates, files, chisels, dies for threading pipe up to 3 inches, the larger threads being cut in the lathe. All lathe and shop tools are of the inserted cutter type, the old forged type having been discarded long ago.

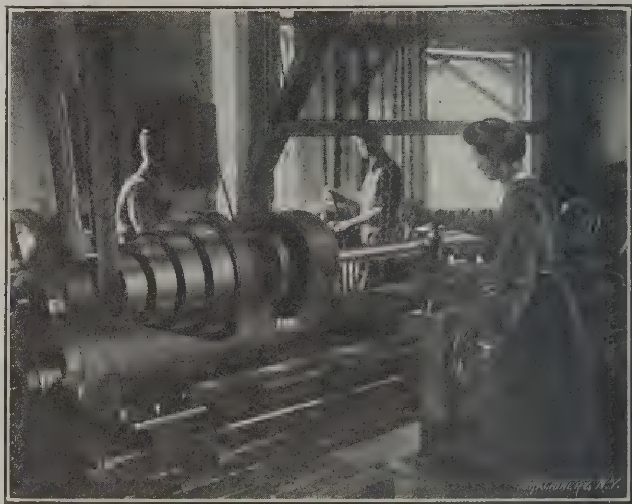

Fig. 3. Another View of the Shop. Note the Business-like Attitude of the Lady Machinist.

An important branch of the business is the repairing of inspirators and injectors, the Hancock and Penberthy instruments being the favorite boiler feeders in that section. A full line of repairs is kept in stock for each of the above-mentioned types, besides reamers and other tools for reseating worn valve seats and putting them into working order as good as when new. This work is almost entirely attended to by the lady machinist.

A few years ago a railroad was built within six miles of the shop, which opened up the surrounding country to a great extent, and work is now brought to the Parkins shop from miles around, coming in many cases from railroad towns where it could be shipped direct to machine shops in the larger towns, but the common saying is: "The people want a Parkins job."

Water is furnished for the boiler from a well about 60 feet deep, the water being pumped into a steel tank 6 feet in diameter and 10 feet high, located on top of a 90-foot tower, by a Marsh deep well pump, 6-inch cylinder by 36-inch stroke. This

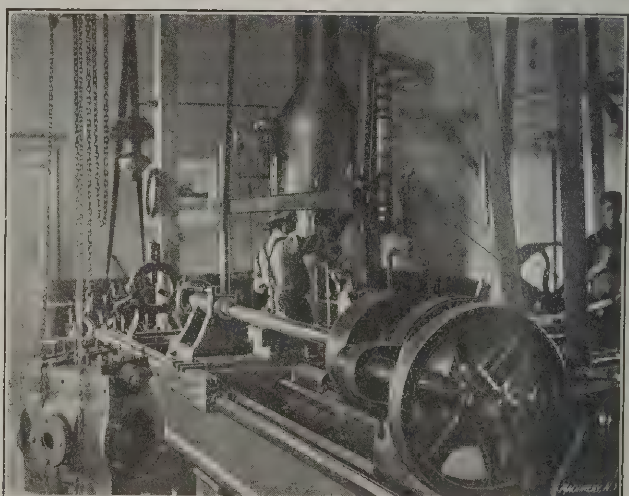

Fig. 4. The Boiler needs a little Attention.

tank also furnishes water for the house which, by the way, is fitted up with all modern city conveniences. Connected to the supply pipe from the tank is 100 feet of 2-inch fire hose, which gives first-class fire protection. The height of the tank insures a pressure which will throw a stream of water clear over any of the buildings.

Being so far from the base of supplies, the shop is obliged

to keep on hand a large stock of supplies, including many parts which the ordinary city shop would not carry; this stock includes, besides the usual supplies, many castings of the machinery used in the vicinity.

* * *

The time when the territory for great engineering feats was limited to America and Europe is past. Recent reports of the progress of the tremendous undertaking of the building

Fig. 5. Shipping a Repaired Job.

of a railroad from Cairo to Cape Town indicate that the work is rapidly being carried to completion. Last June the northern branch had reached within 400 miles of the Victoria Falls, and of the southern branch 2,000 miles are already completed. Between three or four thousand natives are regularly employed in the construction work. The last portion of 300

Fig. 6. The Home Part of the Shop and the Water Works.

miles, with seven bridges of more than 50 feet span, was completed in less than a year. From China is reported the completion of an enormous railroad bridge over the Yellow River, said to be the greatest undertaking of modern engineering in that country. The bridge is about 10,000 feet long, and consists of 103 spans, each varying in length between 75 and 110 feet.

TRACING, LETTERING AND MOUNTING.—2.

I. G. BAYLEY.

Tracing (Continued).

Sectioning.—Sections are shown in several ways. For working tracings line sectioning is far the better. Plates and sections in wrought iron or steel work may be blackened, as shown in Fig. 7. A narrow white space should be left between two pieces, as shown.

A pretty way of showing sections, especially in the case of show tracings, is to represent the various metals, woods, etc., by broken and full lines shown in Fig. 8. The examples are standard, although in case there should be any doubt as to whether they will be generally understood it would be well to make a small note to one side, naming the metal.

A neat little tool for section lining is easily made from a slip of wood a little thicker than the triangle or set square used by the draftsman, illustrated in Fig. 9. The notch cut in one side is a little longer than the side of the triangle. Resting the thumb upon the T-square, the first finger upon the sectioner and the second finger (all of the left hand) upon the triangle, they are alternately slipped along each time a line is drawn with the pen. With a little practice, sectioning can be done quicker than by using a triangle and T-square only, trusting to the eye for correct spacing. Section lining done this way looks very neat and even. Another section liner shown in Fig. 10 can be made to fit triangles having a recess in the center.

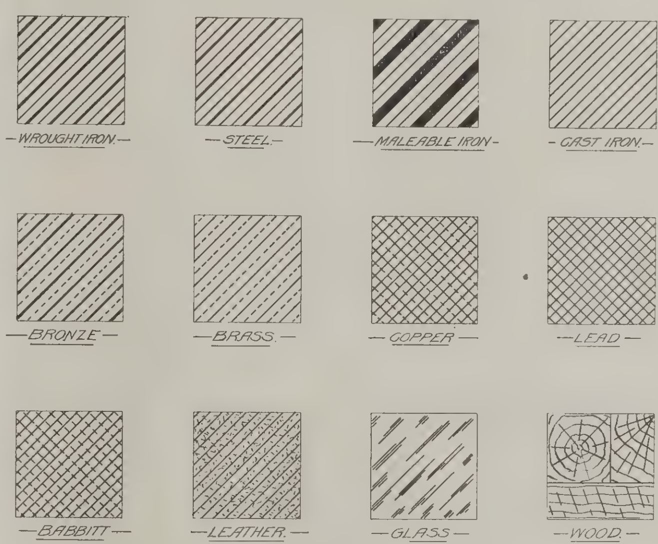

Fig. 8.

Views in section are sometimes colored, generally on the back, turning the tracing over and tacking it down again; or where there is much coloring to be done the tracing should be mounted as described under that head at the end of this article; otherwise the color will cause the tracing to buckle, giving it a very untidy appearance. Having stretched the tracing, you can be mixing the colors while it thoroughly dries. The colors should be rather thin and to make them run evenly a little prepared ox-gall should be mixed in well with them. This should not be omitted or the colors will present a very smudgy appearance. Some draftsmen use a small piece of soap in place of the ox-gall.

By trying the colors upon a scrap piece of tracing cloth or paper and turning it over, the proper shade may be obtained.

Following is a list of representative colors used in many offices:

Cast iron	Payne's gray.
Wrought iron	Prussian blue.
Steel	Crimson lake and small quantity of blue.
Brass	Yellow.
Copper	Crimson lake and yellow.
Brick	Crimson lake.
Wood	Burnt sienna.
Earth	Daubs of ink, Payne's gray, etc.

In the absence of Payne's gray a pale wash of India ink in

which has been mixed a little Prussian blue may be substituted.

Very neat sectioning can be made with crayons, toning them down with a soft rubber.

Dimensions and Center Lines.—Working tracings should have the dimension lines, center lines and all lines black ink, the idea being to make a neat, distinct tracing for use only, whereas a show or estimate tracing should be made with greater care. It is a well-known fact that many contracts have been awarded on the merits of a well-executed piece of work by the draftsman. The time and expense spent upon making a neat show tracing is never lost. Make the center lines of red ink or color, a fine long dash and dot line; the dimension lines one continuous line broken only where the figures come. See Fig. 11.

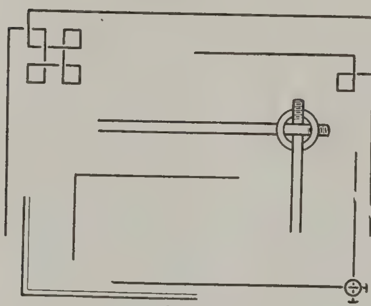

Fig. 12

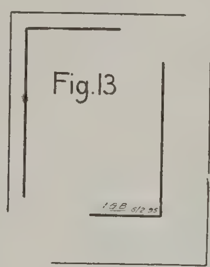

Fig.13

Fig. 14

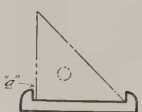

Fig.9

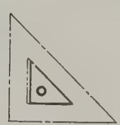

Fig.10

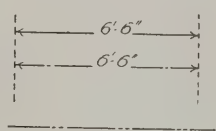

Fig.11

Border and Cutting-Off Lines.—Simple as these may seem, yet many well-executed tracings have been spoiled by either neglecting a border line or making a very poor one. A one-line border is perhaps the best and its thickness should match the work in hand, together with the size of the sheet. There should be plenty of margin between the border line and the

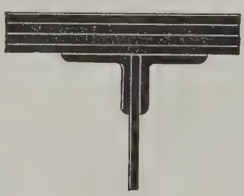

Fig.7

Fig.15

Fig.16

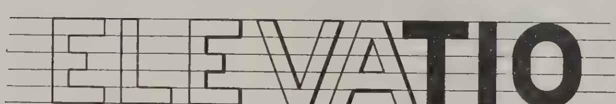

Fig.18

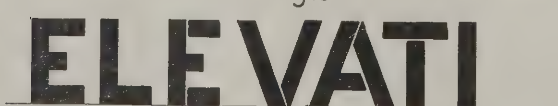

Fig.19

work. A fancy border line may be put around estimate or show tracings, of which a few samples are given in Fig. 12.

The cutting-off line should not be too near the border line, say, from ¾ inch to 1 inch. Nothing looks worse than to see a good tracing spoiled by cutting off within a quarter of an inch of the border line. Compare Figs. 13 and 14. The initials of the draftsman and date tracing was made should not be omitted.

Conclusion.—Attention to details is perhaps the true secret of making a neat tracing. No matter how trifling a detail may seem, it should be made as neatly as the rest of the work. Channels, angles, etc., in section should be made accurately. See Fig. 16. Don't make them, as is so often done, like Fig. 15.

When tracing a blueprint the tracing should be tacked down with few tacks, as it will have to be lifted quite often to see the work distinctly; in fact, in many cases it would pay to make a drawing from the blueprint and trace it.

Drawings which are faint or unfinished should by all means be made clear before attempting to trace them, thereby saving much patience, but in particular the eyesight.

In tracing from another tracing, a clean sheet of white drawing paper underneath will make it stand out clearly.

If the draftsman understands what he is tracing, the work will be much easier and he will not be likely to make so many mistakes as he would if tracing a number of meaningless lines.

The tracing should be wiped down occasionally with a clean, dry duster or cloth. Cotton sleeves are sometimes used to protect the coat. A sponge-rubber or piece of bread may be used to clean a tracing, but if proper care has been taken, a tracing can be taken up as clean and neat as when tacked down. A creased soiled tracing shows a bad workman. In some offices it is the practice to sponge the tracings down with benzine. Waterproof ink must be used by all means if this plan is adopted. When the tracing is complete, the draftsman should look over it carefully, trying to detect any errors, as all such count against him. The shop hands, as a rule, are only too pleased to point out any trifling mistake coming from the drawing office. However, accuracy as well as neatness and quickness is desirable

Lettering.

No matter how neatly or carefully the working lines of a tracing are made, if the lettering and figures are not up to the mark, the tracing will look poor in every sense of the word.

The young draftsman should, therefore, take especial care to get into a neat way of lettering and should devote a little

Fig. 17.

of his spare time each day to this end if he wishes to excel as a neat draftsman. Neat letterers are in demand and are always sure of a position. Many cases have come to the writer's notice where a good letterer has been employed in his spare time to put on the figures and letters of other men's work, and although a poor tracing can be improved by neat lettering, to excel in both should be everyone's desire.

A good instruction book on this subject is difficult to find. Most alphabet books are ridiculous in the extreme; it would take longer to make the letters they describe than the whole tracing. The tracings would look insignificant in comparison with the wonderful lettering.

The letters and figures must conform to the other work—neither should be more conspicuous than the other. For this reason it is preferable for each man to complete his own tracing.

It is an easy matter to tell who made the various tracings in most drawing offices by the peculiar characteristics of each draftsman—this one by its poor lettering or that by a beautiful harmony of lines, letters and figures, the whole standing out in correct proportion, fine lines having small neat figuring, lettering, and arrow points to match, or heavy lines *vice versa*.

Nothing looks more uniform, neater, or is quicker done than good, plain, one-line lettering, even for the titles, though perhaps a little display may be given to them.

A few samples are here given. The small letters are for the general working parts of the tracings, notes, etc. Headings should be a little larger and the title, which will be referred to later, should be distinguished from the rest of the

work by using larger letters either blocked out or capital letters made with a heavier pen.

Figures should be made plain and simple, without the use of flourish or tailpiece. Fractions should be made with one figure immediately over the other instead of to one side. The vertical system of figuring is preferable to the slanting, especially with shop tracings.

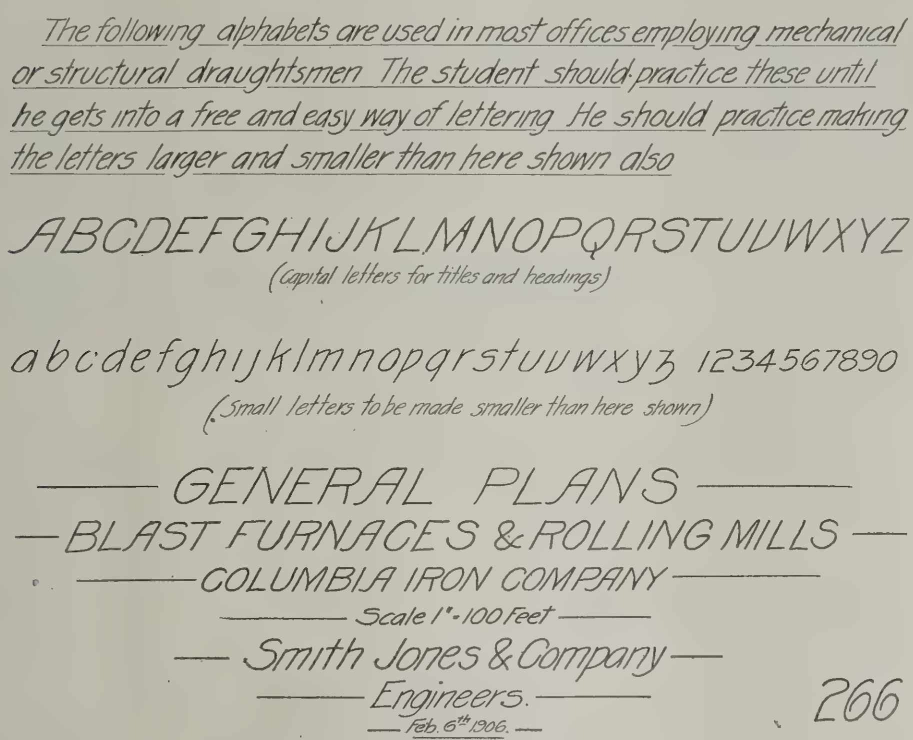

Fig. 20. Examples of Lettering.

For lettering, have plenty of black ink, but not too thick. The best kind of pen points are Esterbrook's No. 333 or Gillot's 303 for fine work. A heavier pen must be used for titles. Make the letters and figures with one stroke of the pen; do not go over them again, but get the required thickness, even with titles, by bearing on the pen more. A pen can be tempered when new by holding it in a lighted match, though pressing it on the thumbnail is generally sufficient.

Headings or Titles.—The heading or title should be in a conspicuous place, and as far from anything which may tend to crowd it as possible. The bottom right-hand corner of the

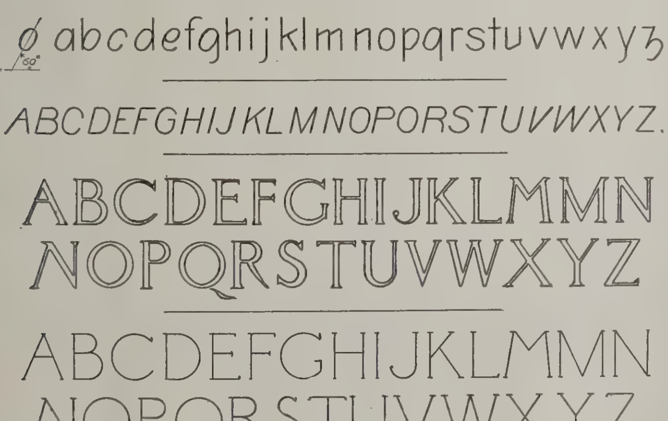

Fig. 21. Examples of Lettering

sheet is a good place. A heading sometimes looks better without lines drawn underneath, as shown in Fig. 17. This is entirely optional, however; if lines are put under they should not be too close to the letters.

Black letters are sometimes used, which can be made by drawing six pencil lines equally spaced, as shown in Fig. 18. The T-square and triangle are used and the letters can be made quite rapidly. They should afterwards be filled in or one edge of the letters made heavier, according to the nature of work in hand. Sloping letters can be made in the same way by using an adjustable-headed T-square or a special triangle made for that purpose.

Stenciling.—Sometimes headings, letters, figures and corner pieces are put on by means of stencil plates cut out of tin or copper sheets. A stiff, short stencil brush is used. The brush is moistened with water, not using too much, and is then rubbed along the stick of ink until it cannot absorb any more. Particular attention is called to this, as here is where so many fail in making clean and clear stencil work; the brush should never be dipped into a saucer of ink, or the ink applied with a pen.

The position for the title having been settled, pencil lines should be drawn on the cloth as a guide for the stenciling. Sometimes the title or heading is stenciled upon a spare piece of cloth or paper first, then slipped into place under the tracing and the stencil work done over it. This is a good plan, as the correct position may thus be obtained. If this is not done, the only way is to make a pencil tick mark after each letter to indicate the position of the next, as, of course, the stencil plate will hide all beneath it except the letter being stenciled. Then the letters must each be filled in, as shown in the first two or three letters of Fig. 19.

Even when the stencil guide referred to is made and slipped into place under the tracing cloth, a pencil guide line should be drawn and all letters stenciled exactly to it. The pencil lines and ticks are then erased. If the brush becomes dry, it may be moistened on the tongue without again rubbing it on the ink stick.

Draftsmen sometimes cut their own stencil plates out of stiff drawing paper, applying a coat of varnish on the upper surface.

Round Writing.—When referring to alphabet books, the writer should have made one exception at least, and that is the round writing system. It is easily learned and not soon forgotten. Letters and figures of all sizes and shapes can be made by using different graded pens. Books of instruction and an assorted box of pens may be had from any stationery store of importance. It is known as the Round Writing System of Lettering.

* * *

Designers, in general, in making use of malleable iron castings, proceed without definite knowledge as to the physical properties of this material, so far at least, as its tensile strength and elongation are concerned. Mr. G. A. Ackerlind read before the Scandinavian Technical Society recently a paper in which he gave some definite information as to the properties of malleable cast iron as made in that country. This information is doubtless applicable to American irons as well. He states that the tensile strength for this material varies between 40,000 pounds and 50,000 pounds per square inch. It has an elongation varying from 1 to 6 per cent with a reduction of area of ¾ to 3 per cent. The ordinary grade of cast iron having a tensile strength from 20,000 to 30,000 pounds per square inch is therefore only about half as strong as malleable cast iron; its compressive strength, however, is much greater. Malleable cast iron shrinks more in the mold than cast iron, but during the process of annealing a slight swelling takes place. If malleable castings have to be straightened by hammering, nothing is gained by heating them, the normal temperature of the surrounding air being satisfactory for this purpose.

THE CONDITIONS OF FAN BLOWER DESIGN.

The velocity with which air escapes into the atmosphere from a reservoir is dependent upon the pressure therein maintained and upon the density of the air. The pressure per unit of area divided by the density per unit of volume gives the head, usually designated as the "head due to the velocity." The velocity produced is that which would result if a body should fall freely through a distance equal to this head. In the case of the flow of water such a head always exists; as, for instance, when a stand-pipe is employed to produce the requisite pressure. Suppose the head of water to be 50 feet and its weight per cubic foot to be 62.5 pounds, then the pressure per square foot will be $50 \times 62.5 = 3{,}125$, and that per square inch $3{,}125 \div 144 = 21.7$ pounds. Its theoretical velocity of flow from an orifice at the bottom of the standpipe would be 56.7 feet per second, as determined by the formula for falling bodies, which is $v = \sqrt{2gh}$, in which

$v =$ velocity in feet per second.
$g =$ acceleration due to gravity.
$h =$ head in feet, here 50 feet.

In the case of air, however, an actual homogeneous head never exists, but in its stead we have to deal with an ideal head which can only be determined by dividing the pressure by the density. As the density of air is so much less than that of water, it is evident that for a given pressure the head will be far greater in the case of air. But the velocity of discharge is dependent only on the distance fallen which is represented by the head, whether real or ideal. As a consequence, air under a stated pressure escapes at vastly higher velocity than water under the same conditions. Calculated in the same manner the velocity of escaping air under a pressure of 21.7 pounds per square inch is 1,626 feet per second. By the employment of formulas based upon this theory, the elaborate basis tables published by the B. F. Sturtevant Co. have been calculated.

From the preceding discussion, it is evident that the pressure created by a given fan varies as the square of its speed. That is, doubling the speed increases the pressure four-fold. The volume of air delivered is, however, practically constant per revolution, and therefore is directly proportional to the speed.

The work done by a fan in moving air is represented by the distance through which the total pressure is exerted in a given time. As ordinarily expressed in foot-pounds, the work per second would, therefore, be the product of the velocity of the air in feet per second, the pressure in pounds per square foot, and the effective area in square feet over which the pressure is exerted.

From this it is evident that the work done varies as the cube of the velocity, or as the cube of the revolutions of the fan. That is, eight times the power is required at twice the speed. The reason is evident in the fact that the pressure increases as the square of the velocity, while the velocity itself coincidently increases; hence, the product of these two factors of the power required is indicated by the cube of the velocity.

The actual work which a fan may accomplish must depend not only on its proportions, but upon the conditions of its operation and the resistances which are to be overcome. Evidently, it is improper to compare fans when operating under such conditions that these resistances cannot be definitely determined. The simplest and most natural condition of operation is that in which the fan is operated without other resistance than that of the case; that is, with open inlet and outlet. For proper comparison of different fans, the areas through which the air is charged should bear some constant relation to the dimensions of the wheels themselves.

It has been determined experimentally that a peripheral discharge fan, if enclosed in a case, has the ability, if driven at a certain speed, to maintain the pressure corresponding to its tip velocity over an effective area which is usually denominated the "square inches of blast." This area is the limit of its capacity to maintain the given pressure. If it be increased the pressure will be reduced, but if decreased the pressure will remain the same. As fan housings are usually constructed, this area is considerably less than that of either the regular inlet or outlet. It, therefore, becomes necessary, in comparing fans upon this basis, to provide either the inlet or the outlet with a special temporary orifice of the requisite area and the proper shape, and make proper correction for the contracted vein. The fan is thus, in a sense, placed in a condition of restriction of discharge, which it approaches in practice only in so far as the resistance of pipes, passages and material through which the air must pass has the effect of reducing the free inlet or outlet of the fan.

The square inches of blast, or, as it may be termed, the capacity area of a closed fan, may be approximately expressed by the empirical formula:

$$\text{Capacity area} = \frac{DW}{x}$$

in which $D =$ diameter of fan wheel, in inches.
$W =$ width of fan wheel at circumference, in inches.
$x =$ a constant, dependent upon the type of fan and casing.

The value of x has been very carefully determined by the B. F. Sturtevant Company for different types of fans; but these values must be applied with great discretion, acquired through experience and a thorough knowledge of all the conditions liable to affect the fan in operation.

BRITISH STANDARD FINE SCREW THREAD.

The committee on screw threads and limit gages, a subcommittee of the Engineering Standards Committee supported by several engineering institutions in Great Britain, recommends the continuation of the use of the Whitworth form of thread as the British standard for screws ¼ inch and larger in diameter. For screws smaller than ¼ inch in diameter the committee recommends the adoption of the British Association form of thread with the same pitches as are now known as the British Association's standard (B. A.).

In regard to the pitches for screws ¼ inch and larger in diameter, the committee recommends the adoption of two standards. One of these is to be known as the British Standard Whitworth Screw Thread (B. S. W.), and retains the same number of threads per inch as is now in use in the regular Whitworth's system. The other standard proposed has a greater number of threads per inch for corresponding diameters and will be known as the British Standard Fine Screw Thread (B. S. F.)

The reason for adopting this latter standard was founded on the complaints of many manufacturers that the regular Whitworth standard gave altogether too coarse pitches for a number of purposes, and while the old system was well adapted for a variety of constructions, it was not the best obtainable for such designs where shocks and vibrations had to be taken in consideration.

The pitches for the system of fine screw threads are based on the formula:

$$P = \frac{\sqrt[3]{d^2}}{10}$$ for sizes up to and including one inch; and on the formula

$$P = \frac{\sqrt[8]{d^5}}{10}$$ for sizes larger than one inch in diameter. In the above formulas

$P =$ pitch, or lead of single-threaded screw, and
$d =$ diameter of screw.

A table giving diameters and corresponding number of threads per inch will be found below.

BRITISH STANDARD FINE SCREW THREAD.

Diam.	No. of Threads per in.	Diam.	No. of Threads per in.	Diam.	No. of Threads per in.	Diam.	No. of Threads per in.

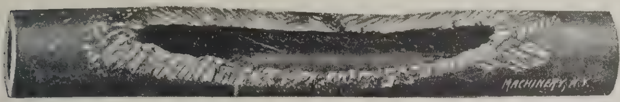
The output of asbestos in the United States for 1905, was 3,109 short tons.

ITEMS OF MECHANICAL INTEREST.

A RAT'S TRY AT HYDRAULIC ENGINEERING.

The rodent dwellers in the floors and partitions of an apartment building in Brooklyn attempted to make a passageway from their quarters on one side of a floor beam by gnawing through to the other side. They succeeded in their undertaking, as the people living in the flat below this floor discovered when deluged by a flood of water from above. The rats gnawed through the beam in a diagonal direction and encountered on the further side of the beam a lead water pipe in which there was the city water pressure. The pipe ran parallel with the beam and was so located that the rats were obliged to gnaw through it in order to gain a passage way. They continued in their diagonal course, however, eating away the pipe, as shown in the illustration, in spite of the large



The Pipe after the Job was Completed.

volume of water escaping. It was a job that probably made them hold their breath. The pipe was brought us by the engineer of the building as evidence of a good piece of hydraulic engineering and incidentally as an indication of the multifarious duties that fall to the lot of one in his position.

FRICTIONAL FEED MOTIONS

The principle used in the jeweler's drop hammer, by which a man is apparently able to lift a great weight by placing his foot in the stirrup at the end of the strap to which the drop is attached, has another application, as shown in the cut herewith. In the case of the drop hammer the strap passes over a rotating pulley at the top of the press. The pressure of the operator's foot in the stirrup draws the strap tight enough over the pulley so that the latter raises the drop through frictional contact.

The illustration, Fig. 1, shows this lifting device, as used by the New Britain Machine Co., New Britain, Conn., for raising the table of their mortising machine to bring the work against the cutters. This lifting motion is an instance of a device almost elementary in its simplicity, yet exactly meeting and accomplishing a variety of requirements. The frictional strap which raises the table passes over the pulley *B* which rotates in the direction of the arrow. One end of the

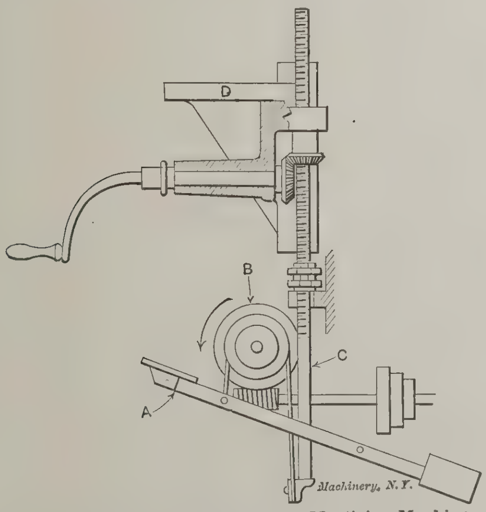


Fig. 1. Friction Feed Device for Mortising Machine.

strap is attached to the treadle, *A*, and the other end to the vertical screw, *C*, by which the table, *D*, is raised or lowered. A slight pressure of the foot upon the treadle results in a lifting force many times as great upon the table and even the greatest pressure cannot cause the table to exceed the rate of travel fixed at the feed cones. A light pressure slows the feed rate for hard spots and the natural weight of the foot on the treadle acts as a cushion when the table drops.

The frictional pulley used for raising the tables in these mortisers appears in section at *A*, Fig. 2, which also illustrates a novel method of clamping the pulley to the shaft, *B*, without the use of set screws. The requirements are such that the shaft cannot have a shoulder against which to clamp the pulley by means of a nut on the end of the shaft; and as it is necessary for the pulley to be removable, the method

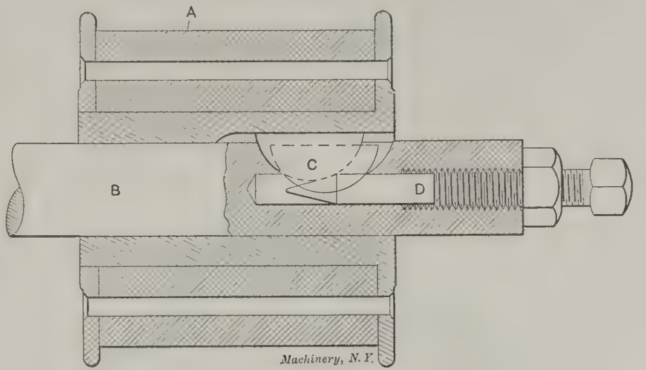

Fig. 2. Method of Holding Pulley to Shaft.

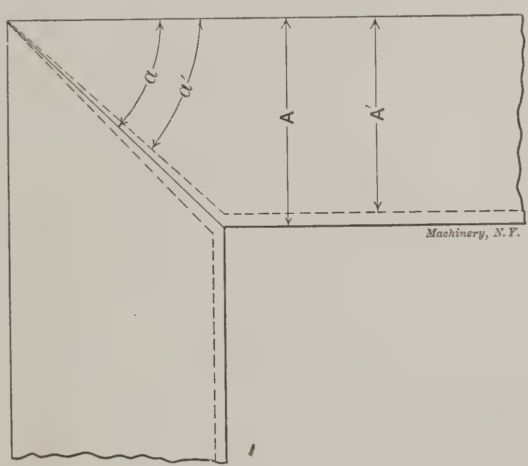
shown in the sketch was devised for holding it. A Woodworth key, *C*, is used, and this is forced out against the keyway milled in the bore of the pulley by means of a set screw, *D*, which enters a threaded hole in the end of the shaft.

CAUSE OF MITERED JOINTS DRAWING APART.

Why do the joints of mitered joint frames, such as picture frames, nearly always gap on the inside corners? If the reader will take the trouble to look at a wide picture frame having mitered joints he will find that while the outer corners are close together the inner corners are almost invariably gapping a distance of anywhere from 1-32 to 1-16 inch, or more. When the frame was fitted up a perfect joint, of course, was made, but as the wood seasons the drawing apart of the



Why Mitered Joints Open Up.

inside corners is an almost invariable result. The cause of this action has been the subject of considerable discussion among patternmakers and other woodworkers, and a variety of reasons have been assigned. The true explanation is very simple, and is illustrated in the sketch given herewith. It will be noted that the wider the frame the greater the gapping. This is caused by the fact that wood shrinks very little in length, the shrinking being almost altogether confined to the width. In the sketch the full lines indicate the original outline of one corner of a mitered joint frame, and the dotted lines the shape it takes after having seasoned. Inasmuch as the wood shrinks very little, or not at all, in length it follows that the outside dimensions of the frame remain practically unchanged, but the narrowing of the width *A* to *A'* changes the angle *a* to *a'*, as indicated by the dotted lines, so that the result must be a separation of the joint at the inner corners.

So long as we see the automobile carrying an extra tire or two, just so long may we regard it as an impractical vehicle for anything save pleasure—pleasure obtained at much cost and trouble.

CURIOUS CHINESE LOCK.

Through the courtesy of the Yale & Towne Mfg. Co., we are enabled to present the accompanying halftone, Fig. 1, showing a curious Chinese lock used for some time on a letter box in Doyer St., (within the purlieus of Chinatown) New York. Although of very simple construction and probably easily pickable by an expert, it nevertheless offers a degree of security sufficient for most purposes for which a lock of this type is commonly used. It will be noted that the lock is not only of the spring or self-locking type, but is also of

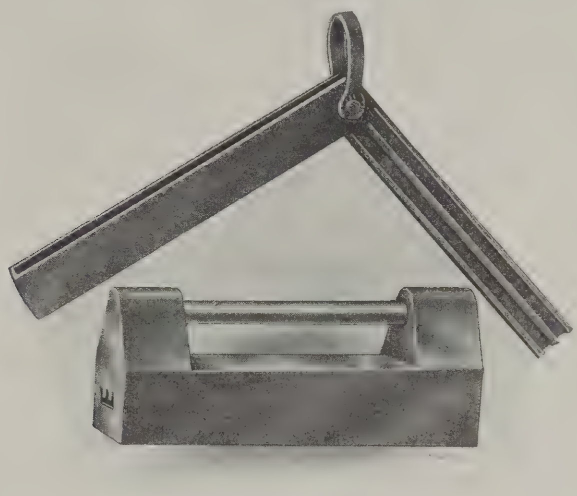

Fig. 1. A Chinese Padlock and Key.

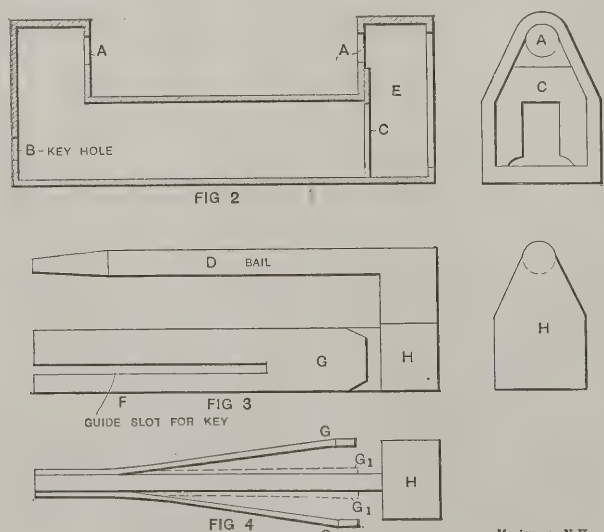
the ejecting type, the shackle being partially forced out when the key is inserted. It is, we understand, a type of "padlock" largely used in China for trunks, portable boxes, etc.

The arms of the shackle are joined by the part *H* which fits closely in the opening *E* and is flush with the end. One arm of the shackle, it will be noted in Fig. 3, has two spring leaves *G*. These leaves spring outward when the lock is closed and the ends engage the sides of the partition *C*, this constituting the essential locking action. The key is of E-section and its insertion into the lock pinches the spring leaves together, unlocking the shackle and partially ejecting it from the case. The middle projection of the E-section performs no function, being a deception or "blind"; a channel-section key would answer the same purpose but such would not be inferred from the keyhole, of course. The security of the lock against pick-



Figs. 2, 3 and 4. Details of Lock.

ing lies quite largely, however, in the length of the key required, it being nearly three inches long in the working part. For convenience in carrying the key is made with a jointed handle into which it can be closed, as shown in Fig. 1.

The body or shell shown in section in Fig. 2, is made of sheet brass, soldered or sweated together at the corners, and is apparently made up of seven pieces carefully joined. This laborious make-up was doubtless followed in order to avoid the use of castings.

BLANKING AND PIERCING DIES FOR WASHERS.

C. F. EMERSON.

One of the simplest dies to make, coming under the head of blanking and piercing dies, is perhaps the die for blanking and piercing brass washers. The reason for this is that in making this die, the file and vise are not used; the construction and shape of this die are such as to allow it to be made by machinery.

To lay out a single washer die is a very easy matter, but to lay out a die for cutting two or more washers at one time, so as to cut the greatest amount of blanks from the least amount of stock, is not understood as it should be.

One of the reasons for this is that it is the custom in some shops to have the foreman, or some one else appointed by him, lay out all the dies before they are given to the die maker to work out.

In laying out a washer die for blanking two or more washers at one time, one of the main points to be remembered is that all the holes from which the blanking and piercing are done must be laid out in an exact relation to each other, so as to

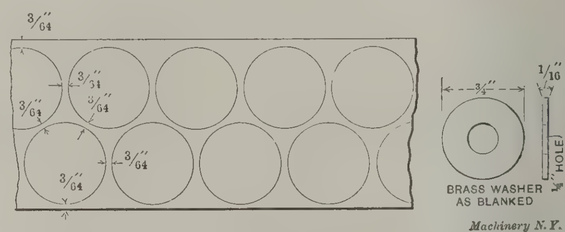


Fig. 1. Stock after having been run through the Die in Fig. 2, and Washer.

eliminate the possibility of "running in" (i. e., cutting imperfect, or half blanks, by cutting into that part of the metal from which blanks have already been cut). The required amount of blanks must also be considered, for it sometimes happens that the amount wanted does not warrant the making of a die that will cut more than one at a time.

Fig. 2 shows how a die is laid out for blanking and piercing two washers at one time, so as to use up as much of the metal as possible. As shown, the ¾-inch holes marked *C* and *D* are the blanking part of the die, while the ¼-inch holes

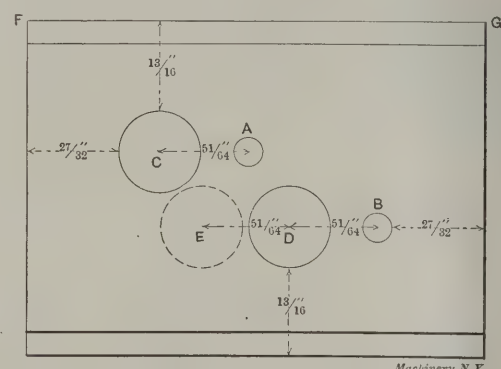

Fig. 2. Plan View of Die for Punching two Washers.

A and *B* are the piercing part. The distance between the center of *C* and *A* is 51-64 inch, as is also the distance between *D* and *B*. By referring to Fig. 1, which shows a section of the stock after it has been run through this die, it will be seen that there is a narrow margin of 3-64 inch of metal, known as "the bridge," between the holes. In laying out the die this margin must be taken into consideration, which is done in this manner. Diameter of washer to be cut plus bridge equals distance from center to center, viz., ¾ + 3/64 = 51/64.

The dotted circle shows that the die is laid out so that one washer is skipped in running the metal through at the start. This is done in order to make the die a substantial and strong one. It can be very readily seen that if the circle *E* was the blanking part instead of *D*, the die would be a frail one, and would not be strong enough for the work for which it is intended.

Another important point in laying out a die of this kind

is to lay out the die "central," *i. e.*, laying out the die so that when it is keyed in position ready for use in the center of the die bed, it will not have to be shifted to the right or left side in order to make it line up with the punch.

It may not be amiss to say in connection with the above that the punch back which holds the blanking and piercing punches in position should also be laid out "central"; this will be more fully described later on.

Fig. 4 shows the layout for blanking and piercing three washers at one time, and hardly needs any explanation; the explanation given in connection with Fig. 2 sufficiently explains Fig. 4.

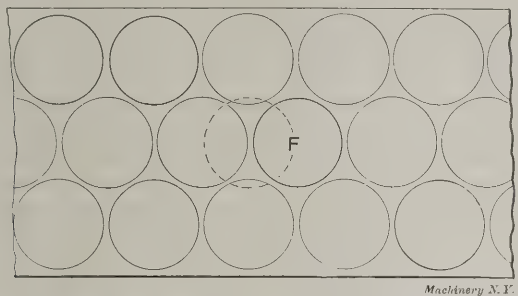

Fig. 3. Stock, after having been run through the Die in Fig. 4.

Fig. 3 shows a section of the stock after it has been run through this die. It can be seen that the holes match in very closely together, and that very little stock is left. It is also seen that the three holes punched are not in a straight line, in so far as the width of the metal is concerned. This is done in order to save metal; the dotted circle *F* is merely drawn to show that wider metal would have to be used if the holes were in a straight line.

Fig. 5 shows the plan of a die for blanking and piercing eight washers at one time. The parts which are numbered are the blanking parts, while the parts that are lettered are the piercing parts of the die. This die is laid out similarly to Fig. 4, with the exception that there is provision for eight blanks instead of for three. Fig. 6 shows a section of stock after it has been run through this die. To give a better idea as to how the blanks are punched out in the manner shown, the sixteen holes in the metal from which blanks have been cut are numbered and lettered the same as the die. It should be understood that the metal is fed through in the usual way, which is from right to left, and that the ¼-inch holes are first pierced out, before the ¾-inch blanks are cut.

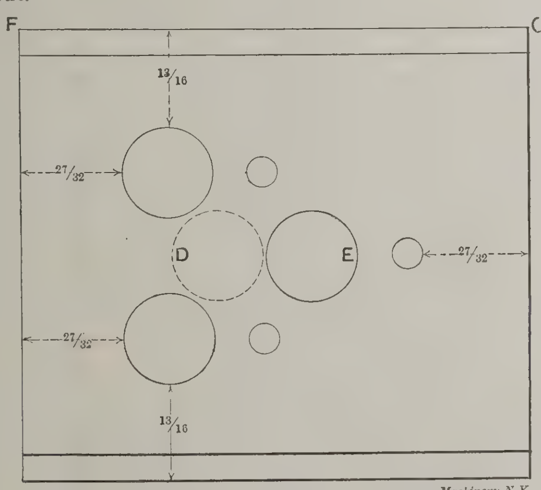

Fig. 4. Plan View of Die for Punching three Washers.

By referring again to Fig. 5, the layout for cutting two, three, four, five, six and seven blanks can be determined. The parts numbered and lettered 1—*A* and 5—*E* are the layout for two blanks. For three blanks: 1—*A*, 2—*B*, and 5—*E*. For four blanks: 1—*A*, 2—*B*, 5—*E*, and 6—*F*. For five blanks: 1—*A*, 2—*B*, 3—*C*, 5—*E*, and 6—*F*. For six blanks: 1—*A*, 2—*B*, 3—*C*, 5—*E*, 6—*F* and 7—*G*. For seven blanks: 1—*A*, 2—*B*, 3—*C*, 4—*D*, 5—*E*, 6—*F*, and 7—*G*.

The die bed used for holding the die in Fig. 5 in position when in use should have its dovetail channel running in the direction *KL*, while the dovetail channel for the dies shown in Fig. 2 and 4 should run in the direction *FG*. The reason for this is the longer bearing surface for the dovetail obtainable by such arrangement.

It should be remembered that all holes in dies of this kind are lapped or ground to size after hardening; they should be perfectly round and have 1 degree clearance. In some shops the holes are left straight for ¼ inch, and then tapered off 2 degrees.

An important point to bear in mind in making the punch is to have a perfect "line up." It may not be generally known, but it is nevertheless a fact, that blanking tools that blank, or that pierce and blank two or more blanks at one time, will run longer without sharpening, cut cleaner blanks, and, in fact, give all around better results, if the punches are a perfect "line up" with the die than if they are lined up in the so-called "near enough" way.

Perhaps some one will ask, "What is meant by a perfect line up?"

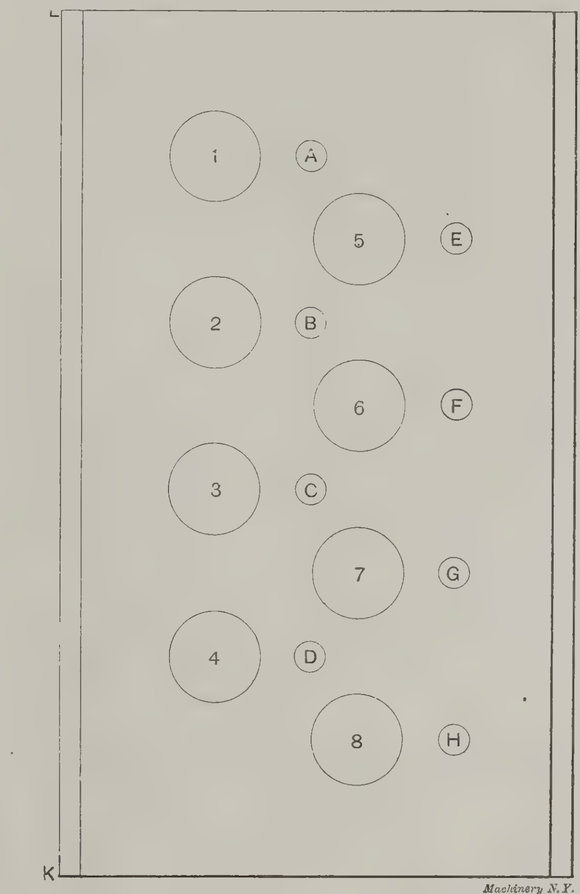

Fig. 5. Plan View of Die for Punching eight Washers.

A perfect line up as referred to in the above is a line up that will allow a punch that consists of two or more punches to enter the die the same as if the punch consisted of just one punch.

The advantage of the perfect line up over the other is that when in use the punches do not come in too close contact with the edge of the die. They enter the die, but do not bear against the edge in such a way as to dull the die, or round over the sharp cutting edge of the punch.

A punch that is almost a perfect line up will enter the die, but it requires more force to make it enter. Why? Because in entering one of the punches for instance, rubs hard against the side of the die, and if set up in the press and allowed to run, that punch, no matter how small, will dull the edges of the die as well as the edge of the punch itself. The result is that the press must stand idle while the tools are being sharpened, and if the real cause of the trouble is not remedied it is "the same old thing" over and over again.

Just a few words in regard to making the punch. In making the punch, the punches must be made so that they will fit the die not too loose, nor too tight. The blanking punches are hardened and ground to size. The taper shank is finished

to size after hardening, so that when the punches are driven into the punch back they will stand straight and not lean to one side.

In laying out the dovetail punch back, first clamp the back central on the face of the die. This is done so that when the punches are driven in position in the punch back, and set central in the ram of the press, ready to be used, no shifting is required in order to make the punch line up with the die, which is keyed in the center of the die bed.

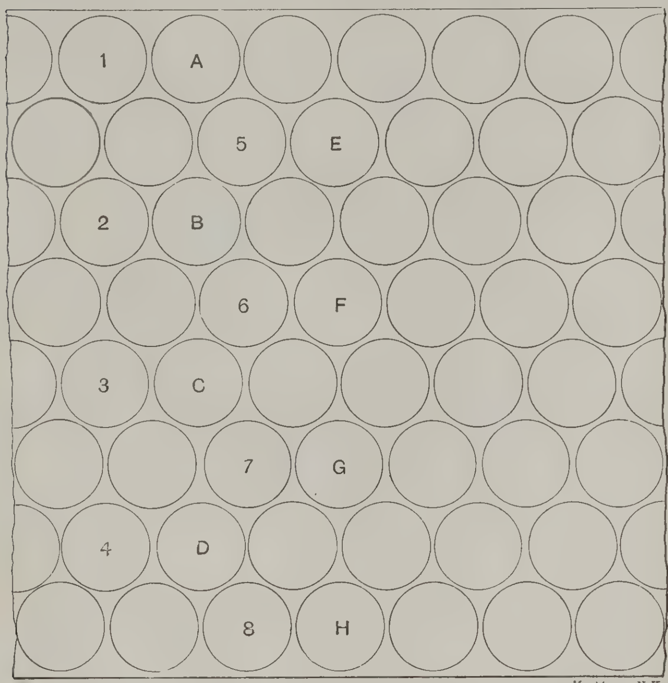

Fig. 6. Stock, after having been run through the Die in Fig. 5.

After clamping the punch back in this position, the blanking part of the die nearest the end is scribed on the face of the punch back. Do not scribe all the holes and rely upon finding the center of each circle thus scribed with a pair of dividers, and then true up these centers on a faceplate in order to get perfect line up; this method increases the chances of error, especially when there are six or eight punches to be set in position. A better way is to scribe one circle as stated

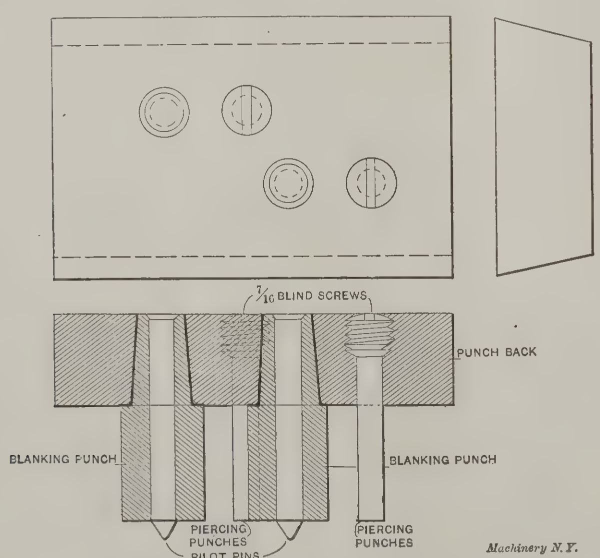

Fig. 7. Punch Back, with Punches Inserted.

above, and remove the punch back from the face of the die; find the center of the circle scribed; true up this center, and drill and bore out the hole to fit the taper shank of the blanking punch.

Fig. 7 shows how a punch of this kind is made. The punch as shown is used with the die shown in Fig. 2. After the hole is bored to size, the already finished blanking punch is driven in tight in the manner shown. Two narrow parallels say ½ × ¾ inch are now laid on the face of the punch back, and the blanking part of the die that corresponds with the punch driven in is slipped over the same, until the face of the blanking die rests upon these parallels, after which the die is clamped tightly thereon. The next hole is now trued up with a test indicator until the hole runs dead true. The die is then removed, and the hole for the taper shank is worked out, and the punch driven in. Where there are more punches to be set in, the same method is used until they are all in position. This insures a perfect line up, providing that ordinary care and precaution has been used in doing the work.

In boring out these holes it is best to use a bolster having a dovetail channel, and to hold the punch back in position with a key.

This is better than using straps to fasten the punch back to the faceplate, as the straps are likely to interfere with the parallels and the die, when locating the exact position for the holes to be bored.

In locating the position for the piercing punches it sometimes happens that the holes are so small that they cannot be bored. The holes are then transferred by a drill that runs true and is the same size as the holes in the piercing die, the die being used, so to speak, as a drill jig.

Fig. 7 shows how the piercing punches are held in position. The punches are made of drill rod, and are prevented from pushing back by hardened blind screws as shown. If thin, soft metal is used, the method for holding the two pilot pins in position shown in the article "Making a Blanking Die," in the June issue, may be employed, or the method shown in Fig. 7.

When the piercing punches are made and held in position as shown in Fig. 7, a spring stripper is sometimes used, and is fastened to the punch back, and the holes for the piercing punches in this stripper are made a sliding fit, in order to prevent the punches from springing or shearing. When the ordinary form of stripper is used, the piercing holes are also made a good sliding fit.

* * *

Spoiled work is probably inevitable in every shop, and it is a considerable problem to handle it in a way that shall be just to the workmen and still protect the interests of the concern. Some men are careless, and if they make a mistake which spoils a piece of work, the incident soon passes out of their minds, and repetitions are common. But it is one thing to make a mistake that spoils a piece of work and another to have it well advertised to the rest of the men in the shop. A conscientious workman earnestly endeavors to avoid spoiling work, and if such a mishap does befall him no one regrets it more than he, and even the most careless, happy-go-lucky chap shares his keen regret to some extent, at least, when the fact is made semi-public in a way that is followed in a certain New York State establishment. Whenever a job is spoiled in this shop it is carefully ticketed with the name of the "spoiler," date, circumstances, cost, etc., and is then prominently exhibited in a so-called "graveyard" for a certain number of weeks, to be there seen and sarcastically commented on by the other workmen. The frantic efforts of these men to avoid this form of "burial" are well worthy of a nobler object, oftentimes, it is said, and it is claimed that salutary effects of the scheme are most marked.

* * *

No improvement in blast furnace practice made in recent years is likely to be of such far-reaching importance as the application of the dry blast, developed by Mr. Gayley. It was discovered that the variations in humidity of the atmosphere were largely responsible for many mysterious troubles in blast furnace practice. The application of the refrigerating principle to the blast so as to reduce the humidity and make it uniform was a long step forward in determining uniform results. A recent example of blast drying apparatus installed is that of the E. & G. Brooks Iron Co., at Birdsboro, Pa. The De La Vergne Machine Co., New York, are putting in refrigerating machinery of 350 tons daily capacity for drying the blast, the air being passed over coils of pipe containing cold brine or ammonia. All excess moisture above a predetermined point is deposited on the pipes, the part remaining being practically constant, so that the humidity of the blast is uniform.

SPRING SCREW THREADING DIES—A CRITICISM.

I was greatly interested in the article in the August number on spring screw threading dies. It struck me as not being written from a practical standpoint, for while most of Mr. Oberg's points are plausibly taken, the difficulties encountered in the use of such dies are somewhat different both in cause and effect from those he enumerates. As one who has had considerable experience in both making and using them, the writer would like to give his views.

In the first place, screw-machine operators who are looking for extreme accuracy in the form of the threads do not use the spring die but prefer the so-called "button" die, which is easy to manufacture and which will give almost faultless results when used on high-grade machines by an experienced man. The chief objection to its use is that it will not stand the abuse which the spring die will and once it is seriously injured cannot be made to do satisfactory work afterward, making the loss on dies heavy when used on rough work or on machines that are abrupt or inaccurate in their movements. A button die would hardly stand up all day threading open-hearth steel with the scale still on, as the writer has seen the other type do.

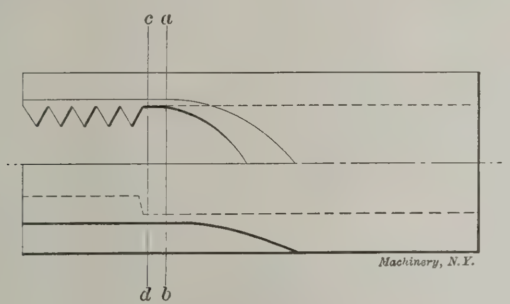

Fig. 1. Spring Screw Threading Die.

Mr. Oberg's method of making the perfect die by taper hobbing from the rear would be all right if we could rely on perfect hardening, but the chances are that when his die came from the hardener it would be no better in lead or form of thread than the die hobbed straight and oversize. If such a die should spring in 0.002 inch say, it would have to be annealed, rehobbed and rehardened with the chance of the same thing happening again, or else lapped out to correct size, which would be a very costly job. A straight die hobbed oversize under the same conditions would still be oversize and could be sprung down. At the same time the error in the form of thread due to springing the prongs down to size need not be over one-third of a thousandth for a 20-pitch thread, an amount which would not be noticed except by an expert gage maker.

Grinding the outside of spring dies is not practicable, and under manufacturing conditions is impossible, as can easily be seen when we take for example a die of ½ inch outside

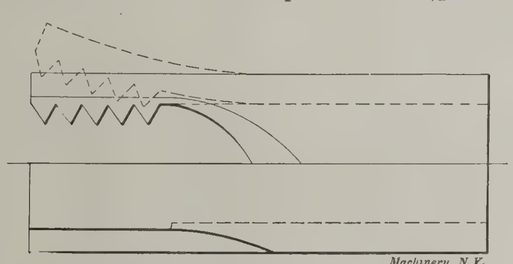

Fig. 2. Effect of Improper Hardening of Spring Screw Threading Dies.

diameter for cutting a 5/32 thread. It would have to be screwed on to a 5/32 threaded arbor with just enough tension to hold it, but not enough to spring the die—a condition which could hardly be met without making the die with lugs on the end of the prongs for a clamp ring, said lugs to be ground off after the die was finished.

The principal troubles encountered in the manufacture of these dies are due to improper handling of the die in hardening and are three in number, as follows: First, imperfect lead, due to unequal lengthening or shortening of the prongs which, with poor steel, is sometimes so bad as to spoil the dies; second, springing out of the prongs in a curve so that when closed down to size the die cuts a taper thread the length of the thread in the die, making it impossible to thread up near a shoulder; third, twisting of the prongs so that when closed down the contact with the piece to be threaded is not on the cutting edge of the teeth, but is back of it, causing a drag which always makes a rough thread and sometimes breaks off the screws.

The first trouble is not much to be feared where good steel is used and the proper temperature is obtained in hardening. The second and third are caused by the way the die is heated and dipped, in connection with the peculiar shape of the back end of the prong where the milling cut leaves off, as shown in Fig. 1. The die should never be heated back of the line *a b* where the curve begins, and need not be hot enough to harden back of line *c d* at the end of the teeth. If this is strictly adhered to the die will come out practically straight, while on the other hand if the die is hardened up into the curve it will always spring badly and even when it is properly dipped, if it is heated too far up, the hardening will run up far enough to cause trouble. Figs. 2 and 3 show the effect of improper hardening.

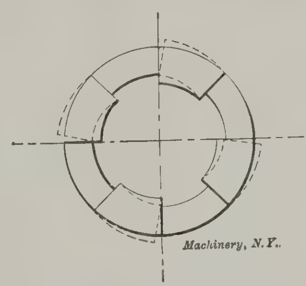

Fig. 3. Effect of Improper Hardening of Spring Screw Threading Dies.

Mr. Oberg's tables are good as far as they go, but it often happens that users of dies wish to use other outside diameters for special reasons. In such cases the following proportions will be found to work well:

The length should be 2½ times the outside diameter, the flute 3/5 of the length, and the finishing hob oversize in the proportion of 0.01 inch for every inch of the outside diameter. The flutes should be cut with a 60-degree mill for a three-fluted, or a 45-degree mill for a four-fluted die, and should be cut clear through, as the tie left by not cutting through is of no value if the die is properly hardened; it is also hard to grind out without drawing the temper. No machinist would try to turn iron or steel in a lathe with a tool

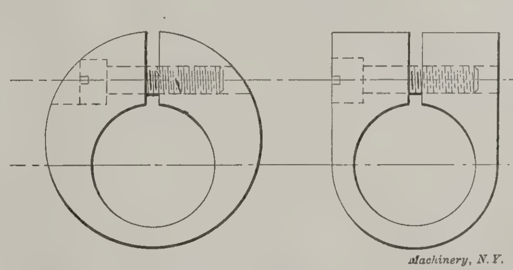

Fig. 4. Clamp Collars for Spring Screw Threading Dies.

having no top rake and, on the same principle, for wrought iron and steel, the cutting edge of the die should *always* be milled ahead of the center in the proportion of 1/64 for every ¼ inch of the diameter of the thread. For rod, brass and other similar material of a low tensile strength, more satisfactory results may be obtained by fluting the dies on the center.

The taper closing ring is a hobby with some operators, but has the objection that when used on automatics the amount of drive necessary to close the die is not sufficient to hold it from throwing the ring off when indexing, and it is nothing uncommon to see it tied back with a piece of string, cramping the die out of shape. In Fig. 4 are shown two forms of clamp collars which work well and which are superior to the one most commonly used.

First class office buildings in lower New York cost about 40 cents per cubic foot and rent for $1 to $1.20 per square foot yearly.

A POWERFUL HOMEMADE SLOTTER.

Several years ago McIntosh, Seymour & Co., Auburn, N. Y., felt the need for a vertical planer or slotter of large capacity to be used on the large vertical and horizontal engine work which they are engaged in. Not finding the kind of tool on the market that they required they resolved to build it, and the result is a very creditable home-made tool containing a number of interesting features. The machine has fulfilled all expectations and is a powerful tool in action. It is particularly well adapted to facing off the ends of vertical engine frames or columns, the floor plate in front having ample capacity for the largest sizes yet built by the company, and this means 7,500 H. P. The general appearance of the tool is shown in Figs. 1 and 3, Fig. 1 showing it at work on the flanges of a large vertical engine cylinder. The line drawings, Figs. 2, 4 and 5, together with the following dimensions will give a fair idea of the design and construction.

The cross-rail carrying the two tool saddles is operated by a screw 4½ inches diameter, ½ inch pitch, triple thread, giving 1½ inch lead. The nominal stroke is 10 feet and the length of the cross-rail is 10 feet 1 inch. The feed of either head or saddle on the cross-rail is 7 feet, and each head has independent cross power feed. The screw nut is 16 inches long and is made of babbitt in halves. These halves are forced into a cast-iron sleeve and keyed in place. This construction has always worked very satisfactorily, giving no trouble whatever.

The screw thrust is taken on a double roller thrust bearing. The rolls are cylindrical instead of conical shape, which would be called for to make them theoretically correct, but they have never given any trouble although the speed of the screw on the reverse runs up to 450 revolutions per minute. The bearing is designed for a tool thrust of 20,000 pounds, and the actual thrust of the screw due to the inertia of the moving parts at the beginning of every reverse stroke amounts to more than 25,000 pounds. The vertical movement of the cross-rail is reversed by tappets similar to an ordinary planer, these being arranged to actuate the belt shifter by means of which the actuating screw is reversed. These tappets are counterbalanced and their position can be altered quickly by means of two cranks at the floor and geared to

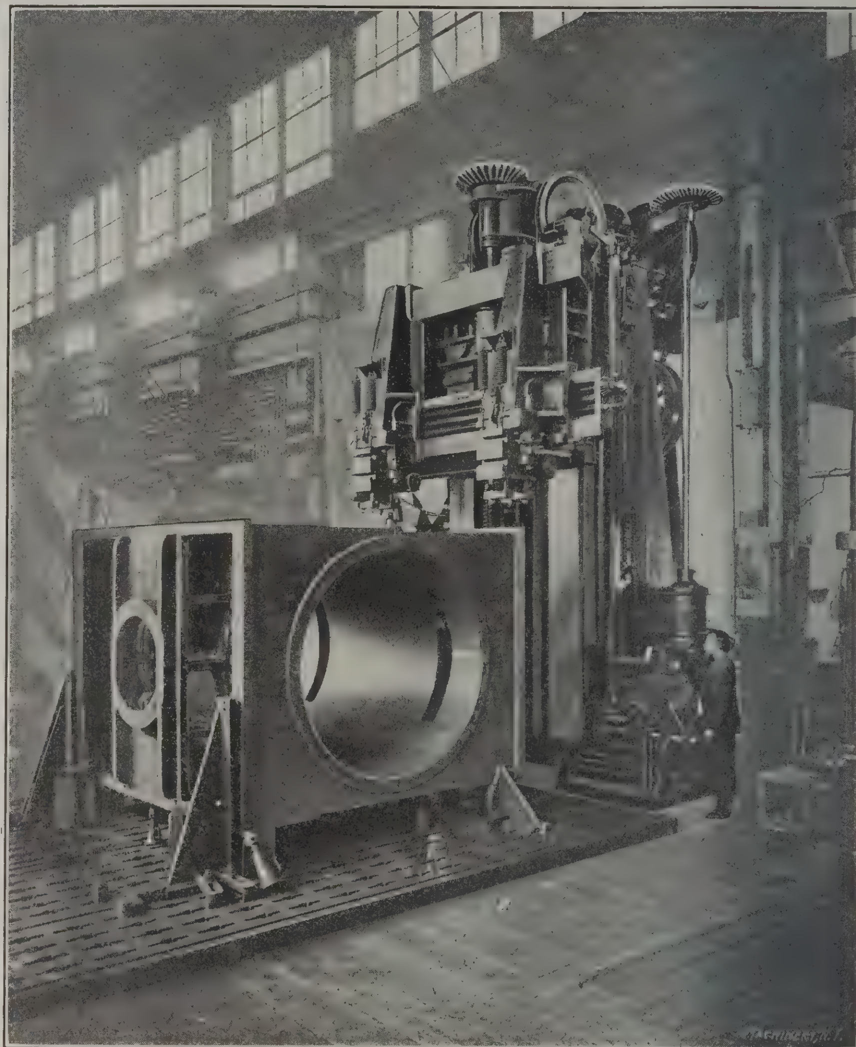

Fig. 1. Slotter at Work on Cylinder Casting.

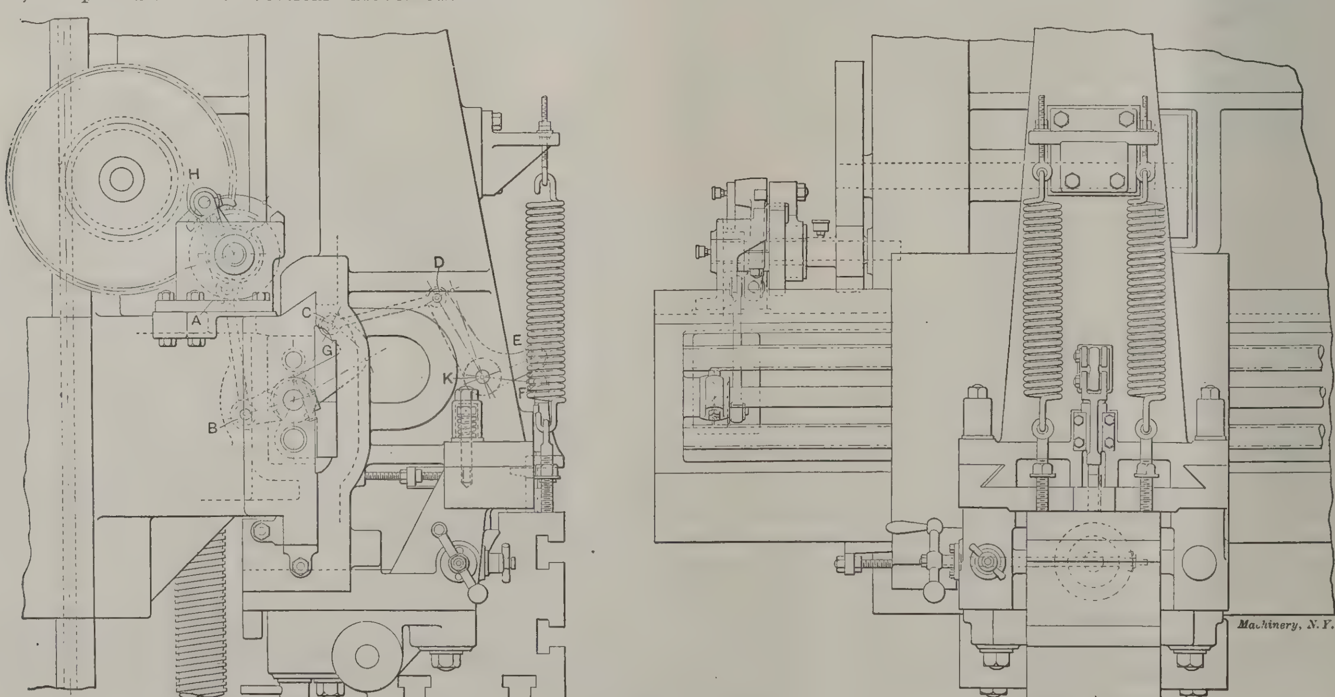

Fig. 2. Saddle of Slotter.

the tappet shifting screws so that a quick and convenient adjustment of both ends of the stroke can be made while the machine is running. This tappet shifting mechanism will be noticed in the side view of Fig. 5. The carriage carrying the cross-rail is counterbalanced. The counterbalance weighs 23,000 pounds and is situated inside the column, being carried by wire ropes running over sheaves. It was found that the inertia of the counterbalance at reversing amounted to more than its weight and it was necessary to increase the number of ropes carrying the counterbalance sufficiently to allow for this in order to secure freedom from breaking the ropes.

The column has a forward and backward feed of about four feet and in addition to the regular power feed it has a rapid power feed for bringing the machine up to the work, this feed carrying with the column all the operating mechanism, including the motor. The column feed and both saddle cross feeds can be operated from either side of the machine by hand, using stationary ratchet levers at the floor. The saddle feeds can also be operated by hand ratchets situated on the cross-rail near the work. In addition to these feeds a short movement of about 4 inches is provided in the tool-heads for advancing the tools to the work. The details of this are included in the view of the saddle, Fig. 2. Fig. 2 shows a relief gear for clearing the tool on the return stroke which does not now appear in the machine for the reason that it was discarded after being built, it having been broken by feeding the saddle too far out on the cross-rail and considerable change of design being necessary to avoid recurrence of the accident.

The machine is driven by a 25 H. P. General Electric motor arranged so that speeds can be ranged from 550 to 750 revolutions per minute, these speeds giving a cutting speed of from 12 to 20 feet with a return speed geared 3 to 1. The machine will work with cuts from 1¼ to 1¾ inch on both tools with feeds up to ¼ inch without showing any weakness or trembling; feeds over 1-10 inch are not desirable, however, on account of the tendency of the tool to break out the casting at the end cut. Its weight is 222,000 pounds.

* * *

CASEHARDENING WROUGHT IRON.*

Wrought iron is nearly pure decarbonized iron and is not possessed of the property of hardening. Articles made from wrought iron may be externally converted into steel without depriving the interior of its natural character of structure. The process is called "casehardening."

The object of casehardening is to obtain an external steel encasement with a core of fibrous iron in the center. The effect is produced in a perfectly air-tight box with animal carbonizing matter. The box should be made of plate or cast iron from ½ to 1 inch thick, the size and thickness of the box depending on the articles to be operated upon. The articles are put in the box in alternate layers with the carbonizing ingredients, commencing at the bottom of the box say with a layer of granulated bone 1 inch thick; upon this a layer of the articles is placed, then another layer of bone about ¾ inch in thickness, and so on until the box is nearly filled, finishing with a layer of bone on top of the articles, which should be 1 inch deep so as to well protect the first or top layer of articles and prevent blistering. The packing completed, the lid is put on and hermetically sealed or luted with loam or fire-clay.

The box or boxes are now placed in a suitable furnace. The furnace should give a uniform heat of about 1350 degrees F. Overheating is injurious, and will crystallize or make the articles brittle. In heating wrought iron for casehardening there are several considerations, the principle ones being heat and duration of time for carbonization, same being governed by the size or bulk of the work to be casehardened.

Heating in point of importance stands first, for if the primary cause of bad casehardening could be traced, its origin in a majority of cases would be found in bad heating. There is no operation connected with casehardening which requires more watchfulness and gives more anxiety than proper heating. It may therefore repay us to examine with care the conditions to be observed in obtaining results. The heat must be constant and uniform and should never exceed 1350 degrees F., for the degree of heat will have a bearing on the fibrous structure of the material. A high and excessive heat will render the material brittle and if the article is light in structure it is apt to break easily in service; therefore, it behooves us not to overheat or unevenly heat articles to be casehardened. Consequently keep the furnace at a regular or constant temperature, for if the articles to be casehardened are overheated the damage is done in so far as a fibrous structure is concerned; the article is hard but the interior is brittle and crystalline when it should be fibrous and showing a dark or black appearance of its natural structure with a fine grained surface analogous to tool steel.

Where I am employed we do a great deal of casehardening, all of which is done under my supervision and direction. We caseharden as high as five tons of wrought material in 24

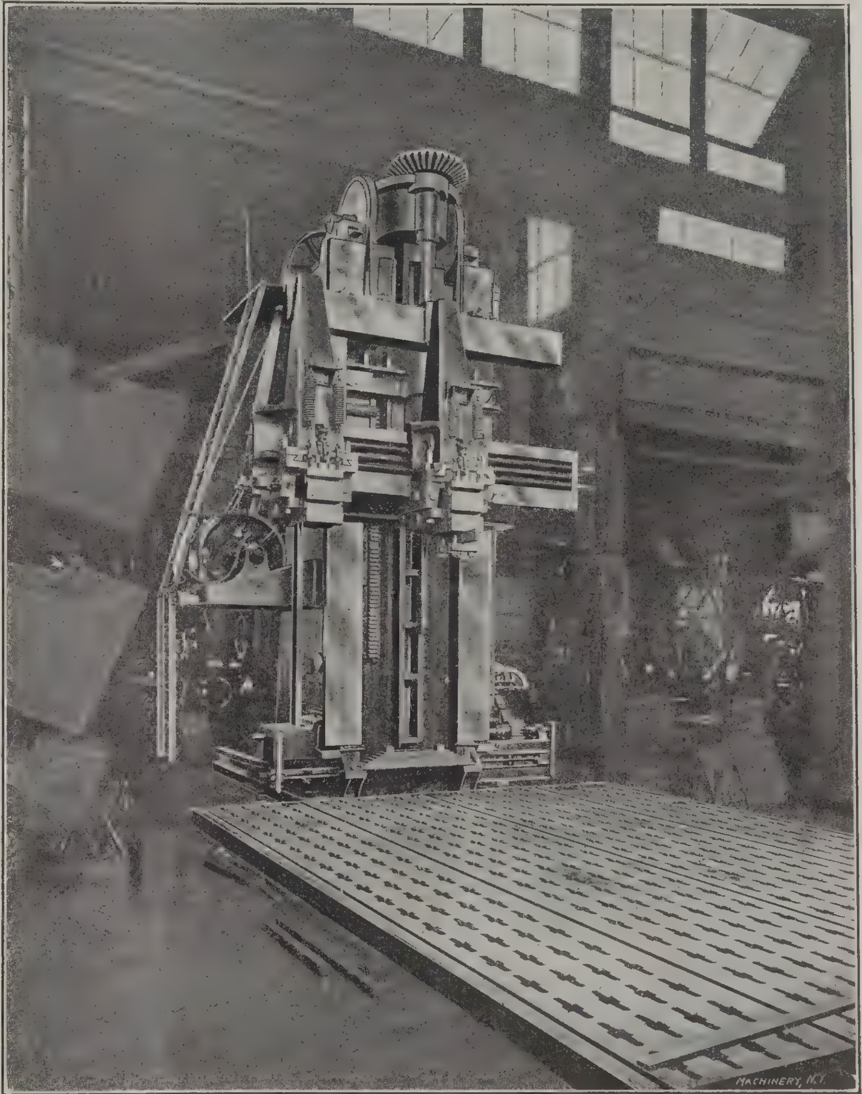

Fig. 3. General View of Slotter and Floor Plate.

* Abstract from a paper read by Mr. George F. Hinkens before the International Railroad Blacksmiths' Association Convention, Chicago, Ill., August 21-23, 1906.

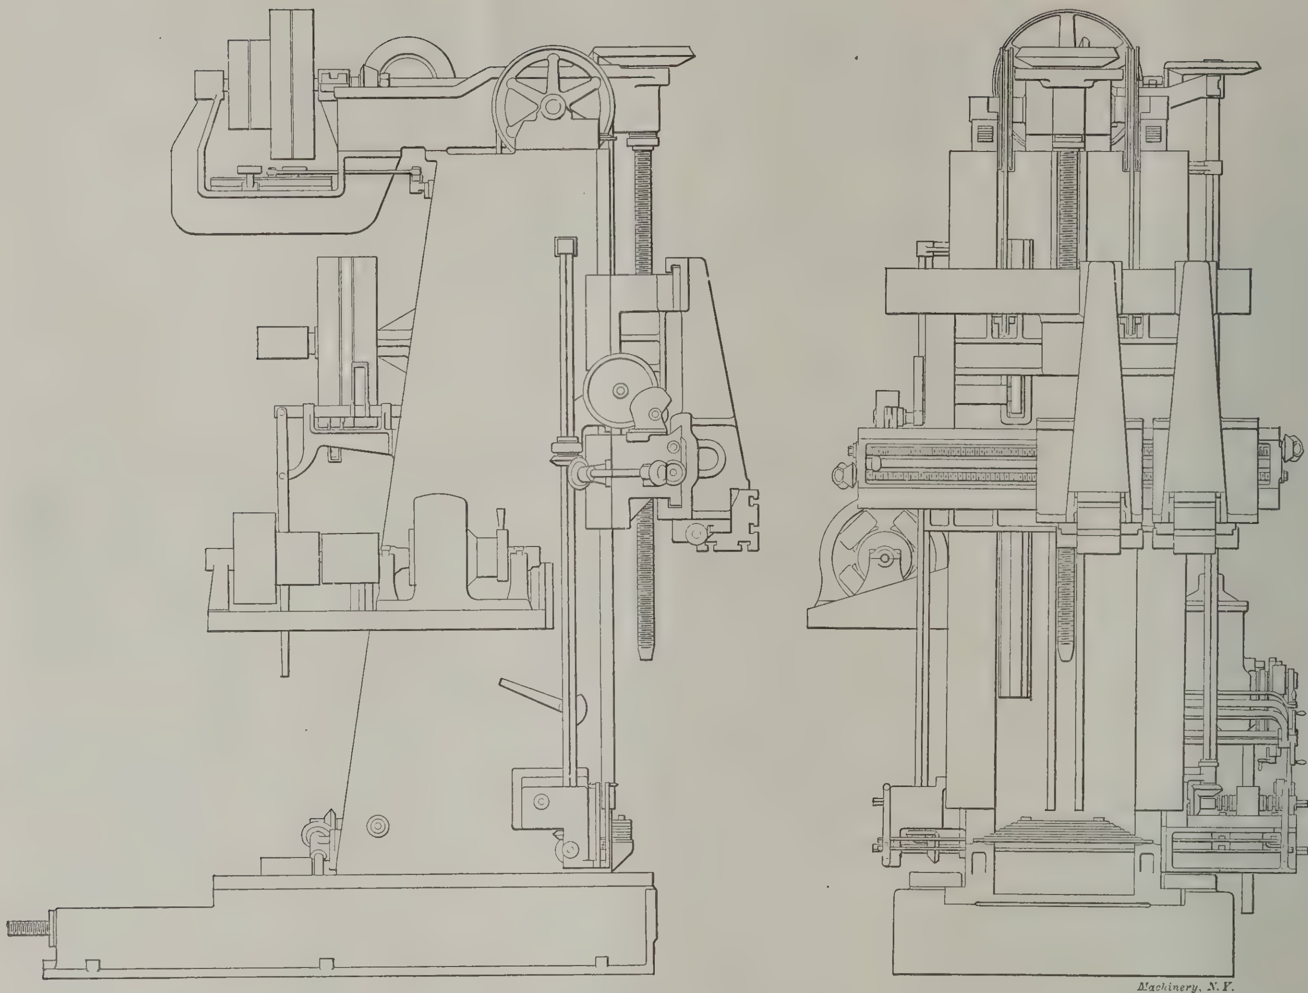

Fig. 4. Front and Side View of Slotter.

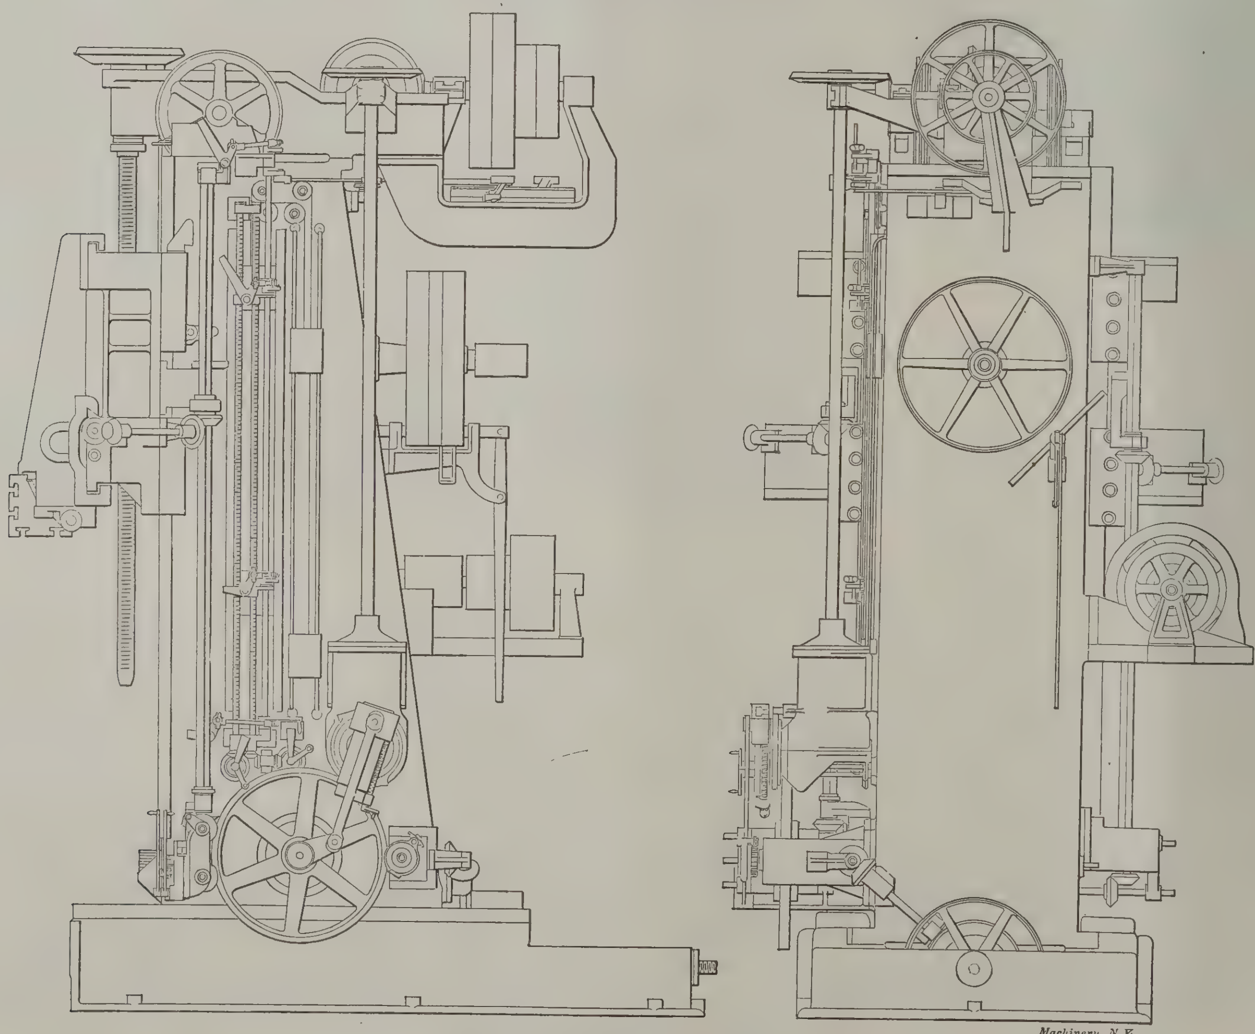

Fig. 5. Side and Rear View of Slotter.

hours, same requiring ten furnaces. We are exceedingly particular about the heat treatment, as much so as we are in the heat treatment of tool steel when tempering.

The furnace is an important factor. An oil or gas furnace to work successfully should be so constructed as to secure proper mixture of gases, a thorough and even combustion in every part of the furnace. The furnace should be constructed with roof arched throughout its entire length in order that the heat may be reflected directly and uniformly upon the boxes. The passage to the chimney is formed underneath the hearth, causing a down draft, the action being to throw the heat down upon the boxes. There are six flues, separated from each other at the end farthest from the fire place. These flues run parallel toward the fireplace or cumbustion chamber where they are connected downward with the main flue under ground, thence into the chimney.

It will be seen that this arrangement of furnace insures as nearly as possible an even heat throughout every square inch of heating parts of furnace. The furnace thus described can be heated with either oil or gas and has a capacity of eight boxes 12 inches wide, 20 inches long, and 8 inches high. The size of the box is of course governed by the size of the articles to be casehardened.

A quick method for casehardening consists in heating the material to be hardened to a red heat and submerging in a bath of molten cyanide of potash or potassium, leaving it in from one to five hours, according to bulk of material to be hardened. Cyanide of potassium gives off poisonous fumes, consequently the vessel containing it should be placed in a furnace with a draft. This method is dangerous for the operators and should, if used at all, be used in a very careful manner.

AN EXPOSITION OF SAFETY DEVICES.

The American Institute of Social Service will hold in New York City, in January next, an exposition of devices for safeguarding the lives and limbs of working men and women, and for preventing accidents under the ordinary conditions of life and labor to which the general public is exposed. This will be the first Exposition of the kind in this country, and it is surprising to note how far behind other nations we are in this respect. As far back as 1889 there was a German exposition for the prevention of accidents. In 1893 an exposition of this nature was held in Amsterdam, and since then there have been several similar expositions in continental Europe and in Canada. As an outgrowth of these national movements there have been organized several Museums of Security; one at Vienna in 1890, one at Amsterdam in 1893, one at Munich in 1900, one at Berlin in 1901, and one at Paris in 1905, and Russia, which we are inclined to look upon as semi-barbarous, has recently established a museum on a large scale in Moscow.

That these expositions and museums have been of real value to their respective countries is evinced by a comparative study of the number of accidents in Europe and in America, which shows that for the same number of men employed in a given trade, we have from two to nine times as many accidents as they have in European countries. It is estimated that the casualties of our industrial army in the United States are at least fifty per cent greater every year than the total number of killed and wounded during the late Russo-Japanese war. Such conditions can exist only through general ignorance of their reality, and it is for the purpose of educating the public to an appreciation of the actual situation and the means of its improvement that the Exposition of Safety Devices is to be held.

The interest of manufacturers generally is solicited, as well as that of organizations whose special function is to improve the conditions of labor, and a widespread response is looked for to this request for representation in the nature of photographs, descriptive drawings, models, and as far as possible, the devices themselves in actual operation. Following are some of the groups of exhibits:

Section 1.—Models, photographs and drawings of scaffolding, as well as the personal equipment of workers in building trades. 2. Protective devices for boilers, water gages, signal apparatus, boiler and pipe valves; also protective devices for electrical machinery and acetylene apparatus. 3. Protective devices for motors and power transmitters, devices for turning on power and shutting it off, belt connection, couplings, etc. 4. Fire protection and the prevention of explosions. 5. First aid to the injured. 6. Mining and quarrying; devices in use on stone crushing machinery, etc. Storing of explosives. 7. Metal industry; safety devices for metal-working machinery. 8. Textile industry: safety devices for looms, carding, etc. 9. Leather and paper industry: safety devices for paper cutting, stamping and moulding machinery. 10. Safety appliances for elevators and hoisting apparatus models. 11. Food products: safety appliances for kneading machines, rollers and cutters. 12. Personal equipment of workingmen: protective spectacles, respirators, suits, etc. 13. Workingmen's dwellings. 14 and 15. Housing: models, plans, photographs. 16. Ventilation. 17. Models, photographs and plans of toilets, dressing and living rooms, baths, etc. 18. Cooking: demonstration in heating food; models, plans, photographs. 19. Other social betterment institutions; reports of labor departments, industrial arbitration courts. 20. Agricultural machinery; safety appliances on same, demonstrated by models and views. 21. Lumber industry: safety devices for band and circular saws, planing machinery, etc., demonstrated by models. 22. Models, photographs and plans of workingmen's industrial betterment institutions of all kinds.

Requests for information regarding space should be made to Dr. William H. Tolman, Director, 287 Fourth Avenue, New York.

* * *

The remarkable extent to which the use of electricity for power purposes has been developed in the industrial plants of the country will be nowhere better exemplified than in the proposed electrical equipment of the new Gary, Indiana, plant, plans for the building of which were recently announced by the United States Steel Corporation. When completed, it is estimated that the plant will handle substantially 5,000,000 tons of ore a year, and produce annually approximately 2,500,000 tons of steel. There will be sixteen blast furnaces, of 450 tons daily capacity each, and eighty-four 60-ton basic open-hearth furnaces. The necessary electrical generating equipment capable of handling such an output is to have an initial capacity of 18,000 K.W., and will be so designed that extensions may be added indefinitely at one or both ends. The initial equipment will have a capacity of 18,000 K.W., 14,000 K.W. being in 2,000-K.W., 25-cycle, 2,300-volt units, and 4,000 K.W. in 2,000-K.W., 250-volt direct-current units. These generators will be built by the Allis-Chalmers Company, Milwaukee, and they will be direct coupled to nine Allis-Chalmers horizontal twin tandem gas engines. The power house building for the present is to be approximately 700 feet long with a span in the main building of 88 feet. An 18-foot extension under the same roof through the entire length of the structure, has been planned in order to provide the necessary room for high-tension switches. The power house will be located immediately adjacent to the blast furnace blowing engine houses, and between the blast furnaces and the open-hearth furnaces, most advantageously placed for fuel supply and for securing a minimum length of transmission lines to the various departments using electric power.

* * *

New York City, already noted for its skyscrapers, is to have another which will overtop them all and be the highest structure in America. It is the Singer Building at the corner of Liberty St. and Broadway. This building will consist of a fourteen-story building, and a tower 65 feet square and 612 feet high, containing forty-one floors, twenty-seven being above the level of the main structure. The total floor space of the building will be about 9½ acres and it is estimated that when fully occupied it will accommodate about 6,000 people. The height of the tower will be 57 feet greater than that of the Washington Monument and will be not far from two times the height of the main part of the Park Row Building, now the highest office building in the world.

RAILWAY MACHINERY

A SPECIAL EDITION OF MACHINERY FOR THE RAILWAY SHOP, DEVOTED TO LOCOMOTIVE AND CAR EQUIPMENT AND MECHANICS.

Published monthly by

THE INDUSTRIAL PRESS,

66-70 WEST BROADWAY, NEW YORK CITY.

DOMESTIC SUBSCRIPTIONS, $2.00 A YEAR. FOREIGN, $3.00 A YEAR. SINGLE COPIES, TWENTY CENTS.

The receipt of a subscription is acknowledged by sending the current issue. Remittances should be made to THE INDUSTRIAL PRESS, and not to the Editors. Money enclosed in letters is at the risk of the sender. Changes of address must reach us by the 15th to take effect on the following month; give old address as well as new. Domestic trade is supplied by the American News Company or its branches.

We solicit communications from practical men on subjects pertaining to railway machine shop practice, for which the necessary illustrations will be made at our expense. All copy must reach us by the 5th of the month preceding publication.

OCTOBER, 1906.

REDUCED COST OF TRANSPORTATION.

One of the encouraging features of the transportation business at the present time is the reduction in passenger rates by such railroads as the Pennsylvania, New York Central, Boston & Maine, and others. This has taken the form in most cases of mileage, 1,000 mileage book being sold at $20. We believe that the policy of cheaper passenger rates is one that will redound to the benefit of all concerned. The more people travel, the more business there will be done, and this means more freight to haul. Many roads are now running passenger trains which for the greater part of the year consist of cars containing but few passengers, and it costs practically as much to haul an empty train of cars as one fully loaded. The policy of reduced fares should tend to make the volume of transportation greater in the slack months. The use of mileage books good for an entire railroad system is a great convenience to the traveling public and should save a railroad company considerable expense in handling waiting crowds where a large number of tickets are usually sold. By all means let us have cheaper passenger rates and the general abolition of all forms of free transportation which might in any way be used as "graft."

* * *

TUNNELING THE HUDSON.

The north tube of the Pennsylvania Railroad twin tunnels under the North River had reached a stage that permitted a party of officials to make an inspection trip from Weehawken to New York, September 12. The headings of the south tube were joined a few days later. The work of boring the tunnels under the North River has progressed rapidly, the actual tunneling work for the first bore being completed about one year ahead of time. Work on both bores was started simultaneously on the Weehawken and New York sides, and the two headings of the north tube met in the river bed almost perfectly, it is claimed. When they were 125 feet apart work was stopped and exploring pipes were driven through the intervening mud so that the alignment, which depended solely upon external measurements, of course, could be corrected. It is alleged that so accurately had the measurements been taken and followed that the alignment was out only about 1/8 inch and the grade about 3/4 inch. Work was then resumed with the necessary correction, so that when the two tubes met the lack of alignment was only about 1-16 inch. The building of these two tubes under the North River is perhaps one of the greatest of engineering feats. It was thought some years ago that tunnels in soft mud such as is characteristic of the North River bed were practically impossible, but the improved methods devised within the past few years have solved the North River difficulties much more easily than was anticipated. The joining of Manhattan to the mainland by railroad tunnels is an accomplishment well worth the great cost, and it means much for improved transportation.

* * *

PROMPT FREIGHT DELIVERIES.

In all the agitation concerning railway rates, rebates, etc., little has been said about one feature of railroad transportation which is fully as important as any question of rates, and that is prompt freight deliveries. It is a lamentable fact that most freight shipments on our American railroads require altogether too long a time, and the worst of it is that the period is of uncertain length. Occasionally a consignee is surprised to receive a freight shipment in about half the usual time, but more frequently he is disappointed by having the time drag out days or even weeks beyond the usual time allowance. The August 15 issue of *American Industries* contains a scathing arraignment of the railroad freight deliveries by Messrs. Giles and Donnan. It is accompanied by tables showing the actual elapsed time required on shipments from Richmond, Va., to various points in the South during 1906. To make a long story short it appears that a freight shipment on the average covered only about 61.61 miles in twenty-four hours, or at the almost incredibly slow rate of 2.57 miles per hour. Compared with this rate of progress, canal packets drawn by horses are swift, the average distance being 144 miles in twenty-four hours, or 6 miles per hour. Of what use are powerful locomotives, improved shops, heavy bridges, stone ballast, etc., if the average time for hauling freight falls below that possible with a horse-drawn vehicle?

* * *

AN "OLD-FASHIONED" CONCERN.

An interesting pamphlet has been received from the Baldwin Locomotive Works containing an account of the ceremonies at the unveiling of the statue of Matthias W. Baldwin, April 17, 1906. This statue stands facing the office building of the works at the intersection of Broad and Spring Garden Streets, Philadelphia, and carries an appropriate inscription. The fame of the Baldwin Locomotive Works extends to the uttermost corners of the earth and it is doubtless, in many respects, one of the most remarkable manufacturing enterprises in this country. Occupying a restricted area in the heart of Philadelphia it employs from 15,000 to 20,000 men and annually turns out more than 2,000 locomotives. A fact of the utmost significance is that upwards of fifty persons now employed in the works date their employment as apprentices back to Mr. Baldwin's time, and he died 40 years ago. It is gratifying in these days to be able to record that a large concern like this has pursued such a liberal policy with its employees. Some of the men who started with it in a humble way are to-day important officers in its management and have accumulated fortunes. It seems to be one of the few concerns in which the leading workers have reaped largely of the benefits of their work, being in a limited sense co-operative in its management.

* * *

GERMAN AIR-BRAKE TESTS.

Experiments made by the governmental railroads of Bavaria indicate the superiority of the new Westinghouse air brake over air brakes previously in use. The experimental train was composed of a locomotive with tender (118 tons) and four cars weighing 36.5 tons each. The results were noted at different speeds, and where the road was not level the result was transformed so as to give the figures for level road. The new Westinghouse air brake brought the train to a full stop in 31.5 seconds when running at a speed of 75 miles an hour, while the common air brake required 41.5 seconds under the same conditions and with the same air pressure. When running at the more moderate speed of 45 miles an hour, the figures were 15.5 and 20.5 seconds respectively. The *Zeitschrift des Vereines Deutscher Ingenieure*, where these results were published at length, adds that the experiments gave great satisfaction and that the new air break works nearly without jars or objectionable vibrations.

GERMAN MACHINE TOOL COMPETITION.

The enormous increase of German machine tool manufacture should not be underestimated by American machine tool builders. The fact that the Germans do not appear as actual competitors in this country on account of our protective tariff does not exclude the inference that they will be, and already are, the most resourceful of all our competitors in the foreign market. The export of German machine tools in 1905 was more than three times as great as in 1900. The import of American machine tools to Germany had during the same period decreased so that in 1904 the import was less than half, and in 1905 about 30 per cent less than the import in 1900. The decreased imports are so much more significant when considering that the German tariff on machine tools is very low, amounting to only five, or at most ten per cent *ad valorem.*

At a recent meeting of German machine tool builders in Dusseldorf the confidence in their increased prestige was plainly in evidence. While recognizing that only a few years back there existed an "American Danger" to the German machine tool industry, it was agreed upon that this danger was now a thing of the past, provided that the German manufacturers continued to follow the path outlined by their successful American competitors.

While there is no doubt but what American machine tool builders will manage to remain in the lead, it may be well to point out the progress made in Germany. There is one distinctive feature about all German machine tools which cannot be overlooked. They all prove that there was a definite knowledge of mechanical principles involved in their design. The ingenuity with which some problems have been solved is surprising, and the only serious objection to a great majority of German makes of machine tools is the lack of recognition of the requirements of the operator. Some, indeed, require far more skill to operate than can be expected of an ordinary machine hand, while others are often to the highest degree "unhandy" to run. To remove these obstacles will probably be the next move of our German brethren, and then their competition may be so keenly felt that we will commence to discard the "cheap labor" which has of late been complained of as taking possession of our drafting rooms, and once more return to the maxim that practical experience without knowledge of mechanical principles is equally inefficient as is theoretical knowledge void of practical common sense.

* * *

WILL THE AUTOMOBILE FOLLOW THE BICYCLE?

The rise and decline of the bicycle was a phenomenon well within the memory of most readers. The building of bicycles and tricycles began in England and the first machines imported into this country attracted much attention. The writer remembers one aged townsman who bought an English tricycle at a cost of $250. Its advent in the town (about twenty-five years ago) was a nine-days' wonder and it was considered of sufficient interest and novelty to warrant giving it a place of honor in the principal exhibition hall of the county fair. The owner had the right of way on the sidewalk of the town, where he could often be seen gravely propelling himself on sunny afternoons, kindling envy in the hearts of small and large boys alike. He had a wide plank walk laid at considerable expense around his large garden, where in dignified retirement he could take exercise runs without the annoyance of being so much on public exhibition. Within a few years after, bicycles were owned by thousands, and every city, town and hamlet had its quota. Century runs were the thing and holidays and Sundays were given up to bicycle riding by a large part of the population. To-day it might almost be said that the bicycle is again something of a curiosity. In many towns it is rarely seen on the streets and is mostly used by messenger boys and others in business. In short, its use for pleasure has been very largely abandoned.

The automobile has, in a sense, displaced the bicycle, and in view of the experience of the bicycle many are asking themselves if the same waxing and waning of popularity will not be its fate. It seems somewhat improbable that as a vehicle for mere pleasure it can long continue to have the great vogue that it now enjoys. The first cost of the higher powered machines and the succeeding expenses put them out of the reach of most men; many who are now enjoying an automobile have discounted the future in order to do so. The memory of the bicycle century runs is recalled on seeing an automobilist tearing through the country at railroad speed, going nowhere in particular and seeing nothing as he goes. This is to say the least unprofitable, and anything which yields no profit and little pleasure is bound to be ephemeral in its popularity. We have always believed that the larger use of the automobile is, or should be, as a commercial vehicle for handling goods that are now largely drawn on trucks, and for the general sober business of the day. Unless it can make good for such purposes we may see the automobile become one of the "has beens" in comparatively few years.

* * *

THE FLAT ON THE TOP OF SHARP V-THREADS.

While theoretically the sharp V-thread is not flatted on the top of the thread, it has, on account of practical reasons, become necessary to provide this kind of thread with a slightly flatted portion. In the first place, it is very difficult to produce a perfectly sharp edge on the top of the thread, and, in the case of a tap, the sharp edge would be very likely to be impaired in hardening, leaving the top of the thread less perfect than if provided with a slight, uniform flat. In the second place, the sharp edge would wear away very rapidly, both in the case of a tap and a screw, and as the wear could not be expected to be uniform, the ultimate result would be far less desirable than the one obtained by slightly flatting the top of the thread from the beginning.

For the reasons mentioned it has always been the practice of tap manufacturers to provide the top of the thread on V-thread taps with a slight flat. But as a standard outside diameter always had to be maintained, the diameter in the angle of the thread had to be increased. This has caused difficulties, inasmuch as there has been no established standard as to *how much* of a flat the thread ought to be provided with, and various manufacturers have each had their own practice in this particular. The result has been that the gages from one firm have not corresponded to the taps manufactured by another, and many customers, not familiar with the reasons for this confusion, have questioned the correct size of gages as well as taps. The question has been still more confusing on account of the fact that many manufacturers did not have even a certain standard for all taps manufactured by them, but working to their old-established gages, they often produced large taps with smaller flats on the top of the thread, proportionally, than the flats on smaller taps.

In order to overcome the difficulties arising from the facts mentioned, we understand that the tap manufacturers are endeavoring to establish a standard flat for the top of sharp V-threads. While, as far as we know, nothing has been definitely agreed upon as yet, there seem to be opinions favoring a flat equal to one-fifteenth of the pitch. This is a greater flat than has hitherto been employed by some leading tap makers. Some have used the same flat for the V-thread as is used for the Brigg's standard pipe tap thread, which, although theoretically rounded at top and bottom, is, in this country at least, made with a small flat on the top of the thread. The width of this flat is selected so as to give exactly the same angle diameter as is obtained when rounding the top of the thread in accordance with Brigg's original proposition. This flat is equal to about one-twenty-fifth of the pitch.

While the exact width of the flat is of minor importance, it will save much confusion, as well to manufacturers as to customers, if a standard is agreed upon, and the country is to be congratulated upon the fact that there is a strong movement toward adopting standards in all the different fields of industrial activity.

* * *

The report of the United States Geological Survey gives the production of Portland cement for the year 1905 as 35,246,812 barrels, having a value of $33,245,867. This represents an increase of nearly 25 per cent over the output of 1904.

ENGINEERING REVIEW.

CURRENT EVENTS, TECHNICAL AND MECHANICAL—LEADING ARTICLES OF THE MONTH.

The extent to which industrial education is carried in Germany is most easily comprehended when we hear that the number of students at the ten higher institutions for technical education was 15,800 during the winter term of 1905-1906. As there is a still greater number of smaller colleges and trade schools, all of which are attended by large bodies of students, it is no wonder that at present men of good technical education have to accept very inferior positions as far as salary concerns; but the excellent system of technical and industrial education in vogue in Germany has undoubtedly been the most active cause in the present progress of the industries of that country.

Regarding the sale of machine tools in China, Consul-General William Martin, of Hankow, China, says that it is a waste of money to send catalogues to China in English, and, in fact, intimates that the use there of catalogues in any language is a waste of time and money. The Chinese will not buy that way; their purchases must be made from the man on the ground who has the goods to show. They are very suspicious and take nothing on faith. The Germans now have many men laying foundations in China for future trade, and the Japanese as well as the British are very active. The consul believes that China will eventually be a great field for the sale of foreign tools and manufactured goods of all kinds.

A writer in a textbook on standard metals for manual training schools says: "Copper is seldom used in the form of a casting for the reason that it has no special merit in any heavy form, but when combined with other metals its greater merit is apparent." This statement is not altogether exact. One very potent reason why copper is seldom used in the form of a casting is the difficulty of making pure copper castings free from blowholes. Molten copper has such an affinity for oxygen that its exposure to the air even during the short period of pouring into a mold is sufficient oftentimes to make the castings porous, and unless the molder is unusually expert, the chances are that his efforts to produce sound copper castings will be without avail.

According to *The Canadian Engineer*, the two electric locomotives which have been used to haul the trains through the Simplon tunnel have proved inadequate for the work. Each of these engines had two motors of 450 horse power, which could be urged up to 550 horse power. As to the cause for the failure of the engines there are two theories. One is that the engines, having a section of two-thirds of the sectional area of the tunnel itself, acted as pistons in a cylinder, and wasted a large portion of their power in compressing the air in front of them. Another theory is that the air, saturated with the moisture from hot springs which keep the tunnel walls at a temperature of 93 degrees, penetrated the insulation of the motors and caused an important leakage of the current.

We have received a reprint of an article, "The Submarine vs. The Submersible," by Mr. Simon Lake, published in the *Journal of the American Society of Naval Engineers*, May, 1906. This paper treates in an interesting manner of the relative stability of the submarine and submersible boats that have been built for naval purposes. It points out the weakness of the submarine type which depends upon angular change of the horizontal axis in order to rise or descend. Comparison with the submersible or Lake type is, of course, favorable to the latter, the reasons given being well worth reading. In fact the whole article is well worth reading by any one interested in the subject from a military standpoint, or for a study of the actions of bodies immersed in a liquid and dependent upon tnat liquid as a resisting medium for all movements.

The German government, always ready for experiments, has undertaken to ascertain the comparative value of a typewritten copy for legal documents as compared with a handwritten one. The object of the experiment was to find whether a typewritten document would stand the test of time equally well with one written with the best writing ink. It was found that a decided difference could be noticed according to what class of ribbons were used for the typewriter, but it was ascertained beyond doubt that by using the best ribbon obtainable a copy could be produced which would have the same lasting qualities as a handwritten one. It is of interest to note that while some German ribbons proved satisfactory, the American-made product proved to be of a higher quality in general. But we may be assured that the Germans will not rest from now on until their typewriter ribbons are prepared equally well with ours.

One of the most progressive of the independent principalities of Asia is the little kingdom of Siam on the Indo-Chinese Peninsula. In the principal city, Bankok, is a modern electric railway power plant, operated by the Siam Electricity Company, and equipped with reciprocating engines and generators. Because of the increased demand for power an additional unit has become necessary and a Curtis steam turbine has been ordered. This is a 500-kilowatt, 575-volt machine, built by the General Electric Company, Schenectady, N. Y. The boiler plant for this station is unique in that paddy husks are burned in place of coal. The fuel is brought down the river from the rice fields in flat-bottomed boats to the power house and unloaded directly into the boiler room by an elevator and belt conveyor, built by the Link Belt Company, Philadelphia, Pa., and operated by several direct-current motors. This method of using rice husks for fuel is an economic utilization of a waste product similar to the use of the crushed sugar cane, or bagasse, on sugar plantation in Cuba and other countries.

Consul Wm. Bardel writes from Bamberg that Engineer Balderauer, of Salzburg, has invented a balloon railroad, experiments with which are now being made in the mountains in the neighborhood of that German city. It consists of a captive balloon, which is fastened to a slide running along a single steel rail. The rail is fastened to the side of a steep mountain, which ordinary railroads could not climb, except through deep cuts and tunnels. The balloon is to float about 35 feet over the ground, and a heavy steel cable connects it with the rail. The conductor can, at will, make the balloon slide up and down the side of the mountain. For going up the motive power is furnished by hydrogen gas, while the descent is caused by loading up with water, which is poured into a tank at the upper end of the trip, and thus serves as ballast. Suspended from the balloon is a circular car with room for ten passengers. The cable goes from the bottom of the balloon through the center of the car to a regulator of speed, which is controlled by the conductor. The inventor of this railroad claims that his patent will force all incline cable roads out of existence. Of course!

The subject of denatured alcohol takes up a considerable part of consular report No. 2,662, it being devoted to the production, manufacture, distribution and consumption in Germany and France. The consumption in Germany of completely and partially denatured alcohol has increased from 25,429,118 gallons in 1901 to 36,943,869 gallons in 1905. Methods of denaturing and the ingredients used are referred to at some length. In France, the government has made considerable effort to stimulate and extend the production and use of alcohol for industrial purposes, but the results have not been altogether satisfactory. The ministers of commerce and agriculture organized a special exhibition and offered prizes for the most effective type of alcohol motors, both stationary and portable, for motor vehicles, alcohol lamps, stoves, etc. The result of this exhibition has been on the whole disappointing, the consumption for such purposes not having increased to

any important degree. It is claimed that the French motor car builders have not found alcohol fully successful, the vapor exploding more suddenly and powerfully than petroleum vapor, and the gases attack bright iron and steel so that it is somewhat difficult to keep cylinders, valves and pistons in order. A mixture of 20 to 30 per cent of benzine gives somewhat better results, but is open to the objection that alcohol and benzine do not volatilize at the same temperature, hence one ingredient of the mixture will be exhausted more rapidly than the other.

The technical schools have filled a want, and have done much good in certain branches of industry, but they assume too much when they undertake to give a young man a course in conservation of forces, statics and dynamics, graphic statics, strength of materials, mechanics, drawing, machine design, mechanical engineering and shop practice, all in the short space of four years. He is given a diploma, signifying he has nothing more to learn and is capable of taking the management of a factory. I had a young man as draftsman, who had taken an engineering course in one of the Boston technical schools. He carried a sample of work with him which he had made during his course in shop practice. It consisted of two pieces of cast iron about two inches square and one inch thick. One piece had a groove about three-eighths of an inch square cut across the face, the other piece had a corresponding projection across its face, together forming a tongue and groove. These pieces were accurately fitted together so that the tongue could slide from end to end and when reversed fit just as accurately. I asked the young man what tools he had to do the job with. He replied: hammer, chisel, file and scraper. I then asked him how long it had taken him to make the piece. He said that he had spoiled two or three pieces before he got them to fit, and that in all, he had probably spent three or four days upon the job. Any modern machine shop could duplicate those pieces with profit for 15 cents or 20 cents apiece. *Time and cost* are the main functions in productive science, and when these essential features are not included in the so-called shop practice, the true object of technology is lost.—*Extract from paper "Value of Technology" read by Mr. Thomas Hill before the Western Society Associated Engineers, July* 18, 1906.

The proposal to utilize metallic colloids for industrial and other purposes opens up at once an extraordinary field of speculation. A colloid, according to Dr. Kuzel, contains energy. "It may possibly be looked upon," to use his own words, "as a primary source of energy. The colloid condition is in fact a dynamical condition of matter, while the crystalline condition is the static condition." "One of the most striking properties of the colloidal condition," he goes on to say, "is that bodies, for instance, metals, which under ordinary conditions are not soluble in water, benzine, or benzol, etc., become at once soluble in these mediums without in any way losing the chemical nature when in colloidal from." Dr. Kuzel instances two colloidal forms of metals, one of which he calls "sols," the other "gels." The latter, according to him, have the property of gelatinizing, assuming the appearance and substance of albumen. In this form metals may be mixed together, forming any desired alloy in a soft or plastic condition. In this form, metals such as wolfram, molybdenum, uranium, tantalum, thorium, etc., may be utilized, according to the inventor, for, among other purposes, incandescent light-giving filaments; that is to say, using Dr. Kuzel's words in his English patents: "Of this plastic mass I form bodies in any known or suitable manner of the shape and size desired for the light-emitting bodies to be produced." A metal or combination of metals in gels, or colloid coagulant form, can be "squirted" in the fashion employed in making ordinary incandescent filaments, or in the manufacture of cordite. The plastic filaments thus produced are then heated to a white heat, when, according to the specification, they return to a crystalline state, "their diameter and specific resistance diminishing notably." Dr. Kuzel, it may be mentioned, has a large laboratory at his home in Austria, and has repeatedly demonstrated there his processes in colloids in a practical form.—*Times Engineering Supplement.*

THE NON-LUMINOUS ALCOHOL FLAME.

Among the points brought out in the investigation of the availability of alcohol as a fuel for the internal combustion engine is the advantage it derives from the non-luminous character of its flame. As is well known to any one who has ever seen alcohol burn, its flame is bluish and gives out little light, which means that it is almost entirely devoid of free carbon particles. It is these particles of incandescent solid matter which give to a flame the greater part of its heat radiating power. When gasoline and most other oils are burning, the flame, made luminous by carbon or soot, radiates heat to such a degree that it is not possible to approach near the conflagration and combustible surroundings are readily fired by pure radiation. Not only does this property of alcohol render the fuel a safer one in case of accidental ignition, but it has a favorable effect as well when used as a fuel in the cylinder of an engine. Since the flame has very slight radiating power less heat will be absorbed by the walls of the cylinder, and consequently much less will be taken up in the water jacket and carried away as lost heat, than is the case when gas or any form of petroleum is used.

POWER TRANSMISSION BY MEANS OF GAS.

In a paper read recently before the Society of Arts, London, on coal conservation, power transmission and smoke prevention, the author, H. A. Martin, as reported in the *Electrical Review*, suggests the possibility that gas may be found a more economical and convenient means of transmitting power over long distances than is electricity. This possibility is especially applicable to the case of London, which has no large hydraulic power near it to serve as an economical source of electricity, but has to depend instead on coal which is brought to it from the northern counties. Aside from the question of cost, the enormous volumes of smoke generated by the burning of this coal intensifies the fog which is one of the most serious problems that that city has to deal with. It is pointed out that gas could be generated from coal at the mines and transmitted under a pressure of about 500 pounds per square inch to the power centers, where it can be used for heating and in internal combustion engines. This high compression, which is the most costly and serious feature of the plan, is necessary, otherwise the cost of the large pipes which would be required for low pressure gas, would swamp the undertaking. This makes necessary a pressure reducing plant at the receiving station. Mr. Martin, to make the system as economical as possible, proposes a number of refinements by which sufficient savings may be effected to counterbalance the cost of transporting the gas, and stress is laid as well upon the by-products of the system—the production of fertilizing and other substances. The utilization of the cooling action of the expanding gases in refrigerating plants is also suggested. The plan would thus involve quite a complication of details, enough, perhaps, to render its success somewhat doubtful.

Power transmission by gas, however, it is considered, would solve some of the problems not solved up to the present time by electrical transmission. While all admit that no small motive power can compare with the electric motor, and that electric lamps are the best illuminating agents yet devised, yet when it comes to heating, the electric system is at a disadvantage. Electric heaters are perfectly effective, that is to say all the energy supplied to them is converted into heat, but the losses which have taken place before the energy reaches the heater are very great; while in the gas system all of the energy of the gas is converted into heat. In other words, we start with our energy in the form of heat which is obtained by burning the gas. In an electric system we must carry this through a number of transformations, one of which, that from heat into motion, is not very efficient. This objection applies only to electric energy generated from fuel; when obtained from other sources the transformation ratio is high and the cost depends mainly on the cost of the apparatus.

Mr. Martin suggests that the amount of coal consumed by coasting steamers, freight and switching engines, which now carry the fuel supply of London, is no inconsiderable factor in determining the most efficient means of transferring the

required energy from the mines to the metropolis. In the proposed gas pipe-line system, however, there happens to be a source of power already available in the heat of combustion from the gas producing apparatus. The gases leave the retort ovens at a very high temperature, the greater part of their heat being generally wasted, when, by means of suitably arranged boilers, they probably might be made to furnish all of the steam required to work the compressors.

SOME USES OF PURE MANGANESE AND ITS ALLOYS.

Mechanical World, August 10, 1906.

A good deal of information has recently been published regarding the uses of magnesium as a deoxidizer for obtaining sound casting of certain metals and alloys. It does not appear to be generally known that manganese can be used with even better results for most purposes; therefore, the following brief remarks are of interest:

With manganese it is necessary to use the purest metal obtainable. Manganese made by the Goldschmidt aluminothermic process has a purity of about 99 per cent, the balance being chiefly silicon; this manganese is free from carbon, and technically free from iron, a point which makes it of great benefit for special brass and other alloys.

Pure manganese is a very brittle metal, and resists atmospheric influences for an unlimited time; its fusing point is about 2,240 degrees F. Among its chief characteristics is the ease with which it alloys with copper, nickel, zinc, tin, aluminum and other metals.

Pure manganese may be added in any percentage to zinc-copper alloys, the result being a very considerable increase of strength and density, and often of elasticity; such alloys can also be more easily rolled. It should not, however, be added to tin-copper alloys containing more than about 2 to 3 per cent of tin, as the quality of the material is thereby deteriorated.

For nickel castings, manganese is used as a deoxidizer to produce a greater density. In this case about 2 per cent is added to the molten nickel. It is also used with beneficial results for making German silver. If about ½ per cent is added a bright color is produced similar to that of silver.

For aluminum alloys an addition of manganese copper, free from iron, which is made from pure metallic manganese and electrolytic copper, is preferable to zinc or nickel additions. About 3 per cent of manganese-copper will increase the strength of the material, give denser castings, and the alloy can be more easily machined.

Copper and bronze castings lose their brittleness if manganese is added instead of phosphorus; a material is thus obtained in which threads may be easily cut. Manganese-copper alloys are made to a large extent, containing from 2 to 12 per cent of manganese. Bronzes with 5 to 6 per cent of manganese have about the same color as copper and are very fire-resisting; they are used in the fire boxes of locomotives.

Manganese fulfills two purposes. First, it is a deoxidizing agent. In general, an addition of about ¼ per cent of manganese is sufficient. Compared with other deoxidizing agents, like phosphorus, manganese has the great advantage that if a surplus quantity is added, it improves the quality of the bath (the only exception being the case of bronze rich in tin); whereas, if too much phosphorus is added, it impairs the quality of the bath. In some cases about 1 per cent of manganese is added, in conjunction with phosphorus.

Second, it improves the quality of a great many metallic alloys. It combines easily with and has a great affinity for oxygen; moreover, since manganese oxide slags are very fluid and have a low specific gravity, they easily and quickly separate out of the baths. All castings with manganese alloys are to be made under exclusion of air as far as possible. It is, therefore, useful to sprinkle a small quantity of borax upon the surface of the metallic bath in the crucible. It then forms a thick plastic slag.

Manganese alloys with tin and zinc can also easily be prepared; generally, the following proportions are used: 20 parts of manganese to 80 of zinc, free from lead; 50 parts of manganese to 50 parts of tin, free from lead. The slag formed on the molten tin and zinc must, of course, be removed before adding the manganese, and the charge is kept heated for a couple of hours. With zinc it is important to take care that the temperature remains constant and does not increase. The loss in the preparation of 20 per cent manganese-zinc is only 4 per cent.

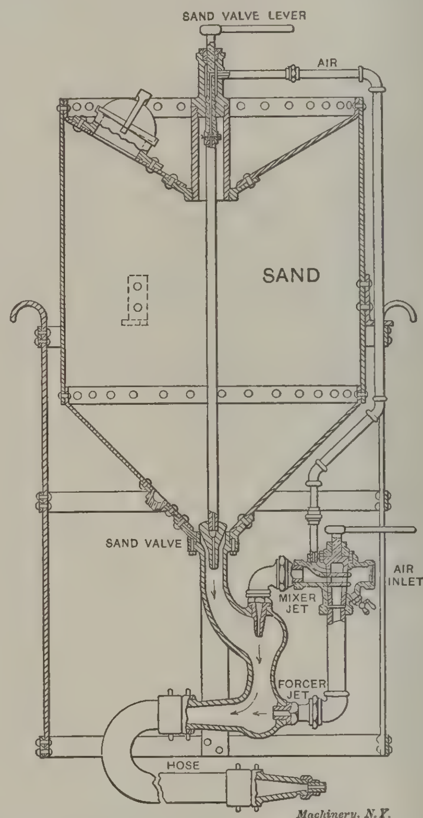
Manganese-copper free from iron is used in the nickel cupro manufacture of cartridge cases, etc., and does away with the annealing process.—W. B., Jr.

CLEANING CASTINGS BY THE SAND BLAST.

J. M. Betton, in *Compressed Air*.

This article on the sand blast and its use in cleaning castings, buildings, bridges, etc., covers practically the entire field of applicability of the sand blast for cleaning purposes, but in the following we have collected only such portions as are of service in foundry work.

In a sand blast apparatus, and especially in the injector sand blast, the injector principle is followed closely in first starting the flow of sand by creating a mild vacuum by means of a vertical jet through the sand valve, equivalent to the suction jet of the steam injector, mixing the sand and air by means of the second vertical or mixing jet, which also starts



Vertical Section through Sand Tank and Injector.

the combined current forward, and by augmenting the velocity of the current, using a horizontal or forcer jet, as well as by contracting the walls of the mixing chamber. In other words, the air supply is sub-divided and applied in such manner as to make its effort cumulative, thus producing a vigorous blast of thoroughly mixed sand and air, each grain of sand being projected upon the work with the highest possible velocity. By sub-dividing the air, the injector sand blast is able to obtain the same results with less consumption of air than the ordinary sand blast, in which the sand drops into a current of air and is blown onto the work. The general arrangement of an injector sand blast is shown in the cut, in which it will be seen that the first current of air to set the sand in motion passes in through the sand valve; the second or mixer jet enters a short distance below this, and the last or forcer jet sends the current of well-mixed air and sand into the nozzle pipe.

To obtain good results with a sand blast it is necessary to provide an ample supply of air. In the following table the

number of cubic feet of free air per minute required under different pressures for nozzles of different sizes is given:

Diameter of Nozzle in inches.	Air Gage Pressures in Pounds. 5	10	15	20	25	30
¼	14.4	21.8	26.7	30.8	34.5	40.
⅜	34.6	49.	60.	69.	77.	90.
½	61.6	87.	107.	123.	138.	161.
⅝	96.5	136.	167.	193.	216.	252.
¾	133.	196.	240.	277.	310.	362.
⅞	189.	267.	326.	378.	422.	493.

AIR PRESSURE REQUIRED.

For light work (stove castings, etc.)............	5 to 10 lbs.
For medium and heavy grade iron castings.......	15 to 20 lbs.
For steel castings..............................	30 to 75 lbs.
For cleaning buildings and steel structures....... (According to height.)	5 to 30 lbs.

The proper size of air tank for ordinary foundry work is about 30 inches diameter by 6 feet long, and it should be provided with a safety valve, a pressure gage and a blow-off, the latter near the bottom to remove water condensed from the air.

It is especially desirable that the air piping from receiver to sand blast be not less in diameter than the air connection of the sand blast. If the distance between the receiver and the sand blast is more than 75 feet, the pipe should be larger than the air connection of the sand blast, to allow for loss of pressure from friction. It is not that the sand blast will take all of this air; it can only take the amount which the nozzle will discharge under the working pressure (a ½-inch nozzle under 30 pounds' pressure will take 161 cubic feet of free air), but the best and most satisfactory results are only obtained by having this backing of air behind the jets.

The air piping should be protected from condensation if the lines be long, and if moisture or water shows in the air at its entrance into the sand blast, it is necessary that some means of removing this and drying the air be provided. This can be done by an "after cooler," or by means of one or more "U" loops introduced in the line of air piping. Drip cocks at the bottom of these loops will draw off the entrained water, or it may be removed by an ordinary bucket steam trap.

Water must be kept from the sand to insure proper working of the sand blast. If it enters the tank it will cause the sand to cake and arch over the sand valve, and the only remedy is to shut down, draw off the sand and start over again with dry sand.

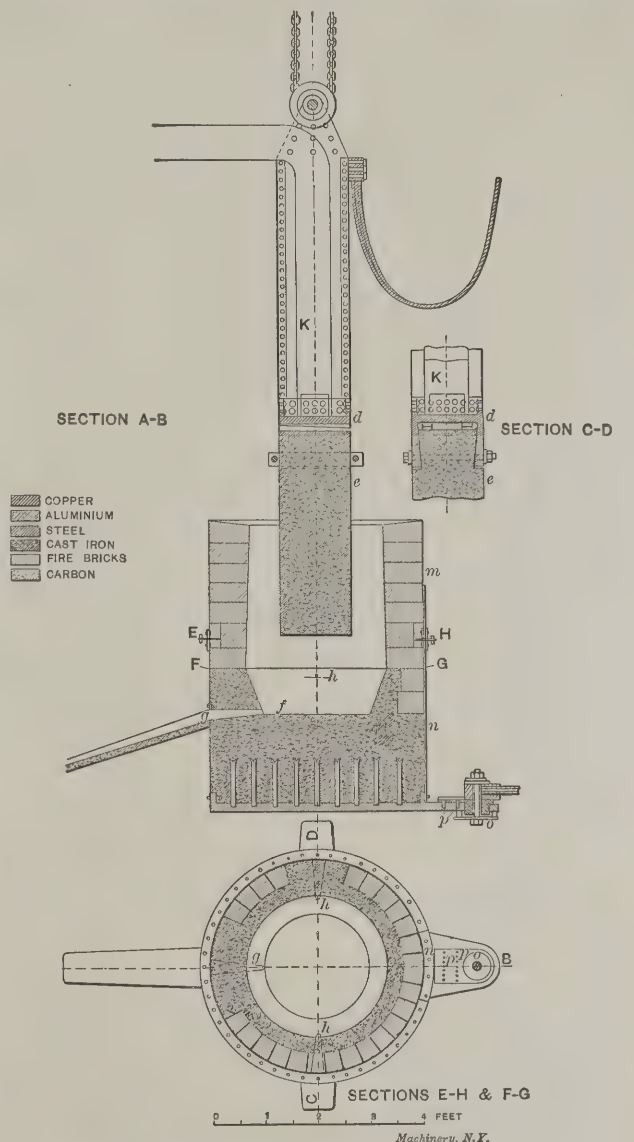
Dry sand, if left in the tank over night, will absorb moisture and may refuse to work the next day. The sand should be perfectly sharp, clean quartz or silica, sifted through a screen of proper mesh, and dried long enough beforehand to have it cold when used. If too warm it will generate steam in the tank, and if heated very hot it will crack and disintegrate. With a ¼-inch nozzle, the sand should be passed through a No. 8 mesh screen. With a ½-inch nozzle much coarser sand can be used, and the injector sand blast has been operated successfully with pebbles averaging ⅛ inch in diameter, using them again and again. These quickly rounded off their sharp edges, and their action upon the castings can be compared to that of peening them with an infinite number of small ball-peen hammers, cleaning them very thoroughly and giving a very good finish. A coarse sand or gravel will be found effective for general work in the foundry, especially for steel castings. W. B. Jr.

ELECTRIC SMELTING OF IRON ORE.

Under the auspices of the Canadian government quite a number of experiments have been made at Sault Ste. Marie, Ontario, on the smelting of iron ores by means of the electric furnace. These experiments have been conducted under the direction of Dr. Eugene Haanel, whose preliminary official report was recently made public. From the information given in this report it appears that the electrothermic process is likely to come into extensive use in the future, in the manufacture of high-grade steel and iron alloys, and possibly even in the production of pig iron.

The furnace used in the experiments is shown in vertical and horizontal sections. The dimensions of the furnace are as follows: Diameter of bottom of crucible, 2 feet; height of lower cone, 11 inches; height of upper cone, 33 inches; diameter at junction of the two cones, 32 inches, and at top of furnace 30 inches. The carbon electrode is 16 inches square and 6 feet long. The lower part of the furnace is made of carbon paste; the upper part of fire brick with a lining of carbon paste.

A 50-volt, 30-cycle transformer furnished the electrical energy. The principal ore experimented with was magnetite, and as it is to some extent a conductor of electricity, it was expected that considerable difficulty would be experienced in smelting it. It was thought that with the furnace used, as the electrode is immersed in the charge, current would leak laterally through the charge and thus prevent a sufficient amount from reaching the fusion zone to develop the high temperature required for fusion. With charcoal as a reducing agent no such difficulty was experienced; in fact, when crushed so as to pass through a ¾-inch mesh it worked as well as coke briquetted with clay.



Sections of Heroult's Electric Furnace for Iron Ore Reduction.

In one of the experiments the charge of the furnace consisted of: Ore, 400 pounds; charcoal, 125 pounds; limestone, 25 pounds; sand, 6 pounds. The data relating to this experiment is as follows:

Length of run, 65 hours 30 minutes.
Current voltage, 36.03.
Current, amperes, 4,987.
Electric horsepower, 221.34.
Ratio of weight of slag to that of iron, 0.41.
Pig iron produced, 11,989 pounds.
Pig iron per 1,000 electrical horsepower days, 9.92 tons.

An important result of the experiments was the fact that ores of high sulphur content, not containing manganese, can be made into pig iron containing only a few thousandths of a per cent of sulphur.

The ores treated, with the exception of the hematite and roasted pyrrhotite, contained a high percentage of magnesia, producing a very infusible slag. When the furnace had been running for some time this infusible material formed a scale around the crucible, the electric energy available not being sufficient to keep it in a molten condition. The crucible and lower part of the furnace were, therefore, partially filled up, preventing easy access of the charge to the reducing and melting zone. This slower feeding left the charcoal on top of the furnace exposed to the air a longer time, thus increasing the amount of charcoal required and decreasing the output. With a greater current than was available and consequent higher temperature, the formation of the scale would have been prevented, and the output correspondingly increased.

The consumption of the carbon electrode is small, as may be seen from the fact that 384 pounds were consumed in the production of 42,711 pounds of pig iron, which is at the rate of about 18 pounds per net ton of metal. The consumption of the electrode is greater for white iron than for gray.

According to Dr. Paul L. T. Heroult, a plant capable of producing 120 tons of pig iron per day would cost about $700,000 and the cost of making the iron would be $10.69. This estimate is based on the assumption that ore contains 55 per cent iron, and costs $1.50 per ton.

From the results obtained in the Sault Ste. Marie experiments, it would seem that the electric furnace stands a chance of competing with the present methods in the production of pig iron, at least under certain favorable conditions. For the manufacture of ferro alloys of high percentage, *Electrochemical and Metallurgical Industry* says that "the electric furnace now stands supreme, specially in the manufacture of those ferros in which a highly refractory oxide (like that of titanium) is to be reduced." For the manufacture of high-grade steel, the same authority says: "The electric furnace seems to be destined to gradually replace the crucible steel process. The advantages of the electric furnace are lower cost of operation, due to larger units and consequently smaller labor charge per ton of output and greater durability of the electric furnace. The cost of electric power is a comparatively small item in this case, and becomes almost insignificant if fluid steel is supplied from an open-hearth furnace or from a Bessemer converter to an electric furnace for refining. It is likely that steel which has been refined in the electric furnace at a small cost may be used in future to a much greater extent than is now possible with the high price of crucible steel."

W. B. Jr.

TECHNICAL CONCLUSIONS FROM THE GLIDDEN AUTOMOBILE TOUR.

The Horseless Age, August 1 and 8, 1906.

The Glidden contest is an annual event in the automobile world which is especially designed to test the economy and reliability of the contesting machines under severe touring conditions. The route of this year's race was about 1,200 miles in length, starting at Buffalo, N. Y., thence eastward across the State and northward to Montreal, and up the St. Lawrence River. Then the route took a southward turn again down through the White Mountains, winding up at Bretton Woods, N. H. This route was a severe one in many respects, including stretches of sandy and rough roads, and many exceedingly steep grades. Albert L. Clough contributes to the *Horseless Age* the main results of his observations made during the tour as to the strength and efficiency of the various parts of the automobile mechanism. We give them here in abstract:

One noticeable feature of this year's contest was that all the American cars are of practically the same type. This standardization of form makes it possible to speak quite generally of the technical merits and demerits of the contesting vehicles as a whole. The greatest chance of drawing comparisons is in considering the details of construction, which still show some diversity. One of the principal points of interest relates to the efficiency of the air-cooled car, five of which entered the contest. This air cooling of the vehicle engine of large power is a distinctly American proposition. The writer kept close watch of the performance of the air-cooled cars and found his previous judgment as to this question far more than substantiated. Of the five air-cooled cars that started from Buffalo, four finished at Bretton Woods, two making perfect scores. At no time have any of the air-cooled engines been noticed in a dangerously overheated condition, and they have not found the pace at all in excess of their capabilities, at least so far as the cooling question is concerned. American builders would do well to give more attention to this type of engine instead of following foreign models so closely as they have done.

The weakest part of the chassis has been demonstrated to be the running gear of the car. This is the salient technical conclusion to be drawn from the contest. It looks as if the engine of the average car possesses enough power to strain the supporting framework to the point of destruction in a few thousand miles of hard running over unimproved country roads, without being itself injured to any serious extent. In the matter of axles, for instance, this tour must have proved an eye-opener to many manufacturers as well as to the owners of the machines themselves. There are very few tubular front axles to be found upon the contesting vehicles which have not more or less of a permanent set, while most I-section axles are in as good condition as they were at the start. It is to be presumed that the tubular axle will now be finally discarded, except for use upon very cheap cars. Notwithstanding the use of the shock absorber, the spring must be characterized as one of the weakest parts of the car. The spring problem is a difficult one and has not as yet received the intelligent attention it demands. It would seem that certain manufacturers must either increase their spring lengths with a corresponding increase of sectional dimensions or else resort to some other form of spring than the half-elliptic, such as the platform type or the double elliptic type. This change may come about when the very low-hung body is seen to be no special desideratum. Is it certain that the list of special steels has been exhausted in a search for the best spring material? Possibly some such improvement as has lately been made in crankshaft material might be made in spring stock.

The brake problem is substantially solved. Some of the cars have required rather frequent brake adjustment, but the problem is merely one of providing more liberal wearing surface. The manufacturers of these cars will, without doubt, profit by the knowledge acquired in this tour. The same cannot be said with so much truth of the steering gears. They have been given severe usage over rocky, sandy and winding roads, and many of them have become quite loose, requiring considerable adjustment. The presence of back lash and the shocks communicated through imperfectly reversible steering mechanisms conspired to very much fatigue and lamed many of the operators.

Both chain and shaft drives have shown themselves able to do their work successfully under difficult conditions. There seems to be no reason to credit the assertion that is sometimes made that the shaft drive is inapplicable to heavy cars of high power.

Perhaps the most astonishing and welcome fact brought out is the great reliability and endurance of the engines. There have been practically no cases of serious mechanical engine troubles. There have been some few valve replacements, but very little tightening of bearings or anything of that sort. Not a few of the motors are too good for their cars and too powerful, capable of driving them to destruction in a short period. One can hardly refrain from being enthusiastic regarding the remarkable performances of these motors. There is no other thermal prime mover which approaches the vehicle engine in reliability, automaticity, and weight efficiency, considering the conditions under which it is used. During the whole tour there was substantially no trouble from faulty ignition. Clutches and change gears also seem to have been developed to a satisfactory degree of strength and reliability. As regards the ratio of speed reduction, however, the writer cannot help thinking that there are not a few high-grade cars which do not possess a large enough gear reduction upon the slowest speed to give them a safe margin of hill-climbing capability. Cars with three or four forward speeds employ the lower gear only at infrequent intervals. When its use becomes necessary, however, it should be so low as to over-

come all car resistances, up to the limit of traction; that is, it should be capable of slipping the rear wheels on good footing. Twenty per cent hills are always likely to be met with in country touring, and the purchaser of a costly touring car does not care to be stalled at such grades, as were not a few of the cars in this tour. A suspicion sometimes crosses the mind as to whether the modern car with the engine in the front part carries sufficient weight upon the driving wheels to meet unfavorable conditions.

To one who observed the slipping of driving wheels on one of the hills met with on the tour which presented a muddy surface, the question must have seemed a pertinent one. In this respect the discarded engine in the body was superior. Another difficulty met with on steep hills was the failure of the gravity gasoline system. On a 20 per cent grade with the tank under the front seat the head of gasoline may be lowered about eight inches, which may be enough, if the fuel supply is low, to reduce the head to nothing.

Besides the vindication of the capability of air cooling for protracted touring purposes, there is one other technical innovation which has had a successful try-out in this contest. I refer to the two-cycle engine. Though there was but a single car of this type in the run, which did not achieve a perfect score, it was penalized by a few points only, due to delays which it was understood were in no way connected with the application of the two-cycle principle. This car finished the tour apparently as well as did the majority of four-cycle cars with its propulsive mechanism in excellent condition. To all who looked forward to the demonstration of the fitness of valveless motors to automobile practice, this fact will be presently significant.

It was indeed a cruel fate which pursued the steam cars entered in this contest and led to the total destruction of two of them. Although these cars have been developed to a high pitch of reliability and efficiency in every other respect, there is always the hazard of the exposed flame to contend with. Gasoline cars were enormously in the majority in this tour, and at least two cars were overturned and several ditched, yet none of them met with destruction or damage by fire. All efforts to render the steam car as safe as the gasoline car in point of fire hazard must be made against heavy odds, and must be expected to result fruitlessly.

This tour has proven a wonderful demonstration of the reliability of the American motor car, being impressive on account of the very considerable number of them which completed the run without penalization, and on account of the large proportion of the entrants that finished. Of the three foreign-built cars in the tour, none escaped penalization and only one of them finished at all. While this fact may not be deeply significant, it will perhaps tend to strengthen the impression that it is folly to pay a fancy price for foreign cars when fully as serviceable American machines can be bought for far less money.

THE GAS TURBINE.

Dr. C. E. Lucke, *Engineering Magazine*, August, 1906.

Dr. Lucke gives a great deal of information on the gas turbine, based on actual experiments; this information is not encouraging to those who expect soon to see gas turbines in general use, but it will be of decided value to those who are or intend to be experimenters in this field, as it points out the almost insurmountable obstacles that stand in the way of success. The main features of the paper are given in what follows:

Inventors and engineers have experimented with complete gas turbines, with and without steam, as well as with the various elements going to make up the system, such as the compressor, the fire, the nozzle and the turbine wheel. Some of these experimental combinations have been made to run, but cannot be regarded as working machines merely because they run. To receive any consideration they must approach the steam or gas engine in efficiency, in reliability, life, space occupied, and other commercial features.

It is to be regretted that by far the most of the experimental results along these lines have been suppressed. The inventors or experimenters apparently hoped to achieve something wonderful, something which must not be disclosed to the world too soon, and so they have concealed their early work. Later, when the machine was built and operated, the failure was so humiliating that in some cases the experimenter was ashamed to publish his results, and in other cases it appears that large sums of money were spent, and those who spent it did not feel inclined to give results to the world, obtained at such large individual expense. If the results of every man who had experimented with this problem had been published, there would have been less experimenting. It is also extremely probable that if the results had been given freely to all who were interested in the problem, we would to-day be nearer success, or more certain of its impossibility.

In a paper published about a year ago, I pointed out one of the difficulties of obtaining a practical gas turbine—free expansion by means of the nozzle. That there were other difficulties was well known at that time, but it seems to me that the most basic difficulty was the one previously made prominent. It was found by experimenting with nozzles that the temperature drop in the nozzles between the place of no velocity and high pressure and the place of maximum velocity and low pressure was very small, and averaged about 12 per cent of what is theoretically possible. Since that time, the temperature drop in an actual turbine has been measured and compared with the theoretical pressure drop and the performance of the turbine operating with air has been measured. For convenience of operation the air was cold air, whereas in the practical gas turbine the air would be hot and possibly more or less mixed with steam, or possibly no air at all but carbon dioxide and nitrogen. In any event, the working fluid would be largely a perfect gas. The turbine used was a De Laval standard 30-horsepower machine intended for steam at 110 pounds pressure and having six nozzles. The turbine wheel runs at 20,000 revolutions per minute, and the power shaft 2,000 revolutions.

With each type of nozzle three different initial pressures were used, each with a different number of nozzles. Readings were taken of the temperature of the air entering the turbine and the temperature of the air in the exhaust chamber, with the corresponding pressures. This turbine was fitted for six nozzles in all, grouped in three pairs of two each. These nozzles were all designed for 110 pounds initial pressure at three different back pressures—atmospheric, 25.5 inches vacuum and 26.3 inches vacuum.

In the best results the figures are as follows: Initial temperature and pressure, respectively, 98 degrees and 85 pounds; final temperature and pressure 58 degrees and 0.03 pound; theoretical temperature, 123 degrees; range of temperature observed, 40 degrees; theoretical drop, 221 degrees; per cent of theoretical realized, 18.1. In the poorest result the temperature dropped 8 degrees, from 90 degrees to 82 degrees, while theoretically it should have dropped 188 degrees, the pressure drop being from 48 pounds to 0.12 pound. The per cent of the theoretical realized in this case was only 4.3. From this it appears that the temperature drop varies between 4 and 18 per cent of the theoretical drop. These results were determined with respect to speed also, which varied from 520 to 1,920 revolutions per minute.

The experiments fully confirm those previously reported and the conclusions drawn from them, that the temperature drop in free expansion with such nozzles as have been used indicates very small conversion of heat into work. Investigations by the author among men who have worked with compressed air and with jets and nozzles has failed to develop a single case where there occurs a substantial cooling of perfect gases by free expansion. One man is probably better fitted to express an opinion than any other, by reason of his life work—Dr. Ernest Körting, inventor for many years of jet apparatus of all sorts, and of gas engines and producers. After a life spent in such work with signal success, he sets it down as a fact that he has never noted a single case of efficient expansion of gases, as shown by temperature drop.

To secure some idea of the attitude of other engineers toward this gas engine situation, I addressed the following series of questions to a number of men whose opinions seem to be desirable:

a. Do you consider that there is anything theoretically im-

possible in the production of a gas turbine, with or without the use of steam?

b. Do you consider that there is anything practically prohibitive in carrying out the necessary process to produce a gas turbine, using either perfect gas or a mixture of perfect gas and steam?

c. What do you consider are the prospects of overcoming such difficulties as exist?

d. Do you consider that there is anything theoretically or practically difficult in the compressor part of the system?

e. In the combustion chamber of the system?

f. In the control of hot gases alone or with steam?

g. In the nozzle part of the system?

h. In the turbine wheel part of the system?

i. In any other part of the system?

These men represent the steam turbine field, the gas engine field, and scientific men not identified with any particular field. The replies are given in the following:

Prof. R. C. Carpenter:

"Respecting the future commercial success of the gas turbine, I would state that I have formed an opinion which is unfavorable, due to the extremely high temperature which the working parts must be subjected to.

"Quite a number of experiments respecting the gas turbine have been carried on in our laboratory during the past eight or ten years. I felt at first that the machine could be made a practical success, but latterly I have concluded that the practical difficulties were almost insurmountable.

"In my opinion there is nothing in fault with the theory of a gas turbine without the use of steam, but I do not believe that there is any immediate prospect of securing metals which will stand the high temperature required for the nozzles and buckets.

"Respecting the use of a combined gas and steam turbine, I have at the present time no definite or positive information which will enable me to express an opinion as to its future practicability. I think, however, that a turbine working on such a combination might have a fighting chance of succeeding."

Prof. Sidney A. Reeve:

"*a.* No.

"*b.* At present, yes.

"*c.* The prospects are excellent. The gas turbine is a new problem. The devices already standard in engineering practice were developed to meet earlier conditions. The conditions of the new problem are different. The usual period for the experimental development of a solution of the problem of building old devices along new lines is all that intervenes between the present and a practicable gas turbine.

"*d.* Theoretically, no. Practically, yes. The compressor is the only unsolved and difficult part of the problem.

"*e.* No, either theoretically or practically.

"*f.* With permanent gases, yes. With steam, no.

"*g.* No.

"*h.* No.

"*i.* No."

Prof. William T. Magruder:

"*a.* I see nothing theoretically impossible in gas turbines, although I am not prepared to predict how economical they will be in the use of fuel and repairs in practice.

"*b.* I feel that the obtainable temperatures which are desired for maximum efficiency may cause great difficulty, unless a suitable porcelain can be obtained.

"*c.* I have faith enough to believe that the difficulties will be overcome.

"*d.* I am not prepared to say that the compression is absolutely necessary, and believe that the difficulties peculiar to the problem can be overcome. A motor-driven, 550-revolution, 3,000-pound pressure, four stage air compressor at 85 per cent pneumatic efficiency is the latest success in this line.

"*e.* Your work is an answer to this question.

"*f.* Without steam it is the most serious proposition.

"*g.* Cannot say. Would try porcelain.

"I believe that a solution of the problem will be effected, which, in its way, will be as novel as the steam turbine. I would, however, prefer not to make any prediction or statement at present."

Mr. F. E. Junge:

"*a.* No.

"*b.* No.

"*c.* Prospects are good if efficiency of proposed turbine is second consideration.

"*d.* Nothing.

"*e.* Yes; difficulty of cooling.

"*f.* Yes; thermal inefficiency when steam is generated by injecting water into combustion chamber before or during combustion.

"*g.* No, if properly designed.

"*h.* Yes, impossibility of cooling blades and finding proper material to stand high temperatures continuously.

"*i.* None but lack of interest in manufacturing circles and among investors."

Prof. Elihu Thompson in his reply says that the gas turbine is certainly a very complex problem, and he is not prepared to answer the questions put, definitely, at this time. He sees, however, no theoretical impossibility in the gas turbine, with or without steam, but considers the practical problems of the greatest difficulty, especially the compression problem. The construction and operation problems are certainly difficult, and considerable time will probably elapse before any thoroughly workable gas turbine is produced, and the problem of its competing with other machines is naturally somewhat doubtful.

W. L. R. Emmet, after a few preliminary remarks relative to the theory of the subject, concludes his answer as follows:

"Even when due allowance is made for these difficulties, theory would indicate that fair economy might be obtained from a gas turbine. The development of any practicable process of this kind involves a great amount of thought and labor, and all that I can say of this process is that it seems to afford a less attractive field for development than many others to which a competent engineer might devote his energies."

After a review of the whole situation, it appears that theoretically there is nothing impossible in the problem, and such difficulties as exist are purely practical but of no mean order of magnitude. So great are the difficulties encountered by those who have experimented, and so great are those that are foreseen by practical men, whose lives are devoted to overcoming difficulties, that those who are engaged in trying to perfect such a machine as this are warned of the certainty that their efforts will be fruitless for a long time at least, that much money will be spent with no tangible results, and that the practical gas turbine is a long way off. W. B. Jr.

CURRENT PRACTICE IN PETROL ENGINE DESIGN.

G. W. Rice, *Sibley Journal of Engineering*, June, 1906.

This paper is an abstract from a thesis by the author for the M. E. degree. Mr. Rice gives working formulas for the dimensions of the various parts of petrol engines, especially the light-weight type used in automobiles. These formulas are deduced from actual practice, as exemplified in the latest designs of such machines, and are of special value to designers. All the essential information is given in the following abridgment of the paper. The author says:

It is the object of this paper to derive rational machine design formulas for the different parts of a petrol engine with the constants of the formulas derived from practice. In May, 1905, an explanation of this project, together with data sheets, were mailed to 200 builders, and from these, data on about seventy-five engines were obtained. In order to get the maximum explosion pressure, which we need in finding the stresses in the engine parts, the assumption is made that the compression pressure is one-fourth of the maximum explosion pressure. This assumption is very nearly correct and is used throughout this article.

Ratio of Length to Diameter.

While in stationary gas engines running at slow speed, the stroke is about 1.5 times the bore for thermodynamic reasons, in high-speed petrol engines the consideration of piston speed outweighs the former and in some cases it is shorter.

$l =$ cylinder length in inches.

$D =$ diameter of cylinder in inches.

Values of l and D were plotted, giving 1.07 as mean value of "A" in formula $l = A\,D$.

The designer's formula is,

$$l = 1.07\,D.$$

$D =$ the cylinder bore.

$l =$ length of stroke.

R. P. M. $=$ revolutions per minute.

$C\,l =$ clearance as a fraction of piston displacement.

The equation for the maximum horsepower is a rational formula, the constant in it being based on the current practice of 1905 and 1906.

$$\text{D. H. P. per cylinder} = \frac{D^2 \times L \times \text{R. P. M.} \times (.48 + 0.1\,C\,l)}{14000.}$$

Thickness of Cylinder Wall.

This depends on the stress which can safely be allowed for continuous repetition. On account of the desire for lightness

and the stiffening action of the jacket wall, this stress is taken as high as possible; in fact, instead of allowing the usual constant for reboring, it was found on plotting the data from engines in actual practice that this constant had a negative value of ⅛ inch.

t = thickness of cylinder wall.

s = allowable stress per square inch.

p = maximum explosion pressure.

D = cylinder diameter.

The design formulas are then:

$$t = \frac{pD}{5300} - \frac{1}{8}'' \text{ (Light automobile practice).}$$

$$t = \frac{pD}{3700} - \frac{1}{8}'' \text{ (Medium weight practice).}$$

$$t = \frac{pD}{3200} - \frac{1}{8}'' \text{ (Heavy marine practice).}$$

$$t = \frac{D}{16} \quad \text{(Rough rule, not considering pressure).}$$

Thickness of Integral Cast Cylinder Heads.

The common form of head is that of a flattened ellipse. Liberal fillets should be used where the head joins the cylinder wall, and the head may be gradually reduced in thickness as you approach the center. Close to the cylinder wall $t = 0.005\, D \sqrt{p}$; at the center $t = p\, D \div 1.5\, s$.

Thickness of Jacket Wall.

This is made as thin as it can be cast in the foundry; in some cases it is deposited electrolytically of copper; in other cases the cylinder is cast without a jacket, turned up inside and out and a thin metal jacket of copper or brass applied. This latter practice has come to the front a great deal during the last year. In cylinders made in this manner you can be sure that the cylinder wall has a constant thickness, which is something which cannot be said of the ordinary type, it is also of a very light construction.

Length of Piston.

The normal pressure between piston and cylinder wall for any point in the piston stroke is equal to pressure on piston head divided by the ratio of connecting rod to crank length. By assuming an average clearance and different ratios of connecting rod to crank, it was found that the average pressure on the piston head when the connecting rod and crank were at right angles, giving the maximum normal pressure on the piston, was 0.23 times the maximum pressure. The design formulas are:

$$l = 0.0167\, p \frac{D}{c}.$$

$$l = 1.125\, D.$$

p = maximum pressure on piston in pounds per square inch.

c = ratio of the connecting rod to the crank.

l = length of the piston.

Thickness of Rear Wall of Piston.

t = thickness of unribbed rear wall of piston.

p = maximum pressure in pounds per square inch.

D = diameter of cylinder.

The designer's formula is

$$t = 0.0034 \sqrt{p} \times D.$$

By plotting between piston head thickness and cylinder diameter, we get the rough design formula: Allow 1-16-inch thickness per inch of cylinder diameter.

Dimensions of Piston Rings.

In the consideration of piston ring dimensions, the first proportion with which we are interested is the diameter to which the outside of the cast-iron ring is finished. This must be a diameter slightly greater than the bore of the cylinder so as to furnish a sufficient packing action to the piston. This diameter is the same for eccentric turned rings as for non-eccentric ones, and by plotting between ring diameter and cylinder diameter it was found that the ring was turned to 1.03 times the cylinder diameter.

Right here it might be well to say that due to the heat of the burning gases expanding the piston head, that end of the piston has to be made slightly smaller down to the first ring than the rest of the piston, this allowance is usually taken as 0.001 inch per inch diameter of cylinder.

For plain rings of constant thickness the width was found to be 0.07 of the cylinder diameter and the thickness of the ring to be 0.5 of the width. The number of rings used by different builders varies widely, the common practice being three at the head end of the piston and one, known as an oil ring, at the open end.

The designer's formulas are:

$$d = 1.03\, D, \quad w = 0.07\, D, \quad t = 0.5\, w.$$

Design of Wrist Pin.

The average pressure on the piston pin will be the same as on the crankpin, neglecting inertia effects.

p = maximum pressure in the cylinder.

d = diameter of wrist pin.

l = length of wrist pin.

D = cylinder diameter.

The designer's formulas are:

$$d\, l = 0.000445\, p\, D$$

$$l = 2\tfrac{1}{4}\, d$$

$$d\, l = \frac{0.7854\, \pi\, D^2}{7}$$

$$d = 0.225\, D$$

Crank Pin Design in Engines with Main Bearing Each Side of Crank Pin.

Below is given data on the ultimate strength of 15 crank shafts having an average ultimate strength of 95,000 pounds per square inch. (See July, 1905, *Horseless Age*.)

Autocar	85,000	Pierce	105,000	Columbia	90,000
Moline	90,000	Lozier	100,000	Covert	80,000
Packard	100,000	S. and M.	125,000	Acme	90,000
St. Louis	70,000	Pierce	105,000	Thomas	105,000
Nameless	85,000	Haynes	90,000	Welch	115,000

and the very latest practice is using steel of special mixture giving it greater hardness and a very high tensile strength.

The designer's formulas for this type of crank shafts—

$$d = \frac{D}{43.2} \sqrt{p} \text{ for diameter of pin.}$$

$$l = 1\,1/3\; d \text{ for length of pin.}$$

Crank Pin Design in Engine not having Main Bearing Each Side of Crank Pin.

Assuming that for this type of engine $d = 2$ inches on the average, approximately,

$$d = \frac{D}{36.5} \sqrt{p} + 0.9''.$$

$$l = 3.75\, d - 3.75''.$$

A general average of all cases shows that the diameter of crank pin $= \frac{D}{2.8}$. Again the general average shows that the projected area of the crank pin is 1/5 of the piston area.

Design of Main Bearings.

d = diameter of main bearing.

The length of main bearing per cylinder in four cylinder engines with five main bearings is 2.82 d.

The length of main bearing per cylinder in four cylinder engines with three main bearings is 1.54 d.

The length of main bearings per cylinder in two-cycle engines is 4.45 d. (This applies to one- and two-cylinder engines only.)

The relative lengths of these bearings, among themselves, varies with the cylinder arrangement—whether they are cast in pair, separately, etc. In all cases, the bearing at the flywheel or power end of the shaft is made longer than any of the others because the weight of the wheel rests almost directly on it and, therefore, the average total pressure is much greater than on the others.

The designer's formulas are—for length of journal—given above.

$$\text{Diameter} = 7.24 \sqrt[3]{\frac{\text{H. P. per cylinder}}{\text{R. P. M.}}}.$$

Crank Throws or Webs.

d = diameter of main bearing.
d' = diameter of crank pin.
h = depth of crank throws.
b = thickness of crank throws.
b' = thickness of crank throws on flywheel side.
b'' = thickness of long crank throws.

The designer's formulas are:

$$d^3 = b\,h^2$$
$$h = 2.6\,b$$
$$b' = 1.25\,b$$
$$h = 1.33\,d'$$
$$b'' = 1.25\,b'$$

Inertia Effects of Reciprocating Parts.

F = inertia effects in pounds per square inch of piston area.
W = weight of (piston + 2/3 connecting rod).
N = R. P. M.
r = one half stroke, in feet.
c = ratio of connecting rod to crank.
D = cylinder diameter, inches.
w = weight of reciprocating parts per square inch of piston area.

$$F = \frac{W \times N^2 \times r \times 0.00034}{0.7854\,D^2} \times \left(I + \frac{I}{c}\right)$$

Now by plotting we find that the weight of reciprocating parts is 0.55 pounds per square inch of piston, and the value of "c" is 4. We may then rewrite the above equation as follows:

$$F = 1.25\ (w \times N^2 \times r \times 0.00034).$$
$$= 1.25\ (0.55 \times N^2 \times r \times 0.00034)$$
$$= 0.0002435\ (N^2 \times r)$$

Giving us a simple equation for inertia effects of a given engine at a given speed.

Stress in Connecting Rod Bolts.

The stress in the bolts of the connecting rod is almost entirely due to the inertia pressures at the end of the stroke. This stress may be found from the preceding formula by plotting the maximum inertia pressures at the engines' rated speed with the reduced bolt area. That is the area at the bottom of the threads. The average ratio of thread area to bolt area is 0.65 for the sizes commonly used in automobile engine construction.

Flywheel Design.

In the design of a flywheel for an automobile engine we have a proposition entirely different from the design of a flywheel for any type of stationary engine. In the automobile the function of the flywheel is not to keep the engine speed constant, but to furnish a storage reservoir of energy sufficient to start the car under any working conditions or to keep the engine turning over when running at very low speed and under heavy load. Current practice does not help us as much as it might in this particular, for the weights of flywheel used for the same powered engine varies widely among the different builders. The weight depends, first upon the diameter, and this depends, to a large extent upon where the wheel has to be put; second, upon the weight of the loaded car, relative to the power of the engine. It also depends upon the gearing ratio of the car and other things relative to the car design.

By plotting between engine stroke and flywheel diameter, we find that the diameter varies from 4.9 to 2.9 times the engine stroke. The average value of flywheel diameter being 3.5 times the engine stroke.

Engine Weight.

Instead of comparing the engine weight with the horsepower, as is usually done, let us compare it with the cubic inches of piston displacement. By plotting between the weight of the complete engine and cylinder volume in cubic inches, we find:

$$W = 1.125\ V + 100.$$

On plotting between engine weight without flywheel and cubic inches of piston displacement, we find:

$$W = 1.125\ V.$$

This indicates that irrespective of the power of the engine, the builders have always used a flywheel of about 100 pounds weight.

By plotting between engine weight and horsepower, we find the average value to be 17.6 pounds per horsepower.

Diameter and Lift of Exhaust Valves.

D = cylinder diameter.
L = length of stroke.
N = R. P. M.
S = allowable speed of gas in feet per minute = 3,520.
d = diameter of exhaust valve.
h = lift of exhaust valve.

In high-speed engines the ring area open to gas passage, seems to be the all important item, and not the diameter of the valve itself. The tendency being to keep the valves large in diameter, and to make the lift as small as possible, 7/16 inch was the highest lift noted on about 80 engines, with cylinder sizes up to 7 × 9 inches, while the theoretical lift would be ¼ of the diameter of the valve. About 5/16 inch is a popular lift in this country, while the French use much lower lifts. These low valve lifts are used in order to get a quick closing valve and to prevent hammering of the cams on the valve push rods.

The designer's formula is:

$$D^2\ L\ N = 84{,}500\ d\ h.$$

Valve Thickness.

For the thickness of the exhaust and inlet valves the formula of Reuleaux may be used:

$$t = r\sqrt{\frac{p}{s}}$$

t = thickness.
r = radius of supporting circle.
p = maximum pressure in cylinder.
s = fiber stress.

Or as given by another designer this is modified to read:

$$t = 0.45\ d\sqrt{\frac{p}{s}}$$

The maximum normal pressure of the valve on its seat is given by several authorities as 900 pounds per square inch and when a conical seated valve is used the angle is usually taken between 45 and 70 degrees, which makes the effective lift of the valve equal to the real lift times the sine of the valve angle which may be approximated at 0.75. Diameter of valve stem is taken as 1/5 valve diameter.

Inlet Valve Design.

Most that has been said relative to the exhaust valve may be applied to the inlet valve. The valves themselves are very often made interchangeable, but they are usually given different lifts, that of the inlet valve being smaller. The designer's formula is:

$$D^2\ L\ N = d\ h \times 107{,}000.$$

Speed of Exhaust Gases through Pipe.

D = cylinder diameter in inches.
L = length of stroke.
N = R. P. M.
S = allowable speed of gas in feet per minute = 6,550.
a = area of exhaust pipe (nominal).

The designer's formula is:

$$a = \frac{D^2\ L\ N}{50{,}000}.$$

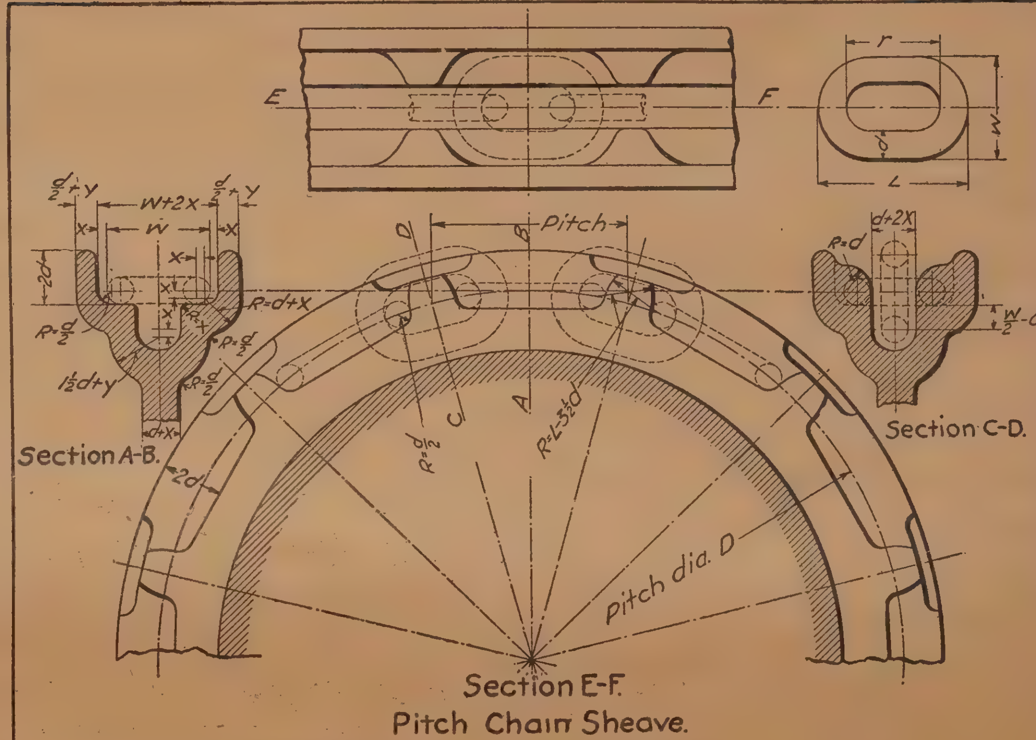
Speed of Gases through Inlet Pipe.

The designer's formula is:

$$a = \frac{D^2\ L\ N}{80{,}000}.$$

S = 10,000 feet per minute.

SPROCKET WHEELS FOR ORDINARY LINK CHAINS.—I.



Formula $D = \sqrt{\left(\frac{r}{\sin\alpha}\right)^2 + \left(\frac{d}{\cos\alpha}\right)^2}$

$\alpha^\circ = \frac{90}{N}$ (Hütte Pag. 502-I)

Two-cycle Port Design.

The design of ports for two-cycle engines depends upon two important factors. First the height of the port determines the valve timing of the engine, and this timing must be arranged to give the proper results when the engine is running at slow speed. Next, the ports must be extended around the cylinder until a sufficient area is obtained to give the required engine speed. The two points then to consider are valve timing, and limiting gas velocities. This valve timing is very nearly constant for all the engines, the average values being 88 degrees for the inlet ports and 110 degrees for the exhaust ports. The velocity of the gases through the ports was found by assuming full port opening from the time the port began to open to the time it closes. The exhaust gas velocity was found to be quite constant at about 7,500 feet per minute. The inlet gas velocity varied with the crank case pressure, but as this pressure is either about 4 or 8 pounds, we find two values for inlet gas velocity. The gas velocity corresponding to 4 pounds is 12,000 foot-minutes, while that corresponding to 8 pounds is 24,000 foot-minutes.

Compression Pressure and Clearance.

Theoretically the compression of an engine depends upon the clearance, and from theory we can compute the compression of any engine of which we know the clearance volume. In practice we never get a full cylinder of explosive mixture, and the percentage which we do get depends upon the engine speed, the amount the engine is cooled, the temperature of entering charge, and the make of carburetor. The compression pressure varies directly as the square root of the R. P. M. and inversely as the square of the diameter of cylinder and inversely as the clearance to the 4/3 power.

A curve plotted between compression pressure and

$\sqrt{\frac{\text{R. P. M.}}{D^2 \times Cl^{\frac{4}{3}}}}$ gives $\sqrt{\frac{\text{R. P. M.}}{D^2 \times Cl^{\frac{4}{3}}}} = \frac{1}{2.25}$ compression absolute + 15.

W. B. Jr.

DENATURED ALCOHOL.

Consular Report No. 2666.

The strongest alcohol of commerce in the United States is usually 95 per cent alcohol and the price varies from $2.30 to $2.50 per gallon, showing that the greater part of the cost is due to the revenue levied by the government. The greater part of the 60,000,000 gallons of alcohol consumed in the United States is used in the manufacture of whisky and other beverages. The revenue tax prevents the use of alcohol to any great extent in the industries of the country. The bill passed at the last Congress, designed to promote the use of untaxed alcohol in the arts and as fuel, takes effect January 1, 1907. The first effect of free alcohol will be, it is said, to supplant the 12,000,000 gallons of wood alcohol which are used in the manufacture of paints, varnishes, shellacs, and other purposes. Another use that is expected of denatured alcohol is in the manufacture of certain products, such as dyestuffs and chemicals, which cannot now be manufactured commercially in this country because of the high cost of alcohol, and which are imported largely from Europe. A very rapid development of the industry of manufacturing chemicals as a result of free alcohol is looked for. In the production of alcohol there is always formed as a by-product a certain amount of fusel oil, which is very useful in manufacturing lacquers which are used on metallic substances, fine hardware, gas fixtures, and similar articles. The industries manufacturing these wares will undoubtedly receive a great stimulus as a result of cheaper fusel oil caused by the increased production of alcohol.

The use of denatured alcohol as a fuel has yet to be fully developed. Although alcohol has only about half the heating power of kerosene or gasoline, gallon for gallon, yet it has many valuable properties which may enable it to compete successfully in spite of its lower fuel value. In the first place it is very much safer. Alcohol has a tendency to simply heat the surrounding vapors and produce currents of hot gases which are not usually brought to high enough temperature to inflame articles at a distance. It can be easily diluted with water, and when it is diluted to more than one-half it ceases to be inflammable. Hence it may be readily extinguished, while burning gasoline, by floating on the water, simply spreads its flame when water is applied to it. Although alcohol has far less heating capacity than gasoline, the best experts believe that it will develop a much higher percentage of efficiency in motors than does gasoline. Since gasoline represents only about 2 per cent of the petroleum which is refined, its supply is limited and its price must constantly rise, in view of the enormous demand made for it for automobiles and gasoline engines in general. This will open a new opportunity for denatured alcohol. Industrial alcohol is now used in Germany in small portable lamps, which give it all the effects of a mantel burner heated by gas. The expense for alcohol is only about two-thirds as much per candlepower as is the cost of kerosene. Even at 25 or 30 cents a gallon, denatured alcohol can successfully compete with kerosene as a means of lighting.

SPROCKET WHEELS FOR ORDINARY LINK CHAINS.

In determining the pitch diameter of a sprocket wheel for use with the ordinary elliptical link chain, the geometrical problem involved is that of finding the diameter of a circle whose circumference can be spaced off into a given number of alternate long and short chords of given lengths. The dimensions of the chain and the number of teeth desired in the wheel form the conditions which determine the pitch diameter. As may be seen by referring to Plate I. in the Supplement, the form of sprocket wheel there detailed has one tooth for every two links. The dimensions which concern us in finding the pitch diameter of the sprocket wheel are: d, the diameter of the stock from which the link is made; and r, the pitch of the chain or length of the opening in the link. These dimensions are shown in the upper right-hand figure of Plate I. Given the number of teeth desired in the wheel, and these two dimensions, d and r, the formula for the pitch diameter, which is taken from a German handbook (*Hütte, Des Ingenieur Taschenbuch;* page 502—I.) is

$$D = \sqrt{\left(\frac{r}{\sin \alpha}\right)^2 + \left(\frac{d}{\cos \alpha}\right)^2}$$

in which $\alpha = \frac{90°}{N}$ when $N =$ the number of teeth. Referring to Fig. 1 below, which shows the impossible three-tooth sprocket for the sake of having the lines on a large scale, the derivation of the formula can readily be followed. The pitch circle passes, naturally, through o, the center of the circle

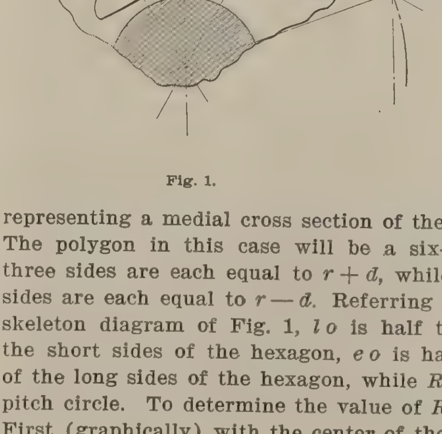

Fig. 1.

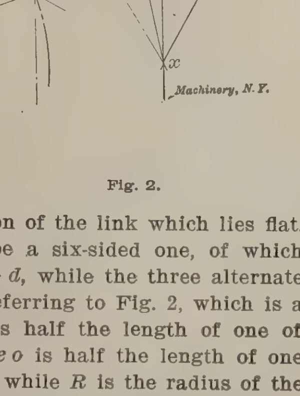

Fig. 2.

representing a medial cross section of the link which lies flat. The polygon in this case will be a six-sided one, of which three sides are each equal to $r + d$, while the three alternate sides are each equal to $r - d$. Referring to Fig. 2, which is a skeleton diagram of Fig. 1, $l\,o$ is half the length of one of the short sides of the hexagon, $e\,o$ is half the length of one of the long sides of the hexagon, while R is the radius of the pitch circle. To determine the value of R proceed as follows: First (graphically) with the center of the sprocket at x, draw

$g\,x$ and $f\,x$ at an angle of a degrees either side of vertical line $h\,x$. Construct the two right-angle triangles, $h\,g\,x$, and $h\,f\,x$, in which $h\,g$ and $h\,f$ each equal $r/2$ or half the pitch of the chain. To find the position of the center of the circular section of the flat link, draw the line $j\,o$ parallel with $g\,x$ at a distance of $d/2$ to the left of h. Draw also line $k\,o$ parallel to $l\,x$ at a distance $d/2$ to the left of h. Then, evidently, the point of intersection o will be the location of the center of the chain section, and R will be the radius of the pitch circle.

To solve this mathematically the problem may be analyzed as follows: In addition to lines previously drawn, draw $h\,m$ tangent to the circle representing the section of the chain, continue $l\,o$ to n and draw $o\,h$. We have first to prove that $\angle h\,o\,m = \angle h\,x\,g = a$. By construction $h\,f$ and $h\,g$ are portions of sides of a regular polygon of n sides, 6 in this case. The exterior angle of a regular polygon is equal to $360°/n$; therefore $\angle\ q\,h\,g$, the exterior angle of $\angle\ f\,h\,g, = 360°/n = 2\,a$. By construction, the sides of $\angle\ n\,o\,m$ and $\angle\ q\,h\,g$ are parallel, therefore the angles are equal; therefore $\angle\ n\,o\,m = 2\,a$. Since $p\,h$ and $m\,h$ are both tangent to the circle, it can be easily shown that line $o\,h$ bisects $\angle\ n\,o\,m$. Therefore $\angle h\,o\,m = a$. Since $o\,m = d/2$, $o\,h = \dfrac{d}{2 \times \cos a}$. Again, since $h\,g = r/2$, we have $h\,x = \dfrac{r}{2 \times \sin a}$. We know that $o\,h\,x$ is a right-angle triangle, since line $o\,h$ bisects the exterior angle of the regular polygon represented by lines $h\,f$ and $h\,g$; this polygon has its center at x. Triangle $o\,h\,x$ is therefore a right-angle triangle whose sides $o\,h$ and $h\,x$ we have just obtained, and from which we may readily obtain the value of R. This will evidently be expressed by the following equation:

$$R = \sqrt{\left(\frac{r}{2 \times \sin a}\right)^2 + \left(\frac{d}{2 \times \cos a}\right)^2}$$

Rearranging this equation to give the value of the pitch diameter directly we have

$$D = \sqrt{\left(\frac{r}{\sin a}\right)^2 + \left(\frac{d}{\cos a}\right)^2}$$

The tables in Plates II. and III. of the supplement give the pitch diameters of sprocket wheels for use with chains of various regular sizes from 3/16 inch stock to 1⅝ inch stock, for sprockets having 5 to 30 teeth. For instance, for an 18-tooth sprocket with a chain made from links of stock ½ inch in diameter the chain link being 2½ inches over all, the diameter will be 17.21. At the right of each of these tables are given two columns headed "x" and "y." These give constants to which reference is made in the dimensions on Plate I. These tables were contributed by Mr. F. Wackermann, chief draftsman of the Jones & Laughlin Steel Co., Pittsburg.

* * *

THE STRENGTH OF GEAR TEETH.

The formula known as "Lewis formula," given in Kent's handbook and in general use for determining the strength of gears is $W = S\,p\,f\,y$ in which

$W =$ the load transmitted.

$S =$ the safe working stress of the material, taken at 8,000 pounds for cast iron when the working speed is 100 feet or less per minute.

$p =$ the circular pitch.

$f =$ the face in inches.

$y =$ a factor taken from a table furnished whose value depends upon the shape of the tooth.

Our contributor, Mr. E. H. Fish, of the Worcester Polytechnic Institute, has prepared a tabulation of the quantities involved in this formula (see Supplement) which makes it somewhat more convenient for use than is the original form in which it was published. The formula proposed by Mr. Fish is

$$W = \frac{S\,f\,W'}{1{,}000\,P}$$

in which

$W =$ the load transmitted in pounds.

$S =$ safe fiber stress.

$W' =$ load carried by a gear 1 diametral pitch, 1 inch face at a maximum fiber stress of 1,000 pounds.

$f =$ face in inches.

$P =$ diametral pitch.

In obtaining the value for W', which is here given for 15-degree involute teeth only, the corresponding value of y in the table given in the handbook is multiplied by 1,000 to include the factor for maximum fiber stresses, and again by π to change the factor from one depending on circumferential pitch to one depending upon diametral pitch. This, carried through the scale from 12 teeth to the rack, gives the table shown in Plate IV. of the supplement; the table of stresses is self explanatory.

To show the use of this formula and the tables with it, let it be required to find the safe load which can be carried by a 4-pitch gear, 40 teeth, 2 inches wide, running with a peripheral speed of 600 feet per minute. This gear is made of steel and is supposed to be subject to considerable shock, so we will use the lower value given for that material in the table of stresses. With a surface speed of 600 feet per minute, the table gives 8,000 pounds as the safe fiber stress for a steel gear subject to shock. The value for the factor W' for 15-degree involute tooth in a gear having 40 teeth is found from the other table to be about 340. Substituting our known quantities in equation,

$$W = \frac{S\,f\,w'}{1{,}000\,P}$$

we have

$$W = \frac{8{,}000 \times 2 \times 340}{1{,}000 \times 2} = 2{,}720 \text{ pounds.}$$

* * *

FRESH WATER PONDS IN THE OCEAN.

A curious phenomenon often noticed in navigation is the existence of shallow ponds or lakes of fresh water on the surface of sea water. The cause of this isolation of fresh water is not fully known but is believed to be principally due to the melting of icebergs, and a subsequent lack of wind and currents to cause a mixture. A still more curious feature is that these strata of fresh water oppose considerably greater resistance to the progress of a vessel than does salt water. An explanation offered is that the passage of the vessel causes two sets of waves in the two strata of water—in short, relative movement which causes friction and retardation of motion. That such relative movement exists was proven experimentally. A large plate glass tank was filled to a certain depth with salt water and then a layer of fresh water was carefully poured on the surface so that two distinct layers of water were obtained. The salt water had been blackened with Chinese ink so that the junction of the two layers of water was clearly distinct. A boat model towed through the tank produced waves which were photographed and these photographs, it is claimed, showed conclusively that waves were set up at the boundary line between the two liquids. The experiment was also extended to actually demonstrate that a greater loss of headway does take place in a tank filled with layers of water of different density than in one filled with water of the same density throughout.

* * *

THE DRYING OF DAMP GOODS IN WET WEATHER.

During the rainy season, when the air is nearly saturated with moisture, drying takes place very slowly under ordinary circumstances, even if a steady current should pass the material to be dried; but as the capacity of air to absorb moisture varies with the temperature, it may be made more absorbent merely by heating it. For example, when the rain falls heavily in Bombay the temperature is frequently 82 degrees F., while the moisture is 90 per cent of saturation. This represents eleven grains of water per cubic foot. By heating the air to 110 degrees the saturation is reduced from 90 to 42 per cent, roughly, and the air is thus able to absorb as much again of water as it at first contained without being damper than its original condition. In this manner, by simply controlling the temperature of the current of air its drying power may be assured whatever the state of the weather may be.

THE MANUFACTURING ADVANTAGE.

TECUMSEH SWIFT.

When manufacturing businesses prosper and grow to the dimensions of some of our modern concerns they are very apt to lose some of their earlier advantages, and one of these is the closeness of touch, the mutual understanding and sympathy, the complete and automatic cooperation of the manufacturing and the selling ends. It is of the greatest importance that these two should grow up together and that in later years they should not be separated. Some of the most continuously prosperous concerns are those which have kept the manufacturing and the distributing branches of their businesses in the same location and in unsevered relationship. It is sufficient to mention the Brown & Sharpe Mfg. Co., the Warner & Swasey Co., the Eastman Kodak Co., and the National Cash Register Co. Surely each of these, and many others which might be mentioned, would have as much reason for locating their main business offices in New York City as most of these who are there, but it is easy to believe that any of these would be losers rather than gainers by such a change.

I, of course, am not writing with the slightest idea of changing the trend of business practice, but only in the way of suggesting how to make the best of it. It would be well for all of us here in the big New York offices and better for the companies with which we are connected if we were better acquainted with our shops and factories. If any of us here at the selling end, as we call it, ever run short of talking material and need filling up, the factory is the place to visit and to hang around. The true inwardness of all our product is revealed there, and the ability to tell the actual facts as to the construction and operation of all the machines we make is the surest way not only to the immediate selling of any specific thing but also to the building up of lasting business. Knowing that the product of our company has made its way upon its merits we can only hope to see it still progress along the same road. It is most essential that the fullest information concerning our output be widely spread abroad, and it can't be spread too thickly.

Not only should the public know as much as we can get it to know about the machines we build, but it would be well, also, for it to know about the magnificent and costly facilities we have for the building of them. The advantage which the large concern, when dominated by large ideas, has over the small competitor with small ideas is one of the most evident facts of modern manufacturing, and the calling of attention to it is legitimate business.

There is no occasion for hesitation about revealing things. Just as it has been demonstrated to pay best to tell the truth, the whole truth and nothing but the truth about the machines and tools of our entire list, I think it pays also to tell just as straight and just as fully and freely about our ways and means for making them. It may be that there are things at our factory which are more or less trade secrets and which it may be to our advantage not to let our competitors know about. If anyone knows what these things are he knows more than I do.

There are, however, many things at our factory which cannot possibly require any holding back or any reticence about, and which may be really among the strongest of talking material. It is possible for me to be very specific and precise here. Of course all the world knows our company as the largest builders of—say, gas engine pumps—in the world. The other day I was at the factory and I came along by a radial drill where a fellow was drilling a gas engine pump bedplate. I guess it was a 20 × 24-inch, and we all know that is a pretty big casting. It is about 15 feet long and 4 feet wide. The bedplate had been planed or milled—it might be revealing one of these trade secrets to tell how this was done—and the planing had left the casting entirely ready for the drilling. You should realize what an immense jig was used for this job. It was as big as the entire top of the bedplate and stiff and heavy enough to stand rough handling and to insure precision in use. It was a jig complete in every respect, with full provision for accurate setting and secure holding and with steel thimbles for all the holes to be drilled. One end of the jig was just planed to fit in between the planed jaws of the main bearings, and two feet resting on the planed flat surfaces of the crosshead slides were finished vertically on the outsides to just coincide with the planed outside edges of the slides. This located the jig laterally and other means equally simple and effective located it longitudinally, and then with screws set up horizontally in the different directions to keep it from sliding, and bolts at different points to hold it down it was all ready for the drilling. The casting was on rollers on the floor and the radial drill in combination with one or two movements of the casting lengthwise commanded all the holes.

This jig of course implies other jigs for the cylinders and the other pieces whose holes must absolutely coincide with those drilled in the bed; and this jig would be entirely worthless without the others, so that the entire outfit cost a lot of money. There is, of course, nothing about the jig requiring any special talent to design or any special skill to work. There are hundreds of men in hundreds of shops who could get up such a set of jigs for such a job, some of them perhaps not as good as this, some perhaps a little better, and there is absolutely no secret or novelty anywhere about the job.

The advantages resulting from the use of the jig in the processes of manufacture are more or less evident, although it takes some thought to get completely at the number and magnitude of them. The most evident and immediate advantage is in the saving of time. Suppose that the cylinders were laid out and drilled first, and the caps for the main bearings and the upper crosshead slides, and then that these all had to be carefully located on the bed "in the good old-fashioned way," to have the holes scratched through them on to the bedplate surface. Then these pieces would all have to be lifted off and the holes would then be prick-punched all around. Then there would be the careful starting of the drill for each hole, the coaxing of the centers this way or that and the not very accurate drilling of the holes after all.

When it came to the final setting and bolting on of the several pieces there would be more or less trouble and trimming of the holes and filing here and there, and the pieces finally fitted to one bed would never quite correctly fit any other. Throughout the job thus done "in the good old way," or even in the way of the small shop to-day, greater skill and care would be required all through, the job would not be nearly as good in any respect, and the cost of the work would be two or three times as great.

I don't know a thing about the figures in this case, but I suppose that when you can build gas engine pumps with cylinders as large as 20 × 24 inches, or other styles and sizes in lots of ten at a time, I am willing to believe that the entire jig outfit will pay for itself on the first batch, that the customers will get much better machines with full interchangeability, and that the company in all subsequent uses of the jigs will get a big interest on their far-seeing investment.

It is not merely, nor hardly at all, the capital of the big company which brings it this opportunity which it uses to its great advantage. It is the large sale of each established line of its product which alone warrants the expenditure. The small concern which must build its gas engine pumps in ones or twos, and which must be continually changing its product in some of its details in the struggle to keep up with the procession, cannot afford and cannot make it pay to rig up in this way, so that no matter how much they may know about the way to do it they must still "jog on the footpath way."

The seeing of the opportunities for economy with precision, and the constant and persistent taking advantage of them at the factory cannot be too highly commended, and the highest commendation lies in full appreciation, and what we fully appreciate we are likely to talk long and loud about, so the one thing to do is to insist upon it that all of our customers, especially those of the future, shall be completely informed as to how we do things, both for their good and for our own.

Whether machines shall be built in quantities which will warrant elaborate and costly preparation is, after all, in the hands of the selling force, for they must sell in commensurate quantities to sustain the production rate, and this is more likely to be realized and worked out to success the more the two ends of the business come in touch with each other.

CHARLES E. BILLINGS.

REPRESENTATIVE AMERICAN MECHANICS AND ENGINEERS.

Charles E. Billings was born in Weathersfield, Vt., December 5, 1835. In his early years he worked in the blacksmith shop of his father, and at the age of seventeen he went to work in the machine works of Robbins & Lawrence Co., Windsor, Vt., which was one of the pioneer machine-building concerns of this country. While serving his apprenticeship the company built a considerable number of milling, drilling, rifling and gun-stock turning machines for the Enfield Armory of Great Britain for the manufacture of the celebrated Enfield rifles. His foreman was Frederick Howe, of Windsor, Vt., who later became superintendent of the Providence Tool Co., and was later superintendent of the Brown & Sharpe Mfg. Co. The Robbins & Lawrence Co. also manufactured a firearm for the United States government known as the Harper's Ferry rifle, and Mr. Billings spent most of his time in the gun department. Here he first became acquainted with the primitive methods then employed for forging the various parts of guns, which he has described as follows (see MACHINERY, May, 1895): "A heavy cast-iron block called the 'sow block' with a suitable opening in the top for the lower die was held fast by keys and stock to guide the upper die, termed the 'jumper.' In the face of the die the forms to be forged were cut as at present, the power being applied by hand hammers and sledges wielded by the smith and his helpers, on the upper die, with the heated bar of metal held between them. Much time was spent in distributing the stock on the end of the bar of metal before the sledging took place in order to have the metal flow properly to fill the points of the die."

It was here, also, that Mr. Billings first saw a drop hammer, which was the forerunner of the present type. It was a crude affair with cast-iron base and uprights, the latter carrying a shaft at right angles on which was mounted a loose pulley for a belt and also a spool with flanges, for winding the belt. One end of the belt was attached to the spool and the other to a hammer. A clutch on the end of the shaft operated by a lever wound the belt on the spool and raised the hammer which was held at the height required by a dog on the side of the upright. This was tripped by a pedal when a blow was delivered.

Mr. Billings' experience in the gun department of the Robbins & Lawrence Co. naturally inclined him to this kind of work, and after becoming of age (1856) he went to Hartford, Conn., and entered the employ of Colt's Patent Firearms Mfg. Co. as a toolmaker and die-sinker in the forging department. Here he first saw a practical working drop hammer, being one designed by Elias K. Root, then superintendent of the works. In this way it happens that Samuel Colt is generally credited with being the pioneer in the manufacture and use of modern drop forgings or "machine blacksmithing," as they are sometimes called.

Mr. Billings remained at Colt's from 1856 until 1862, when he accepted a position with the gun factory of E. Remington & Sons, Ilion, N. Y., to introduce the manufacture of drop forgings. E. Remington & Sons had heretofore never used drop forgings in their gun work, but when the various governments required wrought frames for army and navy pistols it became necessary to use them. Mr. Billings superintended the drop forging plant and introduced his method of forging pistol frames, which was somewhat different from that used by Colt. During the four years he stayed at Ilion a saving of $50,000 was effected on government contracts by one simple feature of his method which saved about one pound of metal for each pistol frame, which had hitherto been rejected as waste. The iron being imported at the time was worth 20 cents per pound, hence the importance of avoiding all unnecessary production of scrap.

Returning to Hartford in 1865, Mr. Billings acted as superintendent of the manufacturing department of the Weed Sewing Machine Co., where he introduced drop hammers for forging the parts of sewing machines, especially the shuttles, which had formerly been made in several pieces brazed together. In 1867 he patented a process for drop forging shuttles from a single piece of steel, thereby effecting a great improvement in this part. In 1869 Mr. Billings left the Weed Sewing Machine Co., and in company with Mr. Christopher M. Spencer organized the Billings & Spencer Co. to manufacture sewing machine shuttles. The company also was interested in the manufacture of the Roper repeating shot gun, which, however, resulted unsatisfactorily, and in 1870 the manufacture of drop forgings was taken up as a specialty and has continued so since. Mr. Billings has made a considerable number of inventions, including wrenches, ratchet drills, measuring instruments, etc. A variety of machinists' tools are now manufactured by the company, being finished from the drop forgings in the machine department of the plant.

Although closely identified with the early development of the drop forging business and in a large sense a pioneer in the industry, Mr. Billings considers that one of his most important achievements made in this line was as late as 1886, when his attention was first called to the existing method of making commutator bars for electric generators while on a visit to the Edison Electric Works. These parts, at that time, were made of two pieces of copper, set together so as to form the well-known characteristic shape, and secured by pins and solder. This method of manufacturing was expensive and frequent interruptions of circuit were caused by the parts becoming separated, thus necessitating the taking apart of the commutator before the part could be gotten out and repaired. Mr. Billings suggested that the commutator segments could be drop forged to shape from pure copper, but his idea was not considered feasible by the foreman of the department. Nevertheless, upon returning home, dies were made and in a few weeks he sent to the Edison Co. drop-forged commutator bars made from pure copper having a homogeneous molecular structure throughout and of great density, and obviously of high electrical conductivity. The cost of making commutator segments was greatly reduced by the drop-forging process and the efficiency of these parts increased to a corresponding degree.

Mr. Billings is past president of the American Society of Mechanical Engineers, succeeding from the vice-presidency in 1895 upon the death of Mr. E. F. C. Davis, then president.

THE MILAN EXPOSITION.

The Milan Exposition has been somewhat of a disappointment to machinery exhibitors who have gone to a heavy outlay in order to secure a creditable representation. The extreme heat in Italy during the summer months has kept the attendance at a low figure, but it was expected that this would improve as the weather became cooler, as there are many attractive features in the exposition and in the progressive city of Milan, which is the principal manufacturing center in Italy, the machine tool industry being particularly active at

present on account of the expansion in the automobile trade. The exposition is peculiar in occupying two distinct and separate sections of ground some distance apart, connected by an electric elevated railway, which is a small mint to its owners. The exhibits occupy one section of the grounds, and the other, which comprises the municipal park, is devoted largely to amusement features, being laid out in the attractive way which Europeans are past masters of.

There are two exceedingly good exhibits of American machine tools at the exposition—made by Stüssi & Zweifel of Milan, and Alfred H. Schütte. Stüssi & Zweifel showed six Brown & Sharpe machines in operation—a No. 3-A universal milling machine, a No. 5 plain milling machine, a No. 3 universal grinding machine, a No. 13 automatic gear cutting machine, a No. 2 automatic screw machine, a No. 13 universal and tool grinding machine—and the following: Five Pratt & Whitney machines, including a 10-inch toolmaker's engine lathe, a 2 x 26-inch turret lathe, a 6 x 48-inch thread milling machine, an automatic cutter grinder, a 12-inch measuring machine and a case of Pratt & Whitney's small tools, assorted; five Hendey-Norton machines, including a 24-inch x 12-foot lathe, 14-inch x 6-foot lathe, with taper attachment; 16-inch x 8-foot lathe, with taper attachment; 18-inch x 8-foot lathe; 24-inch shaper; a Barnes drilling machine and grinding machine, and a 36-inch Bullard vertical turret lathe.

The other exhibit is made by the Milan house of Alfred H. Schütte, showing a 21-inch Gisholt turret lathe and tool grinder, a Potter & Johnston semi-automatic turret lathe, new model, 8½ x 16-inch; a Lodge & Shipley 8-inch x 10-foot lathe for high-speed steel; an 18-inch x 8-foot Bradford lathe; two Cincinnati drills, 21-inch and 32-inch; a No. 1 Bickford radial (improved pattern); a Baker Bros. vertical cylinder boring machine; a Baker Bros. key seater; a No. 3 Landis universal grinder; two Cincinnati milling machines, No. 3 plain and No. 1½ universal; a Cincinnati tool grinder; two 2-inch Cleveland automatic lathes, one with three-hole turret head and one with five-hole turret head; a No. 4 Acme automatic lathe with four spindles; a 26-inch x 6-foot Gray planing machine; a complete plant of pneumatic tools with air compressor by the Consolidated Pneumatic Tool Co., Ltd., an American Machine Tool Company's oil separator; a Washburn drill grinder; a Peerless belt lacing machine, and a set of Starrett's tools and gages.

Other American firms show miscellaneous machinery, and there is the usual variety of manufactured articles representing the different European countries.

* * *

TIME SAVING IN EXTRACTING THE SQUARE ROOT.

It had been the writer's practice for some time, when doing work which required frequent extracting of the square root of quantities, to work with a handbook on his table opened to the table of squares and square roots. Often, however, the three places to which the primary number in these tables are generally carried did not suffice to give the required degree of accuracy. Under these circumstances the extraction of the root was carried as much further as was necessary by the usual methods outlined in the arithmetics. In looking over an algebra the other day, however, the writer's attention was called to a principle which was there explained and proven, to the effect that after $n+1$ figures of a root have been obtained, the remaining figures may be found by simple division. This principle has been found so useful that it is here described with the thought that it may save others quite a bit of mathematical drudgery.

Suppose it is required to extract the square root of 152,409,694. Pointing off in the usual fashion and finding the first three figures of the answer, either by comparing with a table of square roots as suggested, or by the ordinary method, our problem stands as follows, with the remainder given.

$$\begin{array}{r|l} 152{,}409{,}694 & 12300 \\ 151{,}290{,}000 & \\ \hline 1{,}119{,}694 & \end{array}$$

We have now found $n+1$ or three figures of the root. We can find the n or two remaining figures, as suggested above, by simple division. Multiplying the partial root by 2 in the usual manner and dividing the remainder by it we have:

$$\frac{1{,}119{,}694}{2 \times 12{,}300} = 45 +$$

which gives 45 as the next two figures of the root, so, adding the five figures thus obtained together, we have 12,345 + as the result. If we desire to proceed still further we may again find by simple division the answer to four places of decimals. We have found $n+1$, or in this case five figures, so that it is possible to obtain n or four figures more. After performing the division indicated above, we have 12,694 as the remainder; subtracting from this remainder the square of the portion of the root just found. This gives us

$$\begin{array}{lr} \text{Remainder} = & 12{,}694 \\ 45^2 \quad = & 2{,}025 \\ \hline & 10{,}669 \end{array}$$

Proceeding as before to divide this remainder by twice the quotient of the root already found and carrying the division out to the fourth decimal place we have

$$\frac{10{,}669}{2 \times 12{,}345} = 0.4321 +$$

which may be added to that part of the root previously found, giving us 12,345.4321.

It would now be entirely possible, having found nine figures of the root, to obtain eight more in the same way. To do this we would, as before, subtract from the remainder of the last division the square root of the quotient obtained by that division, and then divide the result by twice the portion of the root already found, carrying the division out to eight new places, which may be added to the answer. This process will be found easy with or without the help of the handbook, and gives the required results with considerably less calculation than would otherwise be necessary. A similar plan may be used in extracting the cube root. In this case after $n+2$ figures of the root have been found, n more figures may be obtained by dividing the remainder by three times the portion of the root already found. As this operation is repeated, however, it becomes more cumbersome in the case of the extraction of the cube root.

The process as applied to finding the square root may be expressed by the following rule:

1. Having found any number of figures of the root by any process, subtract the square of the portion of the root thus found from the original quantity.
2. Divide the remainder found, in Operation 1, by twice the portion of the root already found, carrying the quotient to one less number of figures than there are figures in the portion of the root already found. This quotient is to be added to the portion of the root already found.
3. Subtract from the remainder left after the division in Operation 2, the square of the quotient therein found, and divide the result by twice the whole root, so far as found, carrying the division to one less number of steps than there are places in the root so far as found. Add this quotient to the root so far as found.

On analysis Operation 3 will be found to be identical with Operations 1 and 2 combined. Operation 3 may be repeated until the cows come home, with increasing difficulty, but with increasing effectiveness in the number of new figures added at one operation.

R. E. F.

* * *

We are informed by Mr. J. F. Lockwood, manager of the Security Elevator Safety Co., New York, that the Cruikshank elevator safety was *not* involved in the scheme which certain elevator interests tried to foist on New York city some years ago; this took the shape of an ordinance which would have prevented other elevator safeties being used in that city, hence would have effected a virtual monopoly. Mr. Lockwood tells us that the Cruikshank device, owned by his company, has been adopted in a large number of the best buildings in New York City and in many of the government buildings throughout the United States. We are glad to make this correction, with reference to the article "Shock Absorber" in the July issue, and to know that the parties representing this interesting and valuable device were not in the deal referred to.

A NOVEL CRANK ARRANGEMENT FOR SINGLE-ACTING INTERNAL COMBUSTION ENGINES.

Mr. Robert H. Ramsey, of Philadelphia, has brought out a novel arrangement of crank mechanism for use with single-action internal combustion engines, by means of which the side thrust on the piston, during the power stroke is considerably reduced, and at the same time the portion of the revolution effected by this stroke is increased, while the length of crank for a given stroke is reduced. The difference between the ordinary and the Ramsey arrangement is that in the latter the center line of the cylinder runs in a line tangent to the crank circle, as is illustrated in Fig. 1. The solid circle shows the path of the crank in the Ramsey mechanism, and the broken line circle is the crank path of the ordinary

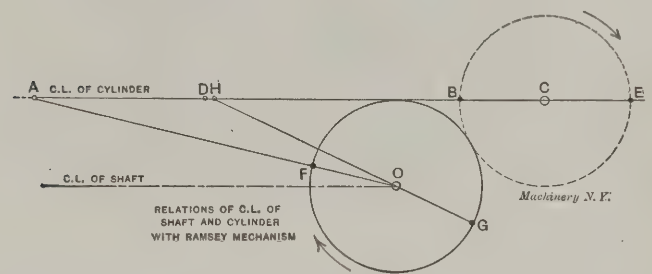

Fig. 1. Novel Crank Arrangement for Internal Combustion Engines.

design. In the latter design, the stroke *A D* of the piston is equal to the diameter *B E* of the crank circle, but in the Ramsey design the stroke for the same length of crank is *A H*. During the power stroke, the crank revolves from *F* over the upper part of the circle to *G*, which, as will be seen, is more than half a revolution. It will also be seen that for quite an angular distance just before reaching the half stroke the connecting rod is very nearly in line with the cylinder,

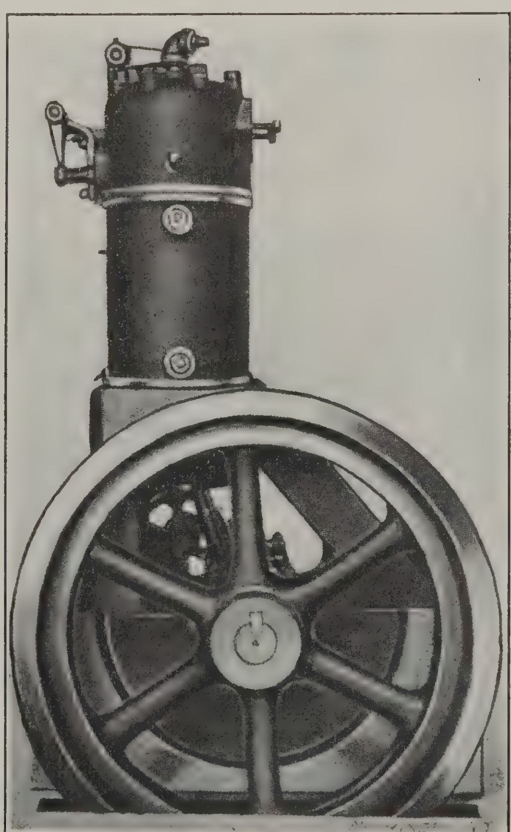

Fig. 2. Ramsey Engine showing Offset of Cylinder.

and at the beginning of the stroke the angle of the connecting rod is less than with the centrally located crank shaft. At the end of the stroke the connecting rod angle becomes greater, but at this point the pressure in the cylinder is greatly reduced; therefore, taking the power stroke as a whole, the side thrust is considerably less than with the standard arrangement of crank, and on that account the connecting rod can be made shorter. During the compression stroke the connecting rod angle is greater than with the central crank shaft, but at the same time the compression pressure is only about one-quarter of the working stroke pressure, and during the first part of the stroke, when the angle is greatest, the compression is very low, so that taken all in all, what is gained in reduced side thrust on the power stroke is much more than what is lost during the compression stroke.

W. B. Jr.

[The Ramsey crank mechanism discussed in the preceding paragraphs has been fully described in most of the technical papers of the country. We do not, however, remember to have seen it mentioned that one of the most interesting things about it is the fact that it at once invites discussion, first, as to the patentability of the principle involved, and second as to the usefulness of the device. If the patent granted covers the principle of locating the center line of the cylinder tangent to the circle described by the crankpin, this claim could be avoided by moving the cylinder slightly to one side or the other of its position. If the absolute location of the cylinder axis is not important, but merely the principle of offsetting the cylinder, that has been used for many years, notably in the case of the Westinghouse "standard" steam engine, of which thousands have been built with the center line offset by an amount equal to one-half the crank length. Granting its patentability, a little thought will still show that the claims made for the device, while they may be valid, cannot be expressed and proved in the simple fashion in which the promoters of the device have undertaken to do it.—Editor.]

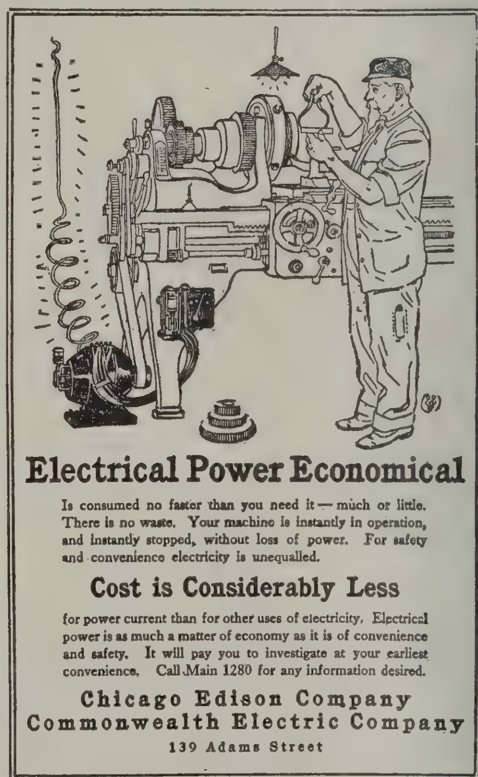
SOMETHING NEW IN MOTOR DRIVE!



—From Chicago *Daily News*.

* * *

A BURGLAR-PROOF VAULT.

Mr. Morris M. Defrees, a civil engineer of Indianapolis, has designed a safe deposit vault, which is described in the *Cement Age*. The initial step in the construction of this fire- and burglar-proof vault consists in the erection of a cage around which concrete is poured. This cage covers the sides, top and bottom of the vault, and is composed of a lattice work of ¾-inch gas pipe, each pipe having inside a steel bar ½-inch in diameter. Assuming that the burglar had the good fortune to get through the concrete and the pipe, he would meet an insurmountable difficulty in striking the bar, for his saw would then come in contact with a movable body on which no purchase is possible. It is suggested that the reinforcing cage be made double with the vertical and horizontal bars of the outer cage staggered in relation to those of the inner cage. Mr. Defrees advises, in the making of the concrete, a mixture of 1 part of cement and 3 of sand as being harder than concrete containing stone or gravel.

LETTERS UPON PRACTICAL SUBJECTS.

THREE-SPINDLE DRILLING ATTACHMENT.

There is nothing elaborate in the construction of tools for the manufacture of dental chairs, because there are constant changes being made in the design of the product which necessitate sometimes a radical change in the tools, even to discarding some of them altogether. The part of the chair called the "cylinder" has three holes drilled in it, equally spaced around its periphery. These pieces have heretofore been drilled at the rate of two per hour, but with the three-spindle attachment herein described, we drill five per hour with accurate results. We have a number of Snyder drill presses in the shop, and it is to one of these that the device is shown attached in Fig. 1. Its members are fastened together in such a way that they may be detached easily and the press used for other work. Details of the device are shown in Fig. 2.

Referring to this cut the outline shows a bracket-shaped piece, *A*, planed to fit the column of the press; the gibbs *D D'* are held on with retaining bolts (not shown). The flange of the bracket *A*, shown at *e*, is bolted to the spindle bracket and the whole fixture is attached to the machine by the bolts at this place. The spindle bracket when lowered to the limit of its travel, lets the bearing of *A* drop off the bearing on the column. Member *B* is a separate casting, but when bolted to *A*, forms a single unit with it. *B* is the carrier of the three spindles which are driven by cast-iron spur gears on their upper extremity; these three gears (26 teeth, 8 P. one-inch face) are driven by a gear of the same size, in the center, keyed to the spindle of the press. The thrust of the central spindle against the member *B* is taken up by a taper shank piece that carries on its end a ball thrust; this is seen at the dotted lines in the side view, Fig. 2. Ball thrust bearings are provided for each of the three spindles also, as shown. Each spindle is fitted with ball chucks and collets and in drilling this identical job, two sets of Novo drills are employed; the ones seen in the photo are ½-inch drills with extension shanks; on the box in front of the press is the other set, 55/64 inch diameter.

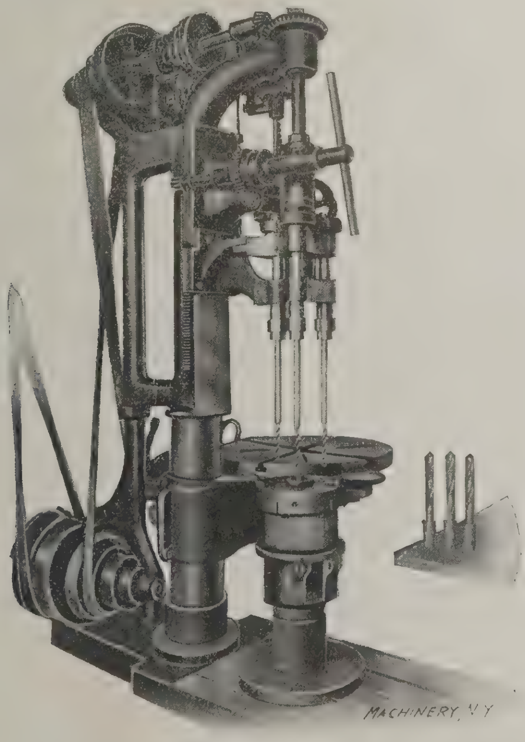


Fig. 1. Drill Press with Three-spindle Drilling Attachment.

The jig is located central with the spindle by means of a hole in the bed, which is exactly in line and central with the spindle; into this hole fits a projection or lug on the bottom of the jig itself.

To remove this attachment, the jig is moved to one side, the drills withdrawn, and the table swung back into place; the fixture is then lowered until the chucks rest on the table, the bolts at *e* are released and the spindle is then free to be raised up and out of *B*. The central gear comes with it, but as it is a slip fit on the spindle it is quickly removed. The fixture being now below the before mentioned bearings of the column it can be laid aside and the press used for other work.

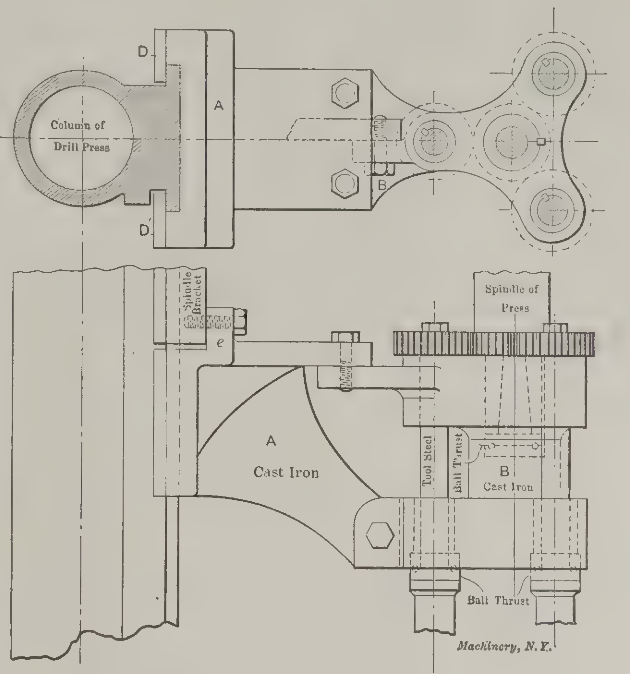

Fig. 2. Details of Three-spindle Drilling Attachment.

The gears are nicely protected by a cast gear guard. It is of course understood that to drive the drills in the right direction, the up and down belt must be crossed.

Rochester, N. Y. CARROLL ASHLEY.

SOME HINTS FOR DRAFTSMEN.

From time to time there have appeared numerous articles relative to drafting room methods, but there are still perhaps many minor suggestions which would be appreciated by many if they were presented.

For example, there is a chance for improvement over the method which is in vogue regarding furnishing the machine department with a print containing many dimensions which do not in any way concern it, but which are used by the patternmaker only. When the pattern has been made and castings made from it, and finally, when the machine is finished and no alterations are to be made on the pattern, the pattern dimensions should be omitted from the machine shop print. It is sometimes customary to make two tracings to accomplish this if the piece is complicated, such as machine beds, etc., but the following method has the advantage of requiring but the one tracing. A finished tracing is made containing all dimensions both for the patternmaker and machinist. The dimensions for the machinist are inked in as usual, but the pattern dimensions are put in with a soft lead pencil. Several prints are taken from the tracing while in this condition, one furnished the pattern shop and as many filed away as desired. The lead pencil dimensions are then erased and the tracing is ready for making prints for the machine shop. In this way the patternmaker can readily understand and pick out his figures, and the machine shop print is kept free from unimportant dimensions which ofttimes cause considerable trouble.

It is sometimes desired to make a tracing of cuts from catalogues, books, etc., and to do this without removing the page. Perhaps it is not well known that by wetting the edges of the starchy side of tracing cloth and rubbing it on the page that it will adhere firmly and the tracing can be done on the dull side without much trouble.

I have found it a good plan when leaving a tracing on the board at night to remove all the tacks from the drawing and tracing except the one which is in the center of the top edge and the one which is in the center of the bottom edge. This allows it to go and come and to be tightened readily in the morning.

In spacing a line for screw threads when it is desired to represent the V, the thread gage furnishes the means as well as anything could; simply choose the pitch and make the impressions.

I have often found that when lines on an outer circle are to be drawn tangent to an inner circle that a cardboard disk is a good substitute for the eccentrolinead and is as much better than a circle as is a pin put in the center for radiating lines, than a lead pencil point.

In order to have a scale divided to one-fourth and one-half size it was necessary to make one, as they are not on the market. The object of making one was for checking purposes only; it could hardly be used for constructing for any length of time, as it is made of paper strips pasted on a wooden strip and shellacked over. The divisions are on bristol board and are engine divided. These paper scales can be procured for a small sum. This makes an excellent rule for checking drawings made one-fourth to one-half size.

It is well to have a piece of blotting paper 2 x 3 inches hung on the wall, for when it is needed it is wanted in a hurry, and this makes a convenient place for it.

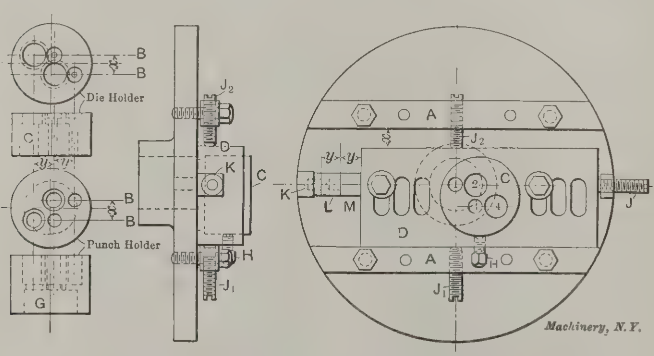
Various means have been devised to keep tracings flat in drawers. They will continue to curl up if the ink is put on the smooth side, but will lay flat of their own accord if ink is put on the dull side.

A small flat oil-can with screw top is very convenient to have among the draftsman's kit; if oil is used frequently on the screws and nuts of instruments they not only work better but last much longer. WINAMAC.

A FACEPLATE RIG FOR BORING PUNCH AND DIE HOLDERS.

At C and G are shown a die holder and a punch holder respectively. In making them the important point to be considered is that the lines B, B, in each case, must be parallel. The rig used to accomplish this is shown in the cut.

The faceplate of the lathe in which the holes were to be bored was taken to the drill press, where it was drilled and tapped to receive the "hexhead" screws and dowel pins by which the two steel strips A and A were fastened to it. In clamping these pieces to the faceplate, cardboard strips about ⅛ inch thick were inserted between them and the faceplate.



Faceplate for Boring Punch and Die Holders.

The faceplate was next taken to the planer and leveled there with the surface gage, face up, and the inner edges of the strips A were planed parallel to each other. The cardboard, in this operation, saves the surface of the faceplate from injury.

Block D was next machined to such a width that, when placed between the strips A and A, dimension x was the same as on pieces C and G. In the center of this block a recess was formed to receive the blank for the punch and die holders, and a setscrew, H, was used to hold them in place. The block D was slotted as shown to accommodate the two bolts used to secure it to the faceplate. Screws J_1, J_2 were tapped into the side strips and in a post at the edge of the plate to adjust block D. In another post, K, were set two plugs, L and M, of which the latter had a projection which telescoped in the first, which in like fashion set in the post. Dimension y of these plugs was made the same as y on punch and die holders C and G.

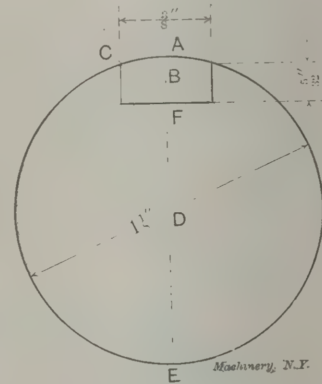
In using the device, the work is clamped in the block D by setscrew H, and with the parts arranged as shown, screws J are tightened up, the block is clamped to the faceplate, and hole No. 1 is bored. The screws are loosened, distance piece M is removed, and, with the screws tightened up again and the other parts arranged as before, hole No. 2 is finished. It is, of course, understood that screw J_1 has not been used all this time. Screw J_2 is now withdrawn and J_1 tightened until the block D seats against the upper strip A, when it is clamped and hole No. 3 is bored. Distance piece L is then removed and the last hole, No. 4, is completed.

This arrangement assures the parallelism of lines B and B in the work, and also makes it certain that the punch will exactly match the die. R. E. HARRYMAN.

Louisville, Ky.

MEASURING KEYWAYS.

I was once milling some keyways that were supposed to be pretty accurate, but the dimension given for depth was not such as could be measured accurately. The depth was given as 5/32 inch at the sides of the cut; now, the cutter could be set for depth comparatively accurately by raising the milling machine table until the cutter was cutting the full width of the keyway and then raising the table 0.15625 inch (= 5/32). This is not very reliable, however, as you cannot see within 0.003 to 0.005 inch and after taking the cut a burr is thrown up at the edge. In filing this off one is apt to take off more or less of the shaft with it, and furthermore the only way to get the depth measurement is with a scale. The first keyway that the boss inspected, seemed to him a trifle deep, but I filed off a little more of the burr (?), and that made it all right. But I wasn't satisfied and wanted some way to measure the depth accurately, with a micrometer, if only to ease my own conscience. I could measure the distance, FE, from the bottom of the keyway to the bottom of the shaft, but what was this measurement? I got a piece of brown paper and borrowed a pencil and started in, while the cutter was running through the next shaft, and soon had it.



Measuring the Depth of a Keyway.

In the right triangle CBD, CD is the radius of the shaft, which is 9/16, or 0.5625 inch, and CB is half the width of the keyway which is 3/16, or 0.1875 inch. Find the side BD of the triangle.

$$(BD)^2 = (9/16)^2 - (3/16)^2$$

$$BD = 0.530 \text{ inch.}$$

Then subtract this from the radius AD,

$$0.5625 - 0.530 = 0.0325 \text{ inch} = AB.$$

Then the whole depth of the keyway from the top of the shaft is $AB + BF$, or

$$0.0325 + 0.15625 = 0.18875 \text{ inch} = AF.$$

Subtract AF from AE to get FE.

$$1.125 \text{ inch} - 0.18875 \text{ inch} = 0.93625 \text{ inch} = FE.$$

Then, when you want to cut the keyway, set the cutter touching the top of the shaft, and run up the table the distance $AF = 0.18875$ inch; and when you want to inspect the finished work, measure $F\ E$ with the micrometer for the dimension 0.93625. C. E. BURNS.

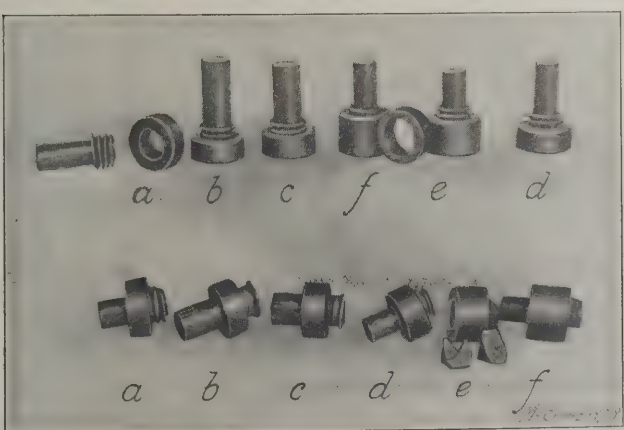
Beverly, Mass.

THE COMPARATIVE STRENGTH OF SCREW THREADS.

C. Bert Padon.

There has been considerable discussion from time to time among mechanics with whom I have worked, as to which of the three forms of thread, V, square and Acme, is the strongest against shear. Having an opportunity during my junior year at the James Millikin University, Decatur, Ill., to do a little laboratory work, I undertook to settle this question with the idea of determining as nearly as possible with the means at hand just what relation these styles of thread bear to each other.

Each of the three forms was tested under two different conditions. First, a screw and nut of each form was made with threads all the same outside diameter, 15/16 inch, and with both screw and nut of the same axial length, 17/32 inch, and of the same material, the grade of steel commonly known in the shop as "machine steel." These three samples are shown at *a*, *b* and *c* in the photograph, in which *a* is the V-thread, *b* the Acme thread, and *c* the square thread. In the second test all three screws were of the same root diameter, about ⅝ inch, and were all made of gray cast iron, while the



Test Pieces used for Finding the Comparative Strength of Screw Threads.

nuts were of machine steel. The length of the thread helix in each screw was such that each of the samples would present the same shearing area, the assumption being that they would shear at the root diameter of the screw since the screw was made of the weaker material. The different thicknesses of the nuts to suit the length of the helix required for this will be noticed in the halftone at *d*, *e*, and *f*, which show respectively the V-thread, Acme and square samples. All the threads were made a snug fit, with the threaded length of the screw exactly the same as the thickness of the nut. The diameter of the shank was less than the root diameter of the thread in each case. The screws were all 6-pitch.

In the cut the upper row shows the samples before testing, while the lower row shows the nature of the failure of each sample under test. A 50,000-pound Olsen machine was used. A nut was supported on the ring shown with sample *f* to allow room for the screw to drop through the nut when it failed, while pressure was applied at the top of the shank, which was carefully squared. The shank of the Acme thread screw *e* in the second set of three samples was not strong enough to withstand compression but crushed before the thread gave way, at a pressure of 29,300 pounds. The fragments of the broken shank are shown. The screw was afterwards pushed through with a short piece of steel rod, failing at 29,600 pounds pressure. The accompanying table gives the results of the test.

RESULTS FOR TESTS OF SHEARING STRENGTH OF SCREWS.

Sample.	Style of Thread.	Material. Screw.	Material. Nut.	Thickness of Nut.	Diameter of Screw.	Breaking Load in pounds.	Remarks.
Threads same outside diameter and all 6 pitch.							
a	Sharp V	M. S.*	M. S.	17/32	15/16	29,980	Threads bent over in both screw and nut.
b	Acme	"	"	"	"	34,090	Sheared at root of screw.
c	Square	"	"	"	"	23,880	" " " " "
Threads same root diameter, ⅝ inch, and same area of section to resist shear. All are 6 pitch.							
d	Sharp V	C. I.*	M. S.	½	.914	20,450	Sheared at root of screw.
e	Acme	"	"	13/16	.792	29,600	Shank crushed at 29,300 pounds, pushed through with steel rod and sheared at root of screw.
f	Square	"	"	1	.792	25,550	Sheared at root of screw.

* M. S. stands for Machinery Steel; C. I. for Cast Iron.

As will be seen from the above table, the Acme, or 29-degree thread, makes the best showing in each case. This has been an interesting experiment to me and I am sure it will prove of some value to at least one firm who was interested in the experiments, and who has adopted the Acme thread as a feature in the design of the machinery constructed in its shops. C. Bert Padon.

Decatur, Ill.

[The V-thread sample, *a*, evidently could not have failed in the way described without expanding the nut enough to allow the distorted threads to slip by each other. In this case then, the thickness and strength of the nut play an important part. If the hole had been tapped in a larger piece of metal, it is difficult to believe that the thread would have failed by shearing or in any other way at a pressure less than that sustained by the Acme thread.—Editor.]

C. Bert. Padon was born at Troy, Ill., December 17, 1870. Besides a common school education he has graduated from Brown's Business College, Decatur, Ill., has taken a correspondence course with the International Correspondence Schools, and is now completing his fourth year at the James Millikin University, Decatur, Ill. He served an apprenticeship as machinist with The Decatur Novelty Works and has since worked as a machinist for that firm and the H. Mueller Mfg. Co., of Decatur. He has also held for two years the position of assistant instructor in machine shop practice in the school he is at present attending. His specialty is experimental work.

ADJUSTABLE SCALE FOR LAYING OUT TABLE.

Among the suggestions received from a man engaged in the tool-room, was one for an adjustable scale for use in setting off vertical heights on the laying-out table, and as the idea seemed good, permission was given to him for making the device himself, according to his own ideas. Fig. 1 shows the tool as made. It consists of a cast iron base, *A*, a round slide *B*, carrying a 12-inch flat steel rule, *C*, adjusted for height by means of the screw *D*, slide and rule being clamped by means of the screw *E*. Its use can be best explained by an example: It is required to set out two lines on opposite faces of a casting, say 5 3/16 inches apart, the lower line being the center of a boss about four inches from the base. The center of the boss being obtained by means of dividers or other instruments, a height gage is adjusted to this center and a line marked across the face of the boss. The height gage is then trans-

ferred to the adjustable scale where it indicates, perhaps, about 4 3/64 inches. Now instead of adding 4 3/64 inches and 5 3/16 inches together, with the consequent risk of error, the scale is adjusted by means of the screw *D* until the 4-inch division is opposite the pointer on the height gage, and it is then an easy matter to add the 4-inch and 5 3/16-inch together, setting the height gage to 9 3/16 inches, this giving the distance apart required.

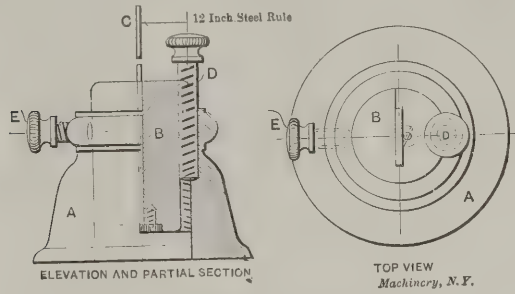


Fig. 1. Adjustable Scale for Laying Out Table.

Upon my accepting an appointment in another shop later, the need was observed there for something similar, and the above device was recalled, but although the idea was good, an improvement suggested itself to me, this being embodied in the scale shown in Fig. 2. In principle the device is the same but instead of the flat scale as originally used, a 12-inch triangular scale was substituted, the lower end of this resting on a projection at the foot of plunger *F*, this plunger being supported by the spring *G*. Adjustment of the scale is effected by means of the nut *H*, the spring keeping the upper end of the scale always against this. Two advantages of this later device are that readings can be taken much nearer the base, and the scale can be used for measuring against a face at times, without the assistance of a height gage.

The graduations on the triangular scale, which was a Brown & Sharpe No. 246, were No. 20, being fully divided along one edge of each face in 1/16, 1/64, and 1/100. It is an easy matter to remove the nut and change the scale to bring any of the divisions to the front.

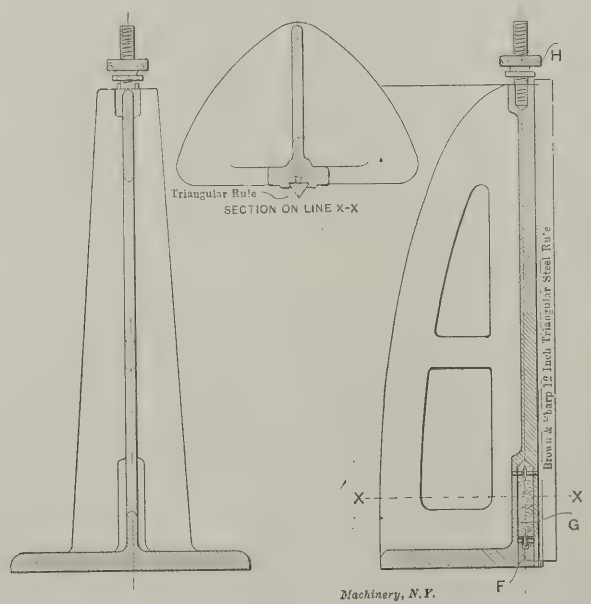

Fig. 2. Adjustable Scale for Laying Out Table.

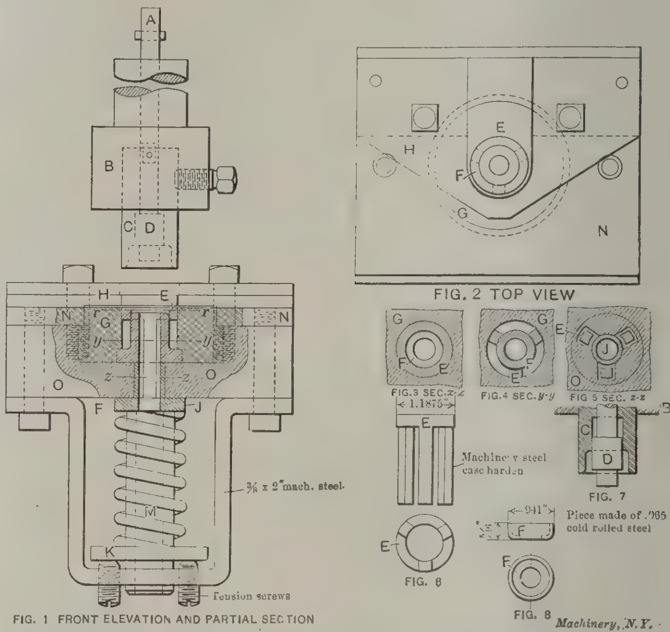
If the inventor of the original device should read this I hope he will forgive me for "pirating" his idea. I can certainly testify to its utility and I hope he will feel pleased that it has now been given publicity for others to copy or improve upon where not already known.

George D. Hadun.

MAKING A BALL-BEARING CUP IN A SINGLE ACTION PRESS.

Having a cup to make for a ball bearing which required rapid and cheap production of the parts, I designed the die shown herewith to produce the same on a single action press, as we have no double-action press.

The die block *O* is of mild steel, with a 3-inch round plug *G* set into the center, which plug is held down by the ⅜-inch plate *N*, shown in Fig. 1. Inside and concentric with this is a combined forming and piercing die *F*, projecting up to within ⅛ inch of the face of die *G*. Between the outer and inner die is a spring stripper pad, detailed in Fig. 6, which forces the finished cup into the punch as it recedes. This pad is held in the position shown by the thimble *J*, which is in turn supported by the stiff spring *M* bearing on washer *K* and the adjusting screws beneath it. The section views, Figs. 3, 4 and 5 make this construction clear. The back gage and scrap stripper *H* are cut away in the back, as shown in Fig. 2, so that as work falls out of the punch it will not catch on the die, but will slide off easily, being used on an inclined press. The upper die or punch consists of 1 3/16 inch blanking punch *C* with the inside formed to draw the sides of the cups and with a central punch *D* for piercing the center hole, which, by the way, does not need to be accurate in size.



When the ram descends, with the stocks in place, blanking punch *C*, in conjunction with die *G*, first cuts out a disk of the proper diameter. As the ram continues to descend, and blank and pad *E* are carried down against the resistance of spring *M* until die *F* is met, when the stock is drawn into the required cup shape. Continued movement punches the central hole through the action of punch *D* on die *F*. As the ram rises, spring *M* and pad *E* force the work into the punch *C*, from which it is ejected at the top of the stroke through the action of central punch *D*, as shown in Fig. 7. The work drops off from *D* readily, since the fact that it is drawn and punched simultaneously produces a hole about 1/64 inch greater than the diameter of the punch.

With this die we can produce from ten to twelve thousand of the cups in ten hours, with a boy running the press.

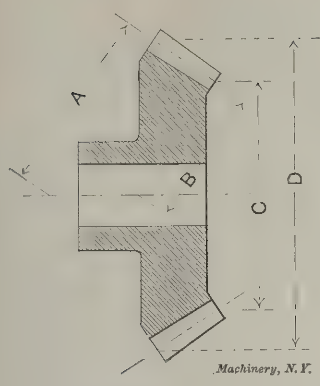
Aurora, Ill. Corwin Lamoreaux.

CUTTING BEVEL GEARS.

I have run across a way to cut bevel gears, which eliminates the guess work necessary in the ordinary "cut and try" method of milling them, in which two or three gears are bungled before the number of holes to turn the dividing head, and the amount to set the cross-slide off center is discovered.

Find the standard spur gear cutter for the large end in the usual manner, finding the pitch by dividing the number of teeth by *D*, and the number of teeth by which to select a cutter by multiplying twice *A* by this pitch. Find a cutter for the small end of the teeth in the same manner, using the measurements *C* and *B*.

Then run the cutter for the small end through one tooth at the right depth, which will give the correct shape of the tooth at the small end; also run in the cutter for the large end, set at correct depth, until it cuts its full depth. Then



CuttingBevel Gears.

take the cutter for the large end and set it so it will trim as near as possible to the sides of these two cuts. By this method you will know just where you are at, and can easily set your machine to cut as perfectly as possible. If you want a special gear for some job, which must be pretty near right, run the cutter for the small end through all the teeth and then you will have a correct surface to file to. C. E. BURNS.

Beverly, Mass.

METHOD OF CUTTING LATHE LEAD SCREWS.

The annexed Fig. 1 shows a method I have used for cutting lathe lead screws which has worked out very well. As usual two cutting tools are used, one in front, right side up, and the other at the back, also right side up, to cut on the reverse trip. The cutting tools in this case were round, like short

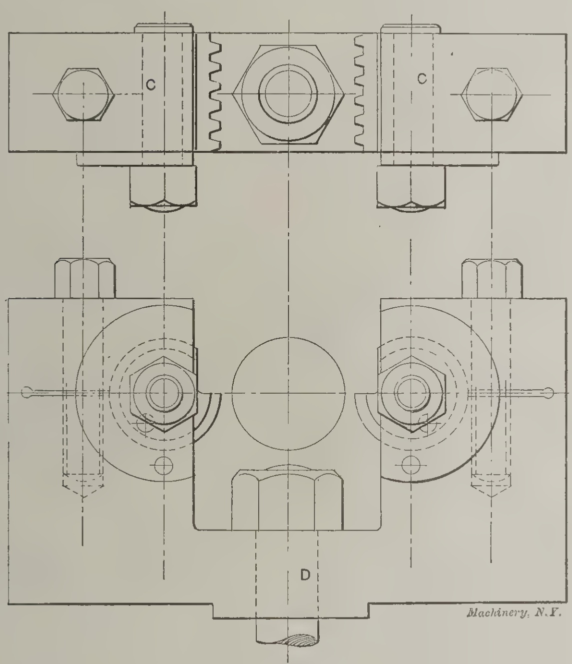


Fig. 1. Double Tool-post with Circular-formed Threading Tool.

sections of the screw to be cut but left-hand to cut a right-hand screw. They were cut with the thread on a taper and the outside turned straight so that the leading cutter tooth cut to the full depth that we could take at each traverse and the succeeding teeth widened the cut, only the last two usually cutting in the full side of the thread, as shown in Fig. 2.

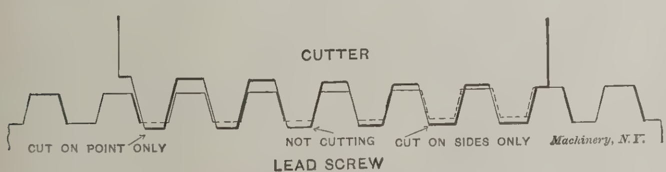

Fig. 2. Illustrating the Cutting Action of the Tools.

The limiting element in using this device became the torsion of strength of the screw we were cutting. We found on our 16-inch size that it was cheaper for us to use 1½-inch stock than 1¼-inch on average lengths just on this account because the time saved in cutting more than covered the increased cost of stock.

The bolts *C C* and their washers and nuts were an afterthought and helped to hold the cutters in place. The dowel pins had to be changed every few grindings. Bolt *D* held the device to the top of the cross slide, in place of the tool post.

Worcester, Mass. E. H. FISH.

THE CONGESTED CONDITION OF THE PATENT OFFICE.

Referring to the condition of the Patent Office at Washington, D. C., regarding the number of applications awaiting action, you will notice by reference to the accompanying statistics that on August 28, 1906, there were 23,811 cases awaiting their turn to be examined. You will also notice that the previous week showed that there were 23,523 cases, consequently the office got behind, in one week, of some 288 cases. This same condition has been partially true of some of the previous weeks, as you will note by reference to the table. Now, if we assume that the Patent Office is going to continue getting back from week to week (and we have every reason to so assume, judging from the table of figures), we can look for nearly 30,000 cases awaiting action by this time next year; this is figuring on the last week's gain of 288 cases.

1906.	Applications Awaiting Action.	Patents Granted.	1906.	Applications Awaiting Action.	Patents Granted.

Apr. 17	20,609	671	Aug. 21	23,523	528
Apr. 24	20,846	640	Aug. 28	23,811	586
May 1	21,406	689			

At the present time most of the divisions which have such classes as automobile parts, machinery, tools, appliances and other divisions with kindred devices, are some eleven months in arrears on *new* work, or on work which has not been heretofore examined, while they are from three to six months behind on responses or amended work. Now, judging from the figures given above, is it not reasonable to believe that this time next year, we shall be waiting about eighteen months on new work and about eleven or twelve months on amended work? Now, what does this mean? It means in the first instance, industrial discouragement, as well as financial discouragement. The man who would invent will not do so unless he sees some immediate return for his labors and the man who would put up money will not do so in view of the fact that the inventor can not get his patent quick enough. Again, the Patent Office is going behind, the race of competition is going ahead—the results are obvious.

Over against this condition of affairs, there is a bank account to the credit of the United States Patent Office of nearly $7,000,000, and this fund is growing daily. Congress, it would seem, is the only power that can adjust these matters, and yet no one seems willing to take the matter up and push it to completion. Some two or three years ago the New York *Times* made some faint efforts toward rectifying the situation, but nothing came of it. I propose that some measure for relief be pressed at the coming session of Congress. FRED. W. BARNACLO.

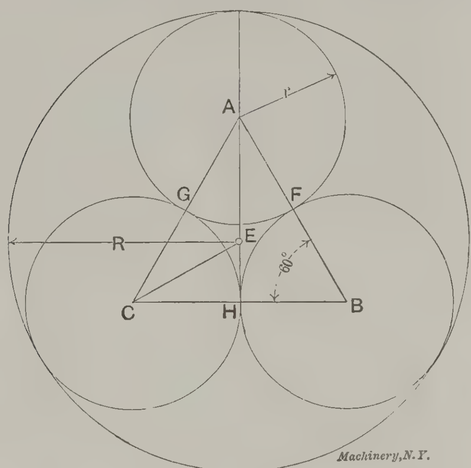
New York.

ANOTHER ANSWER TO THE TANGENT CIRCLE PROBLEM.

In the April issue of MACHINERY there appeared an article in the How and Why column discussing the method of finding the radii of three small tangent circles, tangent to and within a bounding circle. I present herewith a method of solving this problem by geometry alone and also show a way of finding the area of the figure *GFH* bounded by arcs of the three small circles. We will take the second of these problems first.

To find the area *GFH* within and bounded by the three tangent circles *ABC* when the given quantity is the radius of the small circle: Construct the triangle connecting the

centers of the circles at ABC. Then find the area of this triangle and subtract from it the area of the three sectors FGA, GHC, HFB. The angle of one sector is 60 degrees and the three together will be $3 \times 60 = 180$ degrees or ½ a circle. Hence if r is the radius of the small circle, the area of the desired figure will be equal to the area of the triangle ABC minus the area of a semi-circle with radius r. The area of the triangle $= \frac{1}{2}\,CB \times AH = HB \times AH$. But $AH = \sqrt{\overline{AB}^2 - \overline{HB}^2}$; now assuming that the radius of each small circle is unity or 1, the equation becomes $AH = \sqrt{2^2 - 1^2} = \sqrt{3} = 1.732$. The area of the half circle with a radius of unity or $1 = \frac{3.1416 \times 1^2}{2} = 1.5708$. Hence $1.732 - 1.5708 = 0.1612 =$ the required area, which multiplied by the square of any numerical value for radius r gives the area numerically. If, for instance, $r = 2.5$, the area of FGH will be $2.5^2 \times 0.1612 = 1.0075$ square inches.



Problem of Three Tangent Circles.

To find radius r when the radius R of the bounding circle is given: CEH and ACH are similar triangles. From this fact we get the proportion $CH : AH = EH : CH$, or $CH^2 = AH \times EH$. In the previous problem we found that when CH or $r = 1$, $AH = \sqrt{3}$. Substituting these values in the equation we have $1 = \sqrt{3} \times EH$, or $EH = \frac{1}{\sqrt{3}}$. Now $(AH - EH) + 1 = R$ when $r = 1$. Substituting numerical values for AH and EH, we have: $R = 2.1546$. Hence $r : R = 1 : 2.1546$. Therefore $r = \frac{1 \times R}{2.1546} = 0.464\,R$. From this it follows that if the radius of the large circle is known it is only necessary to multiply it by 0.464 to find the radius of the small circle.

Philadelphia, Pa. SAMUEL AROSON.

[In the answer to question No. 16, "How and Why," of the April, 1906, issue of MACHINERY, to which our correspondent refers, an error was made in the table given in the answer. The second and fourth columns should be headed r, and not $2r$, as they are given.—EDITOR.]

A WAY TO INDEX DATA SHEETS.

I show herewith a method of indexing my MACHINERY data sheets. The cut, I think, explains itself, since it is a copy of part of my own index. As will be seen, the data sheets are published, and each one is given a page number in the file which is entered opposite the title in the index. Wherever there is more than one table to a page they are entered separately, as shown for page 102, for instance. The right-hand side of the index is ruled vertically, one for each letter of the alphabet. In these columns crosses are placed to indicate the leading words in the title or subject of the data sheet referred to; for instance, page 110, Table of Gib Keys has a cross under B for "Buffum," the contributor of the table, under G for "gib," under K for "key," and under T for "table." In looking for this particular sheet, if the reader has the word "gib" in his mind, he will follow down the column G, glancing at each title which has a cross opposite it in this column until the right one is reached, which will be done in less time than it takes to describe the operation.

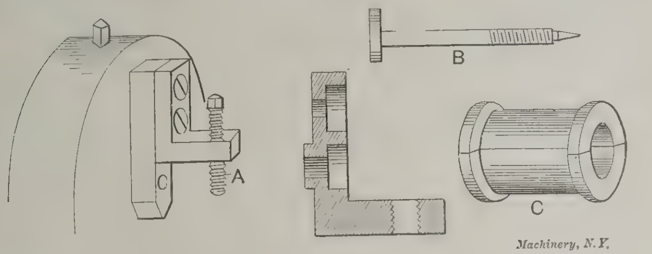
SHOP KINKS.

A DEPARTMENT OF PRACTICAL IDEAS FOR THE SHOP.

Contributions of kinks, devices and methods of doing work are solicited for this column. Write on one side of the paper only and send sketches when necessary.

CHUCK JAW.

The sketch herewith is of a jaw for the lathe chuck, to take the place of the removable piece of the chuck jaw on some work, mostly repair jobs. As a chuck wears, the jaws spring outward, and the inner end of the jaws grip the piece long before the outer end, and the more the jaws are tightened the more this difference is exaggerated. The outward end of a long piece is sure to wobble and it is almost impossible to get it true, and then to keep it so. The attachment



A Handy Chuck Jaw.

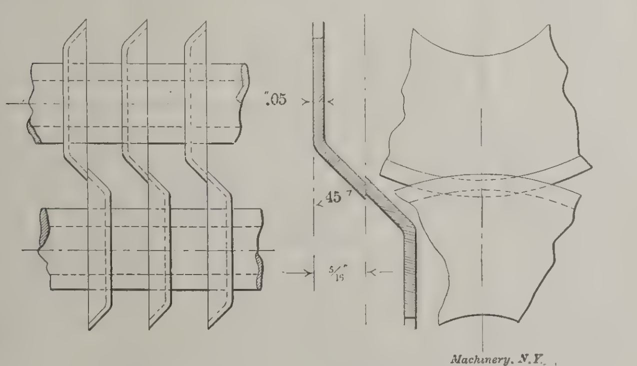
as shown in the sketch is designed to prevent this trouble. Supposing you are going to use a drill in the chuck and you want it to run true; adjust the rear end central with the jaws, then adjust the setscrews *A*, until the outer end runs true, and there you have it. If a piece of rod not long enough for the center rest, is to be turned or threaded, and the stock must run true, or if it is a finished piece, as a stud with the thread stripped, and which is not centered, this jaw will be very handy. On pieces such as the valve stem, *B*, which is to be repointed, or the bushing, *C*, which is to be babbitted and rebored, this jaw will be invaluable, as they must run very true. The surface by which they may be gripped is narrow and offers an insecure hold, and they are too fragile to allow of clamping very tightly. The device is handy for other similar pieces which have to be gripped at two places of different diameters. C. E. Burns.

Beverly, Mass.

DESIGN OF PAPER SLITTING CUTTERS.

A form of paper slitting cutters is here shown which has advantages that the usual styles do not possess, and therefore may be of interest.

They consist of a sheet steel stamping 0.05 inch thick and are so placed upon their arbors that they are always kept sharp by the cutting edges rubbing together. As the edges wear, the arbors are adjusted by a suitable means at each end. They are made of tool steel, but are not necessarily

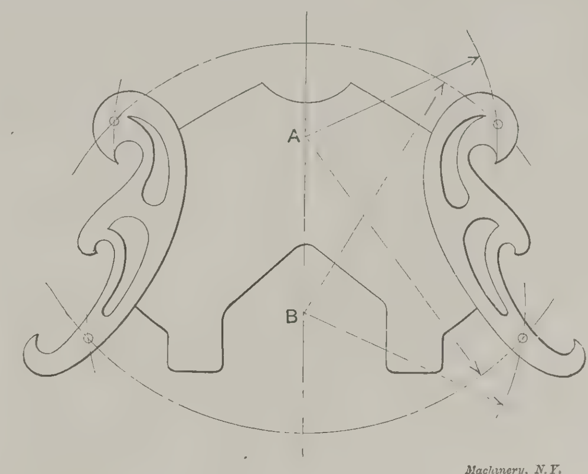


A Satisfactory Form of Paper Slitting Cutter.

hardened. Each set is placed on its arbor with the desired distance pieces between them, and the arbors placed in position on the machine in which they are to run. The machine is started up and the cutters grind each other. End movement for each arbor is provided to allow each set to come into contact. By this means it is evident that the cutters will run true and will need no further grinding, and will cut until they are worn cut, which in some cases has been over a year, although running every working day. Winamac.

TO DRAW SYMMETRICAL REVERSE CURVES.

In drawing a symmetrical figure which requires a right and left curved line some difficulty may be experienced, especially if a celluloid curve is used. By using a wooden curve, marks can be put on it to indicate the beginning and ending of the line desired, but doing this for some time puts the curve in a bad shape and it becomes hard to discern which mark was put down last. It is hard to put marks on the rubber or celluloid curves, so the following method of using curves of any material seems to be ideal:



Method of Drawing Symmetrical Reverse Curves.

As can be seen in the cut, there is a hole about 1-16 inch diameter put in each end of the curve. In use, the curve is laid on the drawing, the location of the holes marked with pencil point, and the desired curve drawn. On the center line of the piece to be drawn select two centers, as *A* and *B*, and from them locate the positions of the holes on the opposite side. Place the holes in the curve over these points and the curve is in the reversed position. The method is simple; in fact, it takes a much longer time to explain it than to follow it. Winamac.

CHUCKING PIECES FOR PLANER WORK.

The two chucking pieces for holding thin pieces on planers, shown by A. Fr. Bierbach in a recent number are very neat and useful, and are on the same general principle as those shown on page 155 of my "Work Shop Hints." I would suggest, however, instead of having two sets, one for through slots and another for so-called dovetail grooves, as shown by

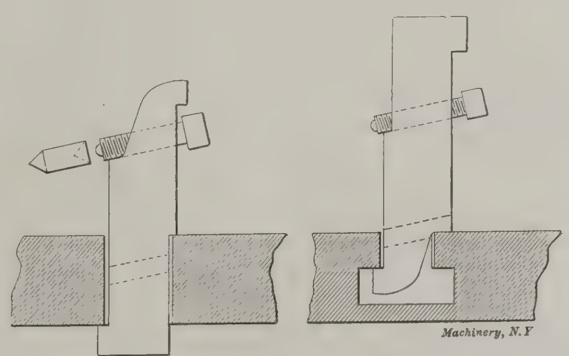


Fig. 1. Fig. 2.

Mr. Bierbach, combining the features of the two kinds in one double-ended device as shown herewith. Fig. 1 illustrates its use on a through slot and Fig. 2 the same device turned upside down for use with a dovetail groove. The screw-holes are to be drilled and tapped before the steps are planed in the pieces. Robert Grimshaw.

Hanover, Germany.

* * *

The copper production of the world amounted to more than 700,000 tons during 1905. The United States produced more than half, or exactly stated, 58 per cent of the total amount. Next to the United States comes Mexico as the largest producer of this metal.

SHOP RECEIPTS AND FORMULAS.

A DEPARTMENT FOR USEFUL MIXTURES.

This page will be used for the publication of shop receipts which the contributors know from experience to be practicable. Nearly all readers of MACHINERY can add something, and it is desired that they use this page as a medium for exchanging useful formulas. It makes no difference if they are old and supposedly well-known, provided they have not already appeared in this department.

240. CEMENT FOR LEATHER BELTS.

To make a cement for leather belts use gutta percha, 16 parts, pure white India rubber, 4 parts; dissolve, and then add pitch, 2 parts; shellac, 1 part; and boiled linseed oil, 2 parts. W. R. BOWERS.
Birmingham, Eng.

241. CEMENT FOR FASTENING GLASS WORK TO BRASS TUBES.

A cement for fastening glass work to brass tubes is made of rosin, 5 ounces; beeswax, 1 ounce, and red ochre or Venetian red, in powder, 1 ounce. W. R. BOWERS.
Birmingham, Eng.

242. SOLDER FOR SMALL PARTS.

To make a solder for small metal articles cut tinfoil into the shape wanted and wet on both sides with sal-ammoniac. Have the surface of the piece clean, place on it the wet tinfoil and then press the parts together firmly and heat until the tin-foil is melted. E. W. NORTON.

243. MIXTURE FOR EBONIZING WOOD HANDLES, ETC.

To prepare a mixture for ebonizing wood handles, etc., use logwood, 2 pounds; tannic acid, 1 pound, and sulphate of iron, 1 pound. Apply hot and polish when the pieces have become dry and cold. W. R. BOWERS.
Birmingham, Eng.

244. TO PREVENT SCALE IN HARDENING FINE DIES.

It is possible to prevent the formation of any scale in the impression of fine jewelers' dies and the like, and retain the finished brilliancy of surface, by applying a mixture of powdered ivory black and sperm oil, mixed to the consistency of paste. It is only necessary to apply a thin coat.
HARDENER.

245. TO CUT CORK.

In cutting cork, the knife is to be kept greased. Where, however, the desired piece is symmetrical about one axis, and of circular cross-section, it may best be roughed with a greasy knife and then ground to profile with a coarse emery wheel. Cork pen-holders are made in this way. Where many pieces are to be cut out of sheet cork, it is advisable to use a band knife, against which there is kept pressed a block of grease.
Hanover, Germany. ROBERT GRIMSHAW.

246. ARTIFICIAL SKIN FOR BURNS, ETC.

Dissolve equal parts of gun cotton and Venice turpentine in 20 parts sulphuric ether, dissolving the cotton first and then the turpentine. Keep in a tightly corked bottle. The use of the turpentine is to prevent pressure or pinching of the flesh caused by the evaporation of the ether when applied. Water does not affect this covering, hence its value for burns on the face or hands. E. W. NORTON.

247. PLASTER OR SALVE FOR USE IN PLACE OF STITCHES.

To make a plaster or salve which can be used in case of accident in place of stitches where a person has sustained a deep cut, melt together white rosin, 7 ounces; beeswax, ½ ounce; mutton tallow, ½ ounce. Pour into cold water and work with the hands until it is thoroughly incorporated, and roll out into suitable sticks for use. When required warm and spread upon a firm piece of cloth, cutting the wax into narrow strips in case of deep wounds. It will be found to hold the edges of the flesh firmly together.
E. W. NORTON.

248. TO HARDEN FINE DIES.

To successfully harden dies for fine work, such as are used by jewelers and others, be careful to have the surface free from all grease or oil, pack face downward in a mixture of equal parts of finely powdered hardwood charcoal and charred bone. Dip in salt water and draw temper to 450 degrees F.
HARDENER.

249. TO PREPARE TRIPOLI OR EMERY CAKE.

Tripoli, emery cake and crocus are all made in practically the same manner, the change being made in the composition when it is desired to have the composition more greasy. Melt tallow and paraffine wax or beeswax together. Beeswax is by far the best, but the cost of the same has led to the use of paraffine, which in many cases will work equally as well. After the tallow and wax are thoroughly melted, add tripoli or emery, whichever is to be made, a little at a time and stir in well, until it is as thick as is possible to make it; then pour out into a large tin, or better still into the moulds made for the purpose, and allow to cool.
Bridgeport, Conn. J. L. LUCAS.

250. TO CASEHARDEN A PIECE LOCALLY.

To caseharden part of a piece to a line or in a spot cover the part or surface to be hardened with a moderately heavy coat of black japan enamel. I prefer this as it bakes on more closely than anything else. Clean the work thoroughly, then put on a heavy coat of copper and the work is now ready to be carbonized, and is packed in a pot in bone or leather in the usual manner. Heat long enough to give the required depth of "case." Then take out of the fire and cool down in the pot. When cold reheat and dip in oil or water. The copper blocks the absorption of carbon while the japan burns off and allows the carbon in the bone or leather to be absorbed by the iron. E. W. NORTON.

251. TO TONE BLUEPRINTS.

After washing the blueprint in the usual manner immerse it for a half minute or less in a solution made by dissolving a teaspoonful of potassium bromide crystals in one-half gallon clear water. Then rinse the print in clear water and hang it up to dry. A galvanized iron or japanned tray may be used for the solution. Prints may be much overprinted and yet give beautiful clear whites and extremely deep blues, easily seen by the workman and a delight to the directors, the latter especially because the solution is quite inexpensive, and can be used over and over again until an objectionable precipitate forms. I have used this toning with Kueffel & Esser's paper and also with a number of local brands of blueprinting paper, all of which gave such fine results that we specify "all blueprints must be toned." F. J. SCHAUFELBERGER.
Denver, Col.

252. TO RECUT OLD FILES.

Brush the old files with a wire brush, put them in a tub, cover them with water and add 6 ounces of caustic soda per each 100 files. In about two hours brush them again. They will then be free of grease and metal. Then put them in a box, lined with sheet lead, on a wire stand made for the purpose, and in such a way that they will not touch one another. Cover them with a solution made of nitric acid and water, one pint of acid to each gallon of water. In 25 minutes remove them, wash them in water, brush them with a hair brush and put them back in the liquid to which one more pint of nitric acid to each gallon of water has been added. In about 50 minutes remove them again, brush them after washing them with water and put them back in the liquid to which has been added ½ pint of sulphuric acid per each gallon of water. In 15 minutes remove them; wash them first in water, then in concentrated lime water till all trace of the acid has disappeared. When dry they will have the appearance and cutting quality of new files. I used this method for recutting old files long ago and found it O. K., and so can recommend it. J. M. MENEGUS.
Los Angeles, Cal.

HOW AND WHY.

A DEPARTMENT INTENDED TO CONTAIN CORRECT ANSWERS TO PRACTICAL QUESTIONS OF GENERAL INTEREST.

Give all details and name and address. The latter are for our own convenience and will not be published.

23. F. O. B.—Why is it desirable to tin the interior of a box before pouring babbitt?

A.—Tinning a box is done so that the babbitt will adhere to it. Babbitt poured into a box without preliminary tinning will not amalgamate with the metal so as to form a permanent connection, even if hot, but by tinning the interior surface of the box the babbitt adheres as its heat is sufficient to melt the tin and permit amalgamation. Tinning, of course, is done with a suitable flux, usually chloride of zinc; and the use of a flux is not feasible when babbitting. Coating a box with tin is analogous to the use of cement.

---

24. P. T. & S. Co.—What is the cheapest, best and quickest process for straightening steel plates, varying in thickness from ½ inch to ¾ inch, and varying in dimensions from 18 x 24 inches to 24 x 36 inches? These plates are not curved, but are slightly kinked, and must be reduced to practically a flat surface without being tooled, as a corrugated milling cut is to be taken across them.

A.—Probably the best method of straightening plates in a kinked or buckled condition is to run them between heavy rolls. In the absence of these the next best thing to do would be to pass them to a blacksmith shop equipped with a steam hammer and a surface-plate. A careful blacksmith with a heavy steam hammer having dies in good condition should be able to straighten the plates so that they would lie on the surface-plate with a variation of not more than 1/32 inch from a true plane. The question is submitted to our readers, some of whom may be able to give our correspondent the benefit of practical experience on a similar job.

---

25. A. D. T.—Starting with none why is it necessary to make three surface plates in order to get one?

A.—It is necessary to make three plates for the reason that two plates cannot be depended on to correct one another's inaccuracies. For example, one plate might be high in the center and another low in the center, in which case an apparently perfect bearing might be obtained and still neither surface be a true plane. By having a third plate such a condition would be readily detected for it is impossible for the third plate to match *both* of the others. Given plates Nos. 1, 2 and 3, Nos. 1 and 2 are fitted together, and Nos. 1 and 3. Now, at this point all three may be out of the true plane and still match, but the moment that plates Nos. 2 and 3 are put together the inaccuracy will be apparent. If both are low in the center, as would be the case if fitted to No. 1 high in the center, they both must be scraped down an equal amount until a bearing is secured. Then No. 1 is corrected by fitting to both No. 2 and No. 3, and so on. In this way three perfect surface plates are necessarily produced in order to get one.

---

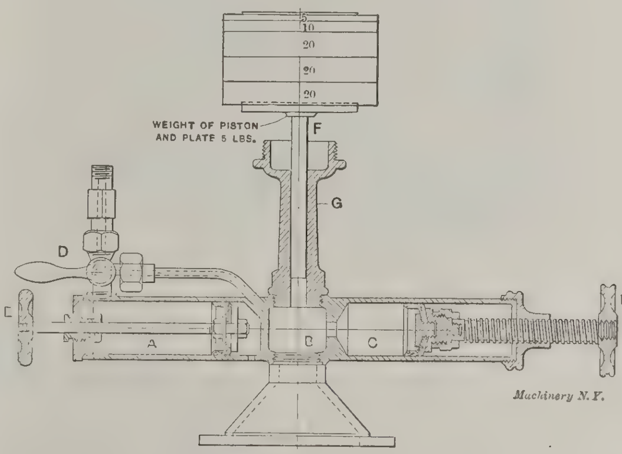
26. H. W. B.—An engine cylinder has six studs in the end and six nuts holding down the head; the nuts are tightened to a pressure equivalent to say 50 pounds per square inch, directly against the head of the cylinder. If steam is turned into the cylinder to a pressure of say 40 pounds per square inch, will there be a greater strain on the nuts with steam pressure in the cylinder than without?

A.—This is a question about which there has been a great deal of controversy. Broadly, for the case you specify, the admission of steam pressure into the cylinder would not increase the stress on the bolts. Suppose that a short section of spiral springs was placed under each of the six nuts and they were screwed down so that each spring pressed against the cylinder head with a pressure equivalent to 50 pounds per square inch on the sector of the head supported. Now, it is clear that the head cannot be pushed away from the end of the cylinder until the total pressure due to the springs is exceeded. Suppose, for clearness, that the diameter exposed to steam pressure is 6 inches; then the area exposed to steam pressure is 28.27 square inches and the total load imposed by the springs will be 1,413.5 pounds. The counter-pressure due to the steam pressure is 970.8 pounds; therefore the given steam pressure, or any internal pressure less than 1413.5 pounds could make no difference in the stress on the bolts. However, the foregoing answer applies only when the elasticity of the materials in compression is neglected. Suppose, for example, a perfectly elastic gasket is used between the cylinder head and the cylinder; then the internal pressure is added to the stress already existing in the bolts due to the compression of the gasket. Therefore, as cast iron and all materials are somewhat elastic it is evident that the broad answer given is not strictly correct, for the internal pressure does, in theory, add somewhat to the load on the bolts. The amount of additional loading depends upon the relative elasticity of the bolts and the surfaces in compression. If the bolts are long the amount of additional loading imposed on them due to the compression of the cast iron surfaces will be comparatively small.

* * *

A DEAD WEIGHT PRESSURE GAGE TESTER.

The American Steam Gauge and Valve Company have placed upon the market a testing apparatus for testing steam and other pressure gages which is reliable at all times owing to the fact that the pressure impressed upon the gage is obtained by weights. This apparatus is shown in sectional elevation in the cut. Its operation is as follows: The chambers *A*, *B*, *C*, are filled with a light oil, the gage to be tested is connected with the pipe leading up from the three-way cock *D*. This cock is then turned so as to connect *A* with *B*, and



Testing Apparatus for Pressure Gages.

handle *E* is pulled out so as to force oil from *A* into *B*, and into the gage, until the latter shows that there is some pressure acting upon it. Handle *D* is then turned to cut out cylinder *A*, weights are placed upon *F*, and handle *H* is forced in until piston *F* is lifted. If the gage registers correctly, its reading will agree with the weights on *F* + five pounds, this being the weight balanced by the piston *F* and its cap. To eliminate any error that may arise through the friction of *F*, the handle *H* can be moved in far enough to lift the weights some distance, and then it can be drawn out and the two readings thus obtained can be compared.

* * *

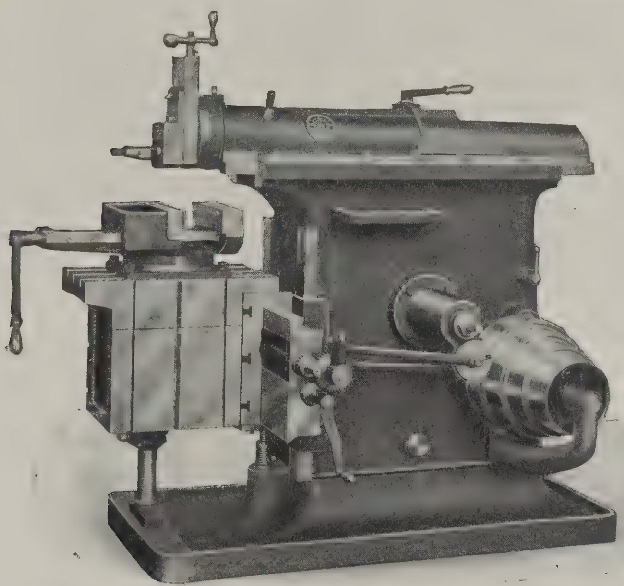
Some time ago we published a kink in regard to making typewriter copy from which clear blueprints can be taken. This is done by placing under the typewriter paper a sheet of carbon paper with the carbon side up so that in writing an impression will be made on the under side of the paper by the carbon, thus producing printing on both sides of the sheet. Blueprints from copy written in this way come out very distinctly and clearly. We have received a letter from Kearney and Trecker, Milwaukee, Wis., also explaining this method, but stating that in their practice it is used for much of the lettering on drawings, which are on bond paper. A typewriter with a wide carriage is employed for writing on the sheets. Much time is thus saved and the drawings have a neat appearance. It will take only a few minutes of any draftsman's time to try this as an experiment and it is believed the system will prove useful in any drawing office.

MACHINERY AND TOOLS.

A MONTHLY RECORD OF NEW APPLIANCES FOR THE SHOP.

TWENTY-INCH ROCKFORD SHAPER.

The Rockford Machine Tool Co., Rockford, Ill., whose 16-inch crank shaper was illustrated in the New Tools column of the November, 1905, issue of MACHINERY, have placed a 20-inch shaper of similar design on the market. This is shown in the accompanying halftone. Among the special features of this make of shaper are a strongly reinforced column, an improved vise in which the screw pulls the jaws together instead of pushing them, a high back gear ratio, and the use of high-carbon steel, ground to size, for all the shafting. The base is of pan construction for catching all the chips, dirt, etc., and has a forward extension for table support. The feed rod adjusts itself to any height of the table and does not have to be changed when altering the vertical adjustment. The actual length of the stroke is 22 inches, the horizontal travel of the table 25 inches, and the vertical adjustment of table 14⅝ inches. The machine has a key-seating capacity of 3½ inches diameter, and the net weight of the machine and countershaft is 2,800 pounds. Further details of this design will be found by referring to the description in the November issue, previously mentioned.



Twenty-inch Rockford Shaper.

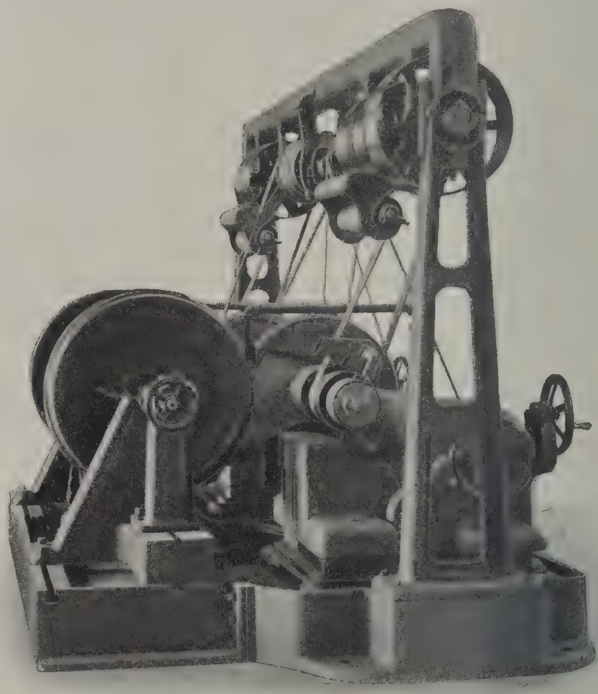


Fig. 2. End View of Norton Car Wheel Grinder.

NORTON CAR-WHEEL GRINDER.

The accompanying cuts show the general construction of a new car wheel grinding machine recently brought out by the Norton Grinding Co., Worcester, Mass.

The car wheels with their axle are driven by a worm and wormwheel near the center of the machine. The wormwheel is provided with a removable segment, and an opening is left in its journal in order to permit the axle to be placed in position. In order to eliminate the necessity of re-turning or re-grinding the journals and also for securing greater rigidity, the wheels revolve on their own journals. These rest at each end in half bearings of lumen bronze which are hemispherical on the external surface, and rest in hemispherical pockets. This latter arrangement permits a slight adjustment for worn wheel journals. In order to make further allowance for variations due to wear in the journals, the bottom of the bronze bearing is cut away, leaving only a small circular bearing at each side, which will act practically as a V-bearing. The journals are oiled automatically as they revolve by means of felt which is placed in the cut away portion of the bearing and saturated with oil. The stands carrying the bearings for the journals are movable in the longitudinal direction of the machine, thus being equally adapted for the support of axles with the journals inside or outside of the wheels.

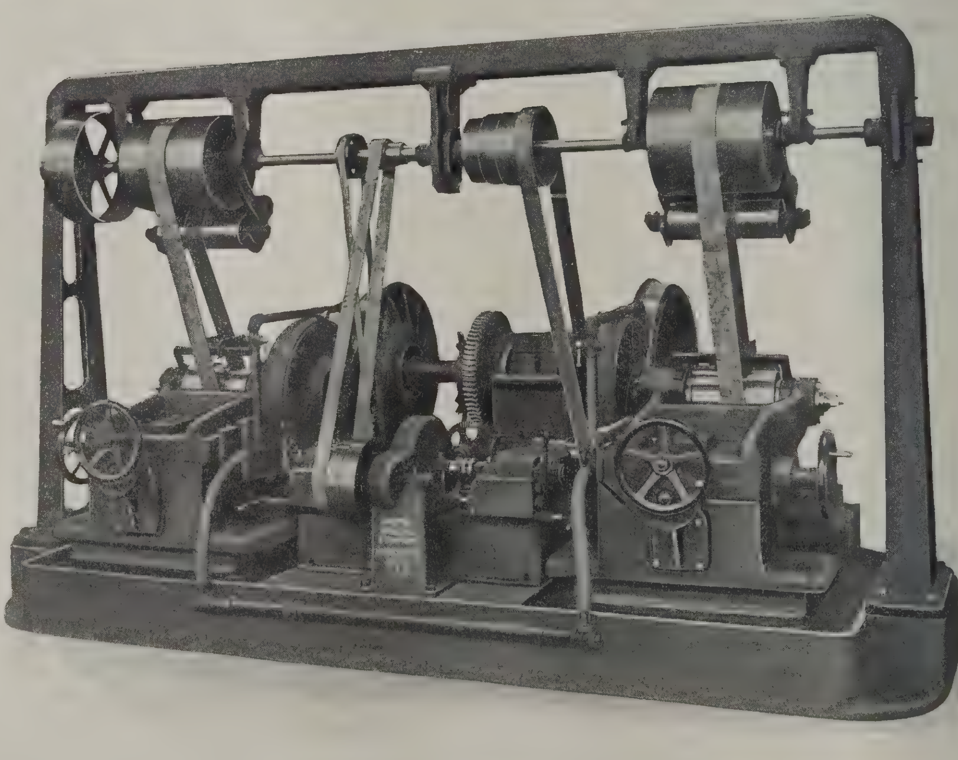

Fig. 1. Rear View of Norton Car Wheel Grinder.

The grinding wheels are 24 inches diameter, with a 2¾-inch face. They are mounted on wheel slides similar to those on regular grinding machines. The wheel slide is mounted on a slide moving parallel with the face of the car wheel, and this slide in turn is placed on a slide base which is pivoted to the bed of the machine, and permits the setting of the grinding wheel to the different angles required.

The slide moving parallel with the car wheel face is provided with automatic feed. It can also be moved for short distances by a handwheel. A special oiling arrangement is provided for this slide which will operate without attention

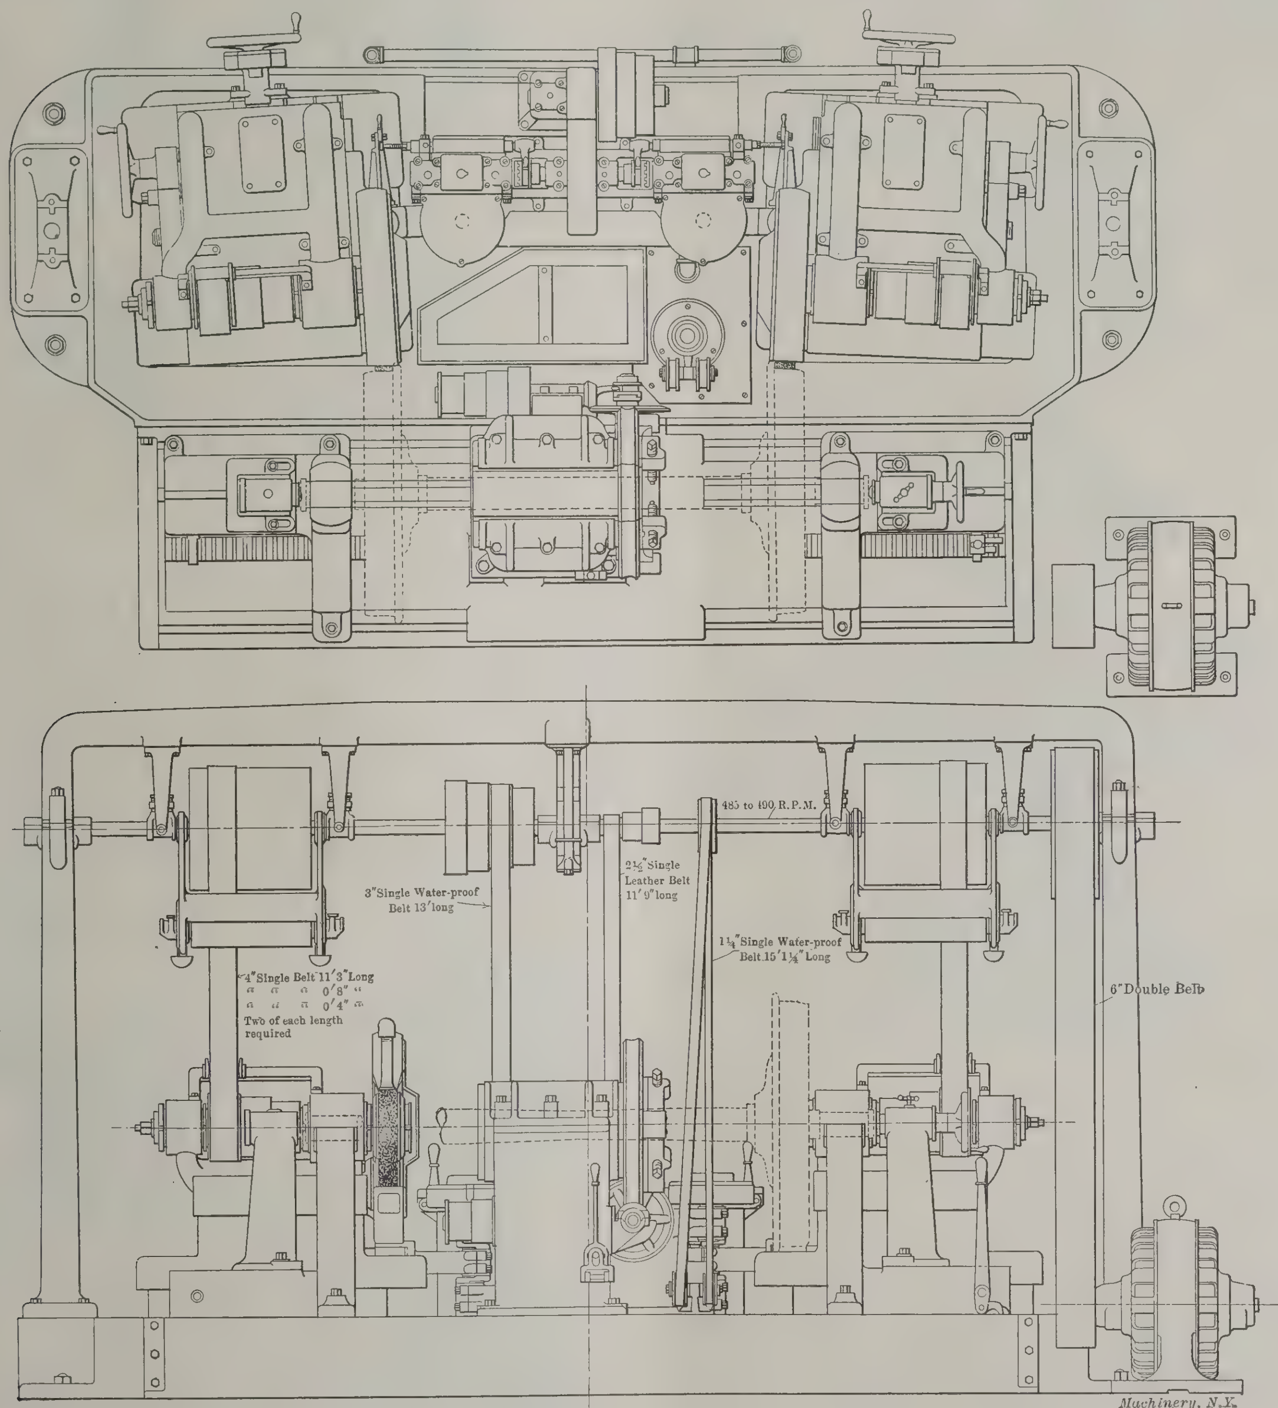

Fig. 3. Plan and Elevation of Norton Car Wheel Grinder.

for long periods. By means of clutches, one of which can be seen in the rear view of the machine, the slide can be moved, and by raising the handles shown in the same view near the water hose, the slide will be brought to stop automatically when in its extreme position toward the flange of the car wheel. This will prevent cutting into the car wheel flange after having thrown the clutch, provided the wheel was adjusted properly in relation to the flange before throwing in the clutch. At the same time, the operator cannot stop the traverse feed in any other position than the one indicated by the automatic stop.

The stopping and starting of the motion of the car wheels is accomplished by means of a lever between the wheels. The arrangement here permits, of course, the stopping of the worm wheel at the exact position, where, by means of removing the section referred to above, the axle can be put in place.

The machine has provision for water, and the base is so designed that all water is conducted to a removable settling tank. The supply is kept in a large water tank in the foundation under the machine, whence the pump distributes it to the wheels.

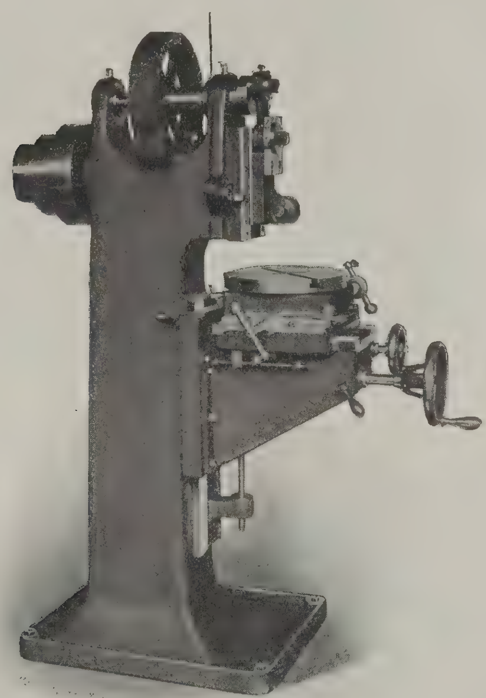
The overhead work is self-containing in order to permit a crane to pass over the machine for the purpose of placing the carwheel axles in, and removing them from, their bearings. The machine is furnished belted as shown in the cuts, and can be driven either from the lineshafts or by a motor. The latter should be a 30-horsepower motor of constant speed, and is shown in place in Fig. 3.

While car wheels have been ground in the past, the machines and devices used have been such as to produce far from accurate results. The present machine, however, is designed with the view of obtaining commercially accurate results, and will grind car wheels within a limit of 0.002 or 0.003 inch as far as roundness and concentricity is concerned. The machine is particularly rigid and weighs 30,800 pounds.

GARVIN DIE-SLOTTING MACHINE.

The Garvin Machine Co., Spring and Varick Sts., New York City, have rebuilt throughout from newly designed patterns the die-slotting machine which is one of the firm's oldest products. Among the changes introduced is the adoption of a solid extended type of knee similar to that used on the builder's line of milling machines. Hand wheels are provided to control the elevating and lowering of the knee and the in-and-out movements of the slide instead of the ball cranks formerly used, these wheels being provided with micrometer dials for reading the adjustments. Stops are also provided for the motion of the table and the slide.

The handle for the rotary table is arranged to use dials for dividing purposes, but for small divisions and rapid work the table can be revolved by hand, using the lock pin device, which gives twelve divisions. The ram is driven from a cone pulley through a reducing gear and has a fixed stroke of 2½ inches, which has been found suitable for the class of work generally performed on this machine; this allows a stronger pin construction than is possible when this part is made adjustable. The ram and the slide in which it is contained are adjustable 5 degrees either side of the vertical, the setting being read from a graduated index. The tool block is of a special shape well suited for holding special tools. It swivels on a



Garvin Die-slotting Machine.

center suitably located to give the proper action, and is rocked by a cam on the lower end of the connecting rod which locks the slide on the downward stroke, and relieves the tool on the upward movement. This machine, which weighs 1,150 pounds, is well adapted to the usual run of slotting, such as small straight or taper key seating, punch and die work, internal or external gear patterns, especially where draft is required; where intricate outlines have to be followed, the combination of the two cross motions and the rotary table provide means for doing almost any work of this character.

GORTON DOUBLE DISK GRINDER.

The Diamond Machine Co., Providence, R. I., who build the Gorton line of disk grinders, have recently added to that line the double disk machine shown in Figs. 1 and 2. The machine is built with two heads, one solid with the bed and the other mounted on the slide in such a way that the distance between their faces is adjustable to suit different widths of work, which may thus be finished on both sides to accurate dimensions.

This machine, which is known as the "6 K Gorton," is regularly furnished with 18-inch steel disks. That on the right-hand head is mounted on a spindle which can be given end motion by means of the handle at the extreme right of the machine. A micrometer stop is provided, reading to 0.001 inch, thus permitting work to be duplicated within very narrow limits. The bearings in which this spindle slides are especially designed to exclude all dirt and emery dust. Not

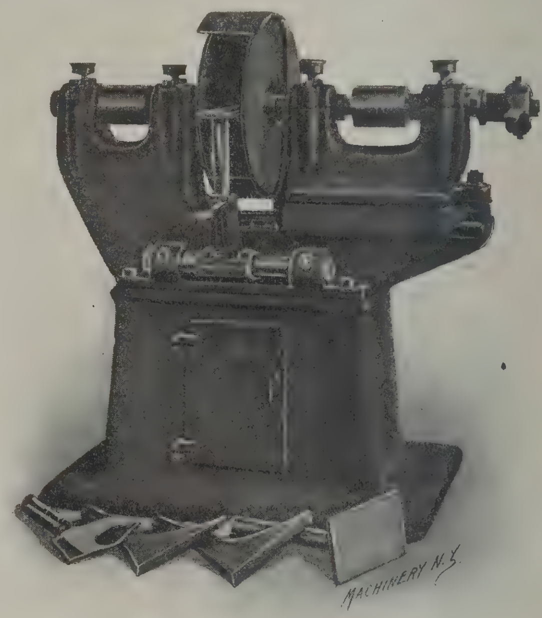


Fig. 1. Gorton Double Disk Grinder.

only is this head adjustable lengthwise of the bed for position, but it may be swiveled as well for any angle up to 10 degrees, so that tapering pieces may be ground as well as straight ones. When the removal of a large amount of stock is desired, emery rings, as shown on the floor at the right of the machine in Fig. 2, are used in place of the disks. Chucks for these rings are furnished at a slight extra cost.

The work is supported between the wheels by a table. These tables, of which a number are shown on the floor at the base of the machine in Fig. 1, are of varying widths to suit various sizes of work. The one at the extreme left is designed to hold thin circular pieces which may thus be finished on both sides at once. The bracket on which these tables are mounted, is

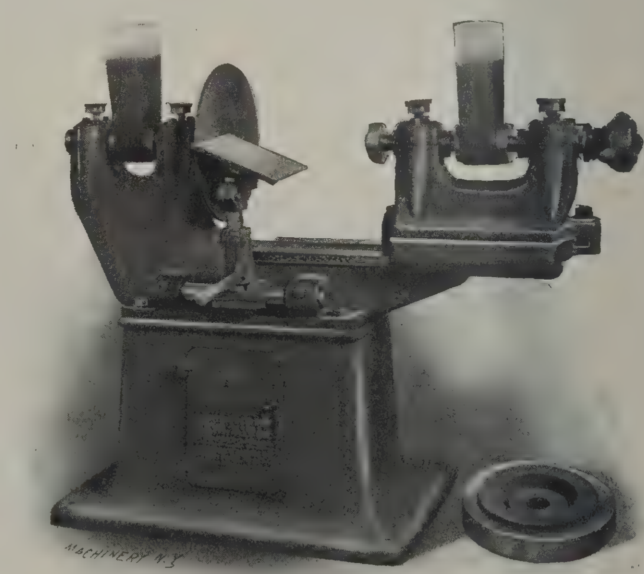

Fig. 2. Gorton Double Disk Grinder used as a Single Head Grinder.

swung about a pivot so as to move the work back and forth across the faces of the wheels. As shown in Fig. 2, the right-hand head may be moved out of the way or taken off entirely if desired, so, by using the adjustable table shown, the machine becomes for all practical purposes a single-head grinder of the usual type. Gages, studs, or jigs for holding irregular-shaped

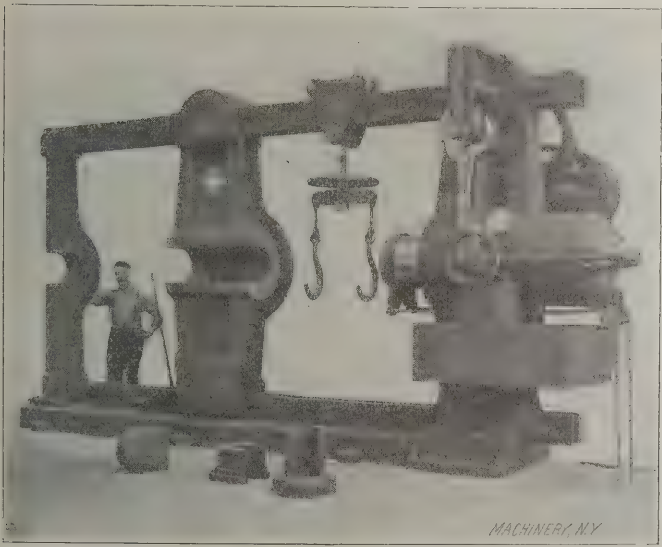
pieces may be fastened to the tables, thus greatly extending the range and rapidity of action of the machine.

The accessories furnished regularly with each machine are four 18-inch steel disks, six disk bolts and nuts, twelve assorted abrasive circles, one gallon of cement, one cementing press, three steel wrenches, four work tables, one adjustable table, one circular work table, and a double countershaft. The net weight with the accessories described above is 2,000 pounds. The machine will also be furnished with pedals in addition to the handles for operating the feeding movements when desired.

NINETY-INCH NILES 600-TON HYDRAULIC WHEEL PRESS.

The increase in weight of locomotives within the past few years has made changes necessary in railway repair shop equipment. This applies particularly to the hydraulic wheel press. Until very recently a hydraulic wheel press of more than 400 tons capacity had not been known, the usual equipment being of 300 tons capacity. Consequently many railway shops had found great difficulty in removing large locomotive drivers from their axles, especially in the case of steel centers with the tires in place. A wheel center forced on with a pressure of say 150 tons grips the axle with a greatly increased force when the tire has been shrunk in place. Often with the old equipment it has been necessary to remove the tires or to drill the hub in order to start the wheel center.

The accompanying illustration shows a 600-ton hydraulic wheel press recently placed on the market by the Niles-Bement-Pond Co. of New York. The distance between the ram and the resistance post is 8 feet 3 inches. The resistance post and the cylinder (which is one piece with its column) are steel castings. The outside diameter of the cylinder is 27 inches. Four tension bars are used to connect the two columns, and the resistance post is so arranged that its weight is entirely carried on the base-plate. The base-plate on which the press is mounted serves only to carry the weight, there being no stress transmitted to it since all pressure is taken by the tension bars. The cylinder is bored and lined with copper, expanded into place and burnished. The piston is packed with a cup leather in the usual form; it is counter-

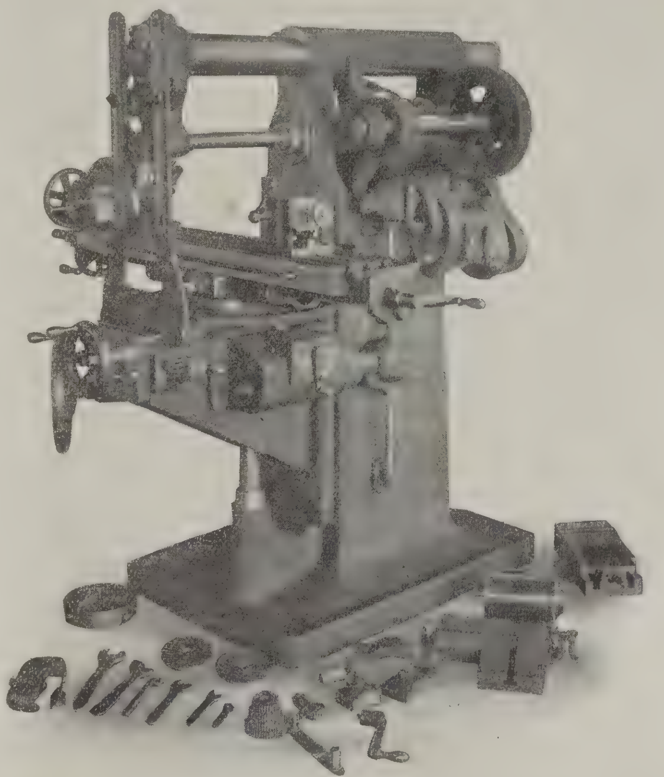


Ninety-inch Niles 600-ton Hydraulic Wheel Press.

weighted for quick return when the release valve is opened. A safety valve is provided which can be set to open at any desired pressure and is protected from tampering by a lock box. The pressure gage is graduated for tons of pressure and for pounds per square inch on the ram. The water tank is bolted to the post under the cylinder and takes the discharge and supplies the pump. The pump has three cylinders, the pistons of which are driven by a three-throw crankshaft and a 12½-horsepower motor is employed to operate it. The height between the tension bars is 90 inches and the machine will take wheels 84 inches in diameter on the tread.

THE OWEN NO. 2A UNIVERSAL MILLING MACHINE.

In re-designing their No. 2 universal milling machine to make it more suitable for use in taking heavy cuts with high duty steel, the Owen Machine Tool Co., of Springfield, Ohio, have added a number of improvements in mechanical detail. The telescopic shaft in the feed motion has been entirely dispensed with, the connection between the spindle and the feed screw on the table being entirely effected by positive gearing and splined shafts, no chain even being used between the spindle and the feed box. The rapid change gear mechanism used employs spur gears and straight steel clutches entirely, allowing the feed mechanism to be changed at all times when the machine is in motion without injuring it or any of the working parts. Thirty-two changes are obtained; four changes are controlled by the handle shown under the large back gear at the rear of the column; four are obtained in the gear box at the side of the knee controlled by a similar



Owen No. 2A Universal Milling Machine.

handle, while another lever on the knee gives still another change, making in all 4 x 4 x 2, or 32 changes. The ratio of feeds is arranged in geometrical progression.

The table has been given double bearing surfaces, the gears, spindles and arbors are made of forged steel, and the front spindle bearing in particular has been given great strength. All of these conditions tend to make the machine more rigid and suitable for the most severe service the tools used are capable of giving it. The knee of the machine has also been redesigned so as to effect a proper distribution of the material, which, with the increased weight given it, makes an exceedingly stiff construction at this point.

CYLINDER RING GRINDER.

The Graham Mfg. Co., Providence, R. I., have designed a grinding machine for finishing piston rings according to the method invented by Mr. Warren Chambers, of Toronto, Ontario. A description of this method was given in the April issue of MACHINERY (page 413 of the Engineering Edition). It will be remembered that with this machine the piston ring is dropped into a container of the same inside diameter as the cylinder in which it is to be used. The ring is shown in place in the container in the line cut Fig. 1, being represented by the heavy black area. The ring is revolved slowly by a projecting pin on the rotating dog in the center. Through an opening in the side of the container the face of the emery wheel is brought to bear on the outer surface of the ring which is here exposed to the action of the wheel. The great advantage of this system is that the ring is finished under exactly the same conditions that obtain when it is in place in the cylinder. With any other known method of finishing the periphery the ring will be found not to follow

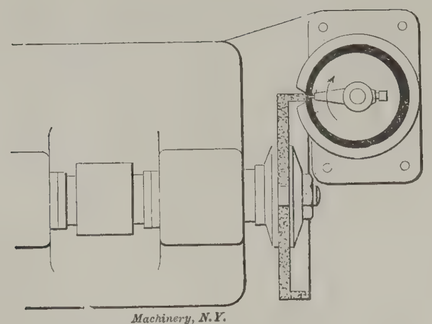


Fig. 1. Diagram of Action of Cylinder Ring Grinder.

exactly the contour of the cylinder, and hand fitting will be necessary if an accurate bearing is desired. For a further discussion of this subject the reader is referred to the article in our April issue.

Figs. 2 and 3 show the arrangement of the machine as designed by the Graham Mfg. Co. On the vertical column of the machine is mounted a head with a spindle carrying a cup emery wheel, whose edge is presented to the work in the manner shown in Fig. 1. From a small pulley at the rear of this spindle a belt is led to a large pulley at the base, which drives, through suitable gearing, the vertical shaft under the work holder. This vertical shaft, which drives the revolving dog, is furnished with universal joints as shown, in order that its upper end may freely follow the movement of the slide which carries the work. This slide may be fed in toward the wheel or brought back from it by means of the handwheel shown. The top of the slide is provided with T-slots for holding the various containers required for piston rings of different diameters. The rotation of the work may be stopped or started by means of the handle at the base of the machine.

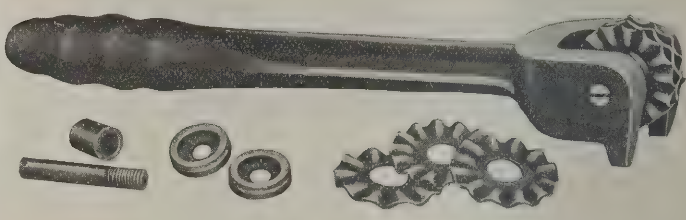
SHERMAN EMERY WHEEL DRESSER.

An emery wheel dresser of new design, made by the Sherman Mfg. Co., Detroit, Mich., is shown herewith. The cutters, owing to the arrangement of the corrugations, always remain sharp until they are worn entirely away. Their life is lengthened by making them of a high grade of tempered tool steel. Each cutter is given a different number of corrugations, thus preventing them from "nesting" together and at the same time giving each cutter a different cutting edge. They are mounted on a bushing which revolves on a spindle, thus giving a better journal than is the case in dressers so designed that the disks revolve directly on the pin. Hardened concave washers are inserted between the cutters and the sides of the handle to prevent wear at this point.

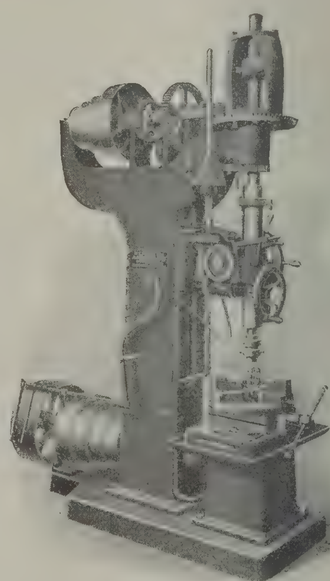


Sherman Emery Wheel Dresser.

THE MURCHEY IMPROVED TAPPING MACHINE.

The tapping machine shown in the accompanying halftone is built by the Murchey Machine & Tool Co., 33 to 37 E. Atwater St., Detroit, Mich. The machine consists essentially of a rigid cast-iron column supporting a vertical tapping spindle, with the necessary pulleys and gearing for driving it. It is especially designed for the rapid production of steam and gas pipe fittings, as well as for special work. Simplicity, strength, driving power and convenience of operation have been considered in designing it.

One of the most important of the improvements introduced in this machine is the means provided for transmitting rotary motion from the bevel gear to the tapping spindle. As will be seen from the cut, this is accomplished by a collar clamped to the upper end of the spindle and carrying two arms on which rollers are pivoted. These rollers travel on a surface provided for them on a casting clamped to the upper face of the bevel gear. The rotary motion is thus transmitted from the bevel gear through the casting to the rollers and the arm to which they are pivoted, which is in turn fast to the spindle. It will be noted that the bearing surface of the casting for the rollers is not vertical, but is inclined at an angle. This assures absolute ease of action in feeding a tap into the work, no matter how great a pressure may be needed to rotate it; this result cannot be obtained with the usual sliding key.



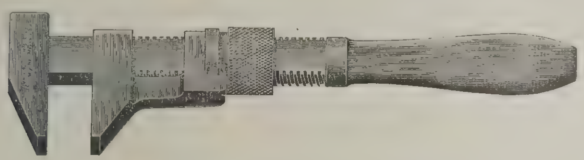
Murchey Improved Tapping Machine.

The table shown has a lateral and transverse adjustment which quickly and accurately centers the tap in a cored hole. This machine is not reversed to back the tap out, being provided with one of the builders' automatic collapsing taps, which have an adjustable stop arranged to come in contact with the sliding head which expands the chasers, and also causes the tap to collapse when it has reached the proper

depth. When desired, this machine will be furnished with a lead screw which may be made to fit any pitch of thread to suit requirements; it can also be fitted with a lever feed, hand feed, or power feed with automatic stop, according to requirements. The back gears and cone pulleys provided give eight spindle feeds. The machine shown has a range for tapping from ½ inch to 4 inches diameter inclusive. The builders are prepared to furnish special chucks for gripping flanges or fittings, and can furnish tapping machines for all sizes up to 12 inches diameter. Any suitable style of table can be furnished.

BEMIS & CALL STEEL NUT WRENCH.

The H. T. Bemis & Call Co., Springfield, Mass., have added to their line of wrenches the new design shown in the accompanying cut. The head bar and shank are made in a one-piece steel forging. The nut gives great gripping power to the jaws since as it has bolts or nuts which have the corners rounded off the whole hand can be applied for tightening the jaws of the wrench. Ordinary adjustments can be made with



Bemis & Call Steel Nut Wrench.

the thumb and finger. A special feature of this tool is the construction of the handle. It is made of steel and is forced onto the wrench under great pressure, then securely riveted in place. Being oval in form, it fits the hand and does not lame it in using as a straight handle will. It is adapted for use where the wooden handle wrench will not answer, as it cannot be injured by water, steam or heat.

* * *

A study of certain toys and mechanical devices put on the market to entertain or puzzle an audience is often of value to the mechanical designer. New applications of old principles are met with which may be profitably used to simplify a mechanism or to effect motions that would be difficult to secure otherwise. Suppose for example that it were desired to rotate a vane inside of a hermetically sealed case. If it were required that no opening be made through the side of the case the rotation of the vane would present seemingly impossible difficulties if the case were made of iron. The use of iron would, of course, prevent the use of magnetism so that about the only substitute for direct mechanical movement would seem eliminated but there still remains the possibility of using certain vibrations which, if properly applied, would rotate a light running vane under the conditions named with no mechanical connection whatever save that of the case itself. To illustrate, a little toy is sold by the street fakers called "Maz-zaz-zas," which is very mystifying in its action. It consists simply of a ½ inch square stick about 8 inches long having a nail driven in the end on which is suspended a light tin strip perfectly balanced and free to rotate. One corner of the stick is notched. The operator holds the stick in one hand while he rubs the notches with a match or toothpick, meanwhile pressing against one side of the stick with his moving thumb. The result is that the tin vane rotates rapidly in one direction. Now, if the pressure of the thumb is removed and pressure is applied by the forefinger on the opposite side of the stick the vane will commence rotating in the opposite direction. The explanation apparently is that the vibrations induced by the rubbing of the match together with the pressure of the thumb on the side of the stick causes the end of the stick to vibrate in a minute circular path which motion is communicated to the vane causing it to rotate. That these peculiar vibrations can be duplicated mechanically there is no doubt, hence the possibility of producing rotary movement of a vane in a hermetically sealed case with no mechanical connection thereto, save that of the case itself.

The fifth annual convention of the National Machine Tool Builders' Association will be held in New York, Oct. 9 and 10.

INDUSTRIAL NOTES FROM GERMANY.

Fifty Years Anniversary of the Society of German Engineers.—On June 11, 12 and 13, the Society of German Engineers held their 47th general annual meeting at Berlin and combined therewith the fiftieth anniversary of the society. Engineering societies from all parts of the world had sent representatives to express their hearty wishes. The American Society of Civil Engineers was represented for its members by Professor K. E. Hilgard of Zurich, who addressed some hearty words to the assembly. He referred to the International Engineering Congress of 1893 in Chicago as one of the most important meetings between German and American engineers. Both before and ever since this date American engineers have reaped much benefit from German science, German research and German skill. He then welcomed in the name of the American Society of Civil Engineers and all other American engineering societies all German engineers coming to the United States, and expressed the hope that the friendly relations between German and American engineers might always increase to the benefit of humanity. He closed with *a vivat, crescat, floreat* for the Society of German Engineers.

In course of the following days various interesting papers were read, of which we will only mention those of Professor Riedler-Berlin: "On the Development of Steam Turbines and their Importance at the Present Day" (a critical review on the various existing types of steam turbines, *Zeitschrift des Vereines deutscher Ingenieure*, 1906, Nos. 31, 32); Mr. O. Lasche: "The Construction of Steam Turbines by the Allgemeine Elektrizitätsgesellschaft in Berlin" (details on the various types, modes of construction, etc. *Zeitschrift des Vereines deutscher Ingenieure*, 1906, No. 33); Professor A. Rateau, Paris: "On the Rateau Steam Turbine (details on the Rateau steam turbine and the Rateau exhaust steam accumulator, *Zeitschrift des Vereines deutscher Ingenieure*, 1906, Nos. 37, 38).

Experiences and Tests with High-speed Drills in Railway Workshops.—By Government Works Manager Seiler, Berlin. The author expresses his surprise that high-speed tools, which have been extensively introduced in private industries, have not found the same reception in government workshops. His purpose is to show the advantage the use of such tools, and particularly high-speed drills in government railway workshops will afford. The reason why high-speed tools have not been successfully introduced in railways works he ascribes to the fact that the tools are generally made at the works themselves, where in consequence of the forging heat and owing to the lack of suitable tempering furnaces a great deal of hardness of the high-speed steel is again lost.

In order to prove the actual advantages of such high-speed steels he made various tests with high-speed steels from different manufacturers, which, however, with the exception of the Phœnix steel of Bleckmann in Steiermark were neither very successful nor satisfactory. Of this steel drills both pressed and drop-forged were employed, the latter, however, proving to be an entire failure, as they were much too soft. The results of the trials with pressed drills made of Phœnix steel are given in the following table:

Number	1	2	3	4
Revolutions per minute	103	165	200	200
Diameter of drill	3/8	5/8	3/4	3/4
Material drilled	Cast-iron brake-shoes.		Tool steel	
Duration of test, seconds	220	170	485	250
Depth of hole, inches	3 3/8	3 3/8	8	8
Speed of feed	15/16	1 1/4	1	1 15/16
Remarks	Drills not weakened, but belt slipped.		drill began to break out at edge.	

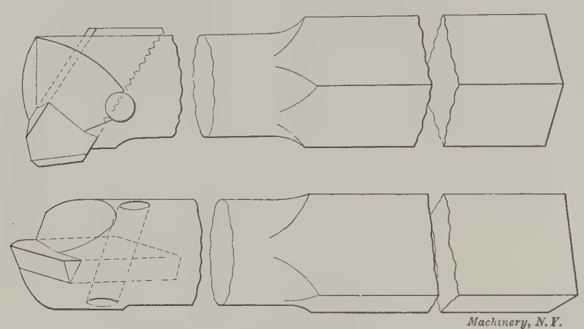
A drill made of ordinary steel, being subjected to the same tests was blunted after only a few revolutions.

The tests with the other steels were not all satisfactory for reason of inferior quality of the steels; occasionally also the machines on which the tests were made were not strong enough, or the power at disposal not great enough to allow of obtaining the full capacity of the tools. This also might frequently be the reason why customers complain of not having been able to obtain full satisfaction with the steel.

At a later series of tests the author was able to obtain a feed of up to 3 inches with a ⅞-inch drill running at 260 R. P. M. in wrought iron, the test being, however, terminated by the tool splitting up. Such splitting of the drills he ascribes to the feed limit being exceeded and fears steel manufacturers frequently claim too high capacities for their high-speed steels only to beat competition.—*Glaser*, 1906, Vol. 59, No. 2, 4.

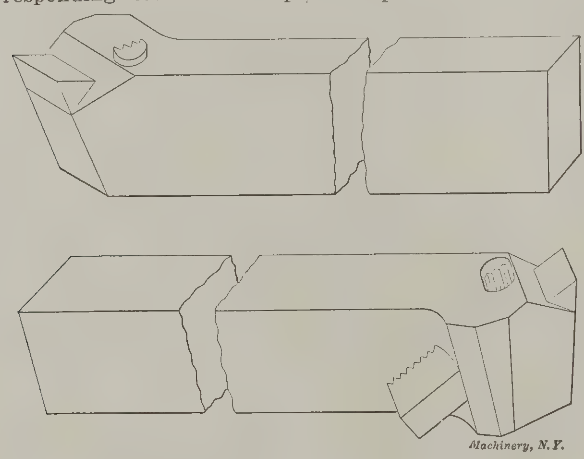
Machine Tool Trade in Germany.—Extraordinary activity exists among German manufacturers of machinery and machine tools. Various great iron works, ship-yards and other establishments are increasing their plants; also, the export trade to Russia is not so bad as might be expected under the present conditions. Great hopes are, however, entertained as to the expected increase of trade, when Russia calms down at last. Germany exported to Russia from March to June, 1906, machine tools to the amount of 8,350 pounds. This figure is very low compared with the figures of 1905-1903, viz.: 92,000, 72,000, 64,000 pounds respectively; or even compared with the export in January and February, 1906, viz.: 30,000 pounds, the figure is low. The reason is the increased duty on machine tools imported into Russia.

Tool-holder.—A new high-speed cutting tool-holder has been patented by Messrs. Mummenhoff & Stegemann of Bochum. The holder is made of very tough forged steel in the form of



Mummenhoff & Stegemann Inserted Cutter Boring Tool.

a cutting tool and encloses the cutter proper so entirely that the latter appears to be welded into the holder. The cutter has a rack-line set of teeth on its side into which engage the corresponding teeth of a taper lock-pin. As the cutter is



Mummenhoff & Stegemann Inserted Cutter Turning Tool.

closely and entirely enclosed by the holder the heat produced by cutting will readily pass over into the holder. On the cutter wearing down it can be advanced tooth by tooth.

International Motor Car Show, Berlin, Autumn, 1906.—A fine new building has been erected in the Hardenbergstrasse along the Berlin Zoological Gardens, intended to serve as hall for periodical exhibitions, etc. It will be inaugurated on November 1, 1906, on occasion of the festival opening of the Autumn Motor Car Show, 1906. This show has been arranged to last from November 1 to November 12, thereby enabling exhibitors to visit the London and Paris shows following. Emperor William II., who like his brother, Prince Henry, has a lively interest in motoring, has promised to be present at the opening. 13,000 m^2 covered, and 2,000 m^2 uncovered area is at disposal for exhibition purposes in these new premises.

The well known machine tool works of Ernst Schiess of Düsseldorf, have been converted into a limited company. The principally concerned are the Deutsche Bank and the banking firm, C. G. Trinkhaus of Düsseldorf. The capital of the new firm amounts to 5,500,000 marks, of which 3,500,000 marks will be invested in shares.

Benz & Co. Rheinische Gasmotorenfabrik, Aktiengesellschaft, Mannheim, are intending to extend their works, thereby meeting a long-felt want. No definite decision has as yet been made as to the site of the new premises.

Messrs. Thyssen & Co., of Mühlheim o/Ruhr (Germany), have purchased about five acres of land in addition to the area already covered by their works. They intend to take up the manufacture of locomotives as a specialty.

Concordia Elektrizitäts A-G. Cologne-on-Rhine (Germany): Under this name a new concern has been established with the purpose of erecting electric power stations and plants.

Berlin, September 15, 1906. D.

* * *

OBITUARY.

William H. Owen, formerly president of the Owen Machine Tool Co., Springfield, Ohio, died at his home in that city August 31.

James A. Burden, the well-known ironmaster and inventor of Troy, N. Y., died at his New York home September 23. He was born in 1833 and was the son of Henry Burden, the inventor of the horseshoe machine.

William F. Kennedy, who is said to be the inventor of the base burner radiator stove with shake and dump grate commonly used for heating rooms, died a few months ago in Providence, R. I., at the age of 82.

* * *

PERSONAL.

Erik Oberg, for the past three years draftsman in the small tool department, Pratt & Whitney Co., Hartford, Conn., has joined the editorial force of Machinery.

A. L. De Leeuw is engineering the new plant to be erected by the Cincinnati Milling Machine Co. at Oakley, Ohio, a suburb of Cincinnati.

Mr. and Mrs. Amos Whitney celebrated their golden wedding September 8 at their residence, No. 568 Farmington Ave., Hartford, Conn.

Arthur W. Cole leaves the University of Maine to act as instructor of steam engineering for the coming year at Purdue University, Lafayette, Ind.

Mr. M. Koyemann, the representative for Northern Europe of the Jones & Lamson Machine Co., the Fellows Gear Shaper Co., and other American manufacturers, is in this country and expects to stay until the latter part of October.

T. E. Barker, for ten years with the Miehle Printing Press & Mfg. Co., Chicago, Ill., in various executive positions, has resigned to accept the position of superintendent with the America Co., hardware specialty manufacturers, Momence, Ill.

Edward R. Markham, 66 Dana St., Cambridge, Mass., a well-known contributor to Machinery, is now giving up part of his time to consulting engineering practice, making a specialty of advice on hardening, tempering and annealing steel, and general shop work.

Thomas M. Brown has taken charge of the machinery department of the William Skinner Shipbuilding & Drydock Co., of Baltimore, Md. Mr. Brown had been identified with the machinery trade for many years, but for the past two and a half years was in another line of business. His friends will be pleased to learn of his return to his former work.

Wm. A. Bole, for many years superintendent and works manager of the Westinghouse Machine Co., East Pittsburg, Pa., has been made consulting engineer of that company, and vice-president and general manager of the Westinghouse Consolidated Foundries Co. This concern, located at Trafford City, about five miles from East Pittsburg, will do all the foundry business of both the Westinghouse Machine Co. and the Westinghouse Electric & Mfg. Co.

FIRE EXTINGUISHER FOR MARINE COAL BUNKERS.

One of the most difficult things to combat on board ship is fire in the coal bunkers. Bituminous coal containing iron pyrites is likely to become on fire by "spontaneous" generation of heat sufficient to cause ignition. When fire is discovered in stored coal the common impulse is to fight it by pouring streams of water upon it but this is generally ineffective. A smouldering fire at the bottom of a coal pile forms a mass of coke around it which will not permit the entrance of water in sufficient quantity to drown out the fire, but the heat will change the water to steam and then to water gas which if confined in close places like the hold of a ship is likely to form explosive mixtures. Prof. Vivian B. Lewes suggests that a valuable and effective fire fighting apparatus for coal bunkers would be carbon dioxide stored in strong steel cylinders provided with a fusible plug. Carbon dioxide compressed to liquid state requires a pressure of 1,700 pounds per square inch, and when it expands it produces intense cold, and is also a non-supporter of combustion. In case of fire in the vicinity of one of these cylinders the combustion would be stopped by the reduction of temperature as well as the absence of oxygen. One hundred cubic feet of carbon dioxide can be condensed in a liquid state in a steel cylinder having a capacity of about 7 cubic feet. A ton of average coal contains about 12 cubic feet air space so that one of these cylinders should be put in for every 8 tons of coal in order that the carbon dioxide gas would be sufficient to displace all the air within the coal mass.

* * *

FRESH FROM THE PRESS.

THE Machine Tool Pocket List formerly published by Angus Ballard Co. has been purchased by the Geo. H. Gibson Co., Park Row Building, New York. The size of the publication will be increased from 3½ x 6 inches to 4 x 9 inches. The buyers' finding list of machine tools and supplies will be made still more complete and definite. Brief articles of interest to manufacturers of machinery will also be added and the list will be combined with *Manufacturing*, a journal published by the Geo. H. Gibson Co., which describes and lists important patents and other industrial opportunities.

THE MCCONWAY & TORLEY CO., Pittsburg, Pa., have recently issued a new edition of the "Car Interchangeable Manual," covering all decisions of the Arbitration Committee from November, 1888, up to and including case No. 703 of May, 1906. They are making a general distribution of this book to railway car men, but any who have not received a copy may obtain it free of charge on request. The McConway & Torley Co. have also issued a pamphlet entitled "Ready Reference Tables," designed particularly for car men, and they now have in press a new edition of "Catechism of M. C. B. Rules." Any or all of these books will be sent to railway men free of charge.

CATECHISM ON PRODUCER GAS. By Samuel W. Wyer. 42 pages, 4¼ x 6½ inches. 3 cuts. Published by the McGraw Publishing Co., New York. Price, $1.00 net.

This timely little book is gotten up in the familiar catechism style popular for instilling elementary knowledge on engineering subjects. It contains a considerable amount of information on producer gas, its manufacture, the apparatus employed, etc. The subject is one which is rapidly becoming more and more important. The gas producer plant and the gas engine are quite likely to displace the steam power plant, wherever economy is a prime requisite. As a primer or introduction to the subject, this little work can be recommended.

WIRING A HOUSE. By Herbert Pratt. 21 pages. 5⅛ x 8 inches. 6 cuts. Published by the Derry-Collard Co., New York. Price, 25 cents.

This little book is No. 6 of a series of practical papers published by the Derry-Collard Co., and is written by one who has had much experience in the planning of wiring and the actual wiring of houses and other buildings. It is chiefly devoted to the wiring of houses already built which, of course, is a much more serious job than the wiring of new houses. The necessary calculations for obtaining the sizes of wire are given and other practical information which should be useful to those contemplating the doing of such work.

HELPFUL HINTS FOR HARDENING STEEL. By Jos. W. Bennett. 83 pages 3½x5 inches, 12 cuts. Published by the author at New Britain, Conn. Price $1.00.

The author has had thirty-five years' experience in hardening and tempering tool steel and should, therefore, be in a position to give some good practical hints to other workers of tool steel. A number of the hints given could easily be worth many times the cost of the book to some steel workers. Following are a few of them: How to anneal steel containing hard and soft spots; how to harden blanking dies; how to harden a drill jig or reamer bushing to prevent shrinking; how to harden spring collets; how to prevent taps from shortening in the lead, etc. The author includes a coupon in each book which entitles the purchaser to the privilege of asking questions from time to time concerning hardening and tempering steel, a feature that doubtless will be appreciated by some purchasers.

THE AMERICAN STEEL WORKER, by E. R. Markham. 366 pages, 5½ x 7¾. 163 cuts. Published by the Derry-Collard Co., New York. Price, $2.50.

This is the second edition of Mr. Markham's excellent work on the working, hardening and tempering of the various kinds and grades of steel. It is doubtless the best practical work on the subject for the smith, toolmaker and general mechanic. The second edition has been improved in a number of ways. It is printed on thinner paper, making the volume more compact, and an appendix of 24 pages has been added on high-speed steel. An excellent feature of this work which cannot be too highly commended is a copious index of contents, this part covering 28 pages. The value of a complete index to a work of this kind can scarcely be over-estimated for its chief value lies as much, perhaps, in being a work of reference, as for the general information to be obtained by one reading, and the index is an important time-saver.

DESIGNS OF SMALL DYNAMOS AND MOTORS. By Cecil P. Poole. 186 pages 6 x 9 inches, 231 cuts. Published by the McGraw Publishing Co., New York. Price, $2.00 net.

This book is designed for the amateurs and others who desire to build small electrical motors. Most of its chapters were originally articles published in the *American Electrician*. The book gives directions, with sketches, for building a 1-6 horse-power motor with drum armature and with ring armature and the same designs for ¼ and ½ horse-power; also for 1 horse-power bi-polar motor and four-polar motor with drum armature; 2 horse-power four-polar motor with two-path drum armature; direct current 110 volt motor; three horse-power launch motor, etc. The designs and sketches have, we believe, been verified by actual construction, so that they are, for the most part, reliable guides for the amateur builder. Perhaps one of the best ways of getting the elements of electrical science well grounded is to construct some simple electrical apparatus like examples shown in this work and to such this book should appeal.

BRAZING AND SOLDERING. By James F. Hobart. 33 pages, 5½ x 8 inches. 16 cuts. Published by the Derry-Collard Co., New York. Bound in paper. Price, 25 cents.

This little book is No. 5 of a series of practical papers, and it should meet with general approval, being on a subject on which there is more or less general demand for "pointers." It treats of soldering, hard and soft, that is, brazing with spelter and soldering with the tin and lead solders. The author has had much practical experience in this class of work and he has illustrated the text with sketches which show plainly the various tool and methods employed. Hard soldering, or brazing, is one of the most useful methods of making sound joints, and next to welding, is the strongest. But, unlike welding, it is applicable to a considerable class of metals either similar or dissimilar; as, for example, brass to brass, or brass to iron, and so on. In the chapter on soldering various forms of soldering bits are illustrated and the correct method for taking solder from a bar. We have no doubt that amateur users of a soldering kit can learn a number of useful hints by reading this little work.

COMPLETE EXAMINATION QUESTIONS AND ANSWERS FOR MARINE AND STATIONARY ENGINEERS, by Calvin F. Swingle. 367 pages, 4¼ x 6¾ inches, 212 cuts. Published by Frederick J. Drake & Co., Chicago, Ill.

As indicated by the title this book is of the familiar and popular catechism type in which questions are proposed and answered in a succeeding paragraph. This form of technical literature appeals to the firemen, engineers, and those who are required to pass an examination in order to obtain a license. It formulates the question and a presumably accurate answer thereto in a way which is concise and to the point. The book in review appears to be a fair example of this class. It covers a considerable range and must necessarily be more or less superficial when the available space is considered. It touches on steam, heat, combustion, fuel, boilers, boiler construction, boiler settings and appurtenances, boiler operation, types of engines, condensers, pumps, sea-water, auxiliary machinery and fittings, the indicator, principles of the indicator, the steam turbine, etc. The cuts are a collection of wood cuts, zinc etchings, and halftones, and are in many cases of a totally disproportionate size to the page and subject. The book, on the whole, is one that will doubtless be of considerable benefit to the class for which it is designed.

HANDBOOK OF MATHEMATICS. By J. Claudel. Translated and edited by Otis A. Kenyon. 708 pages 6 x 9 inches, 422 figures. Published by the McGraw Publishing Co., N. Y. Price, $3.50 net.

The original of this book is a French work intended for engineers and engineering students and the translation is from the seventh French edition. It is intended primarily as a reference book, but it is also well adapted for home study. The translator says in the preface: "The use of text books for reference by the busy man is discouraging. For example, if he wishes to solve an integral which is not given in the table he naturally refers to his text book on integral calculus, spending several hours studying, and then finds that his trouble is farther back, most likely in algebra. The chances are that due to lack of time he will give up and declare that he has forgotten his calculus." In the preparation of this work the trouble mentioned has been anticipated by the very frequent use of cross references, completely interconnecting all parts of the book. The book is divided into six parts, as follows: Arithmetic, Algebra, Geometry, Trigonometry, Analytic Geometry, and Elements of Calculus. From a somewhat superficial examination of the work it appears to be one that almost any engineer would be glad to have on his book shelves to occasionally refresh his knowledge of mathematics. It is well gotten up, the type being large and clear, formulas distinctive, and the tables well arranged.

TECHNICAL DICTIONARY, Vol. 1. By K. Deinhardt and A. Schlomann. 403 pages, 4 x 7 inches; illustrated. Published by the McGraw Publishing Co., New York. Price, $2.00 net.

The scheme of this dictionary, which is to be published in eleven volumes and in six languages, is to present (if possible) a sketch of the thing named in the middle of the page and to give its name in English, German, French, Russian, Italian and Spanish, in parallel columns one at each side. The dictionary presents three distinct features: 1, index; 2, systematic arrangement of matter; 3, alphabetical index of words. For example, in the division Screws and Screw Bolts, the first sketch shows a helical line around a cylinder. This is defined in the six languages, then follow "angle of inclination, "pitch," "helicoidal surface," "thread of screw," "the screw has *x* threads per inch," "screw-thread," etc. It is, of course, obvious that certain ideas cannot be represented by sketches, so that each definition does not necessarily have a sketch to accompany it. The general arrangement of the work makes its use very convenient. Vol. 1 is on the elements of machinery and the tools most frequently used in metal and wood-working. Among the machine elements are listed Screws and Bolts; Keys, Rivets, Axles and Shafts, Trunnions, Bearings, Lubricators, Couplings, Gearing, Friction Wheels, Belting, Chain Transmission, Rollers, Ratchet-gearing, etc. Under the general head of tools we have Vises, Tongs, Anvils, Hammers, Chisels, Files, Scrapers, Drills, Milling Cutters, etc. The scheme of illustrating each machine part, etc., by means of sketches, which is a universal language understood by all, makes the work one of great general value and one to be commended to the needs of those having to make technical translations.

THE DESIGN AND CONSTRUCTION OF CAMS. By Chas. F. Smith, Frederick A. Halsey and others. 70 pages, 9 x 12 inches. 62 cuts. Published by the Hill Publishing Co., New York. Price, $3.00

This book is largely a reprint of the articles on cams that have appeared in the *American Machinist* during the last year or two, and which undoubtedly constitute one of the best treatments of the subject to date. Mr. Smith, the principal author, has been connected with the construction of machinery involving the use of cams for twenty-five years, and naturally he has made the study of cams a specialty. When it is known that he has designed machines containing as many as twenty cams, all of which were laid out and keyseated from drawings and assembled without change, working in entire harmony, it must be admitted that his system is one that gives correct results. The book by chapters is as follows: Classification of Cams in Order or Work; the Machine from which the Illustrations are Drawn (being a wire chain-making machine); the Operation of the Chain-Making Machine; Charting the Movements; Laying out an Actual Face Cam, Making the Former and Milling the Cam; Laying Out and Making Periphery Cams; Raised Pathway, Yoke and Conical Cams; Cams for Prescribed Movements; Repeated and Return Movement Cams; Charts with a Separate Base Line for Each Cam, Abbreviated Charts, Extreme Angles, Locating Keyways; the Double-Cam System of the Monotype; Cam Movements Obtained from Base Curves Other Than the Circle; the Location of Lever Fulcrums for

Face Cams; Minute Adjustment of Cam Lever Movements; Grinding Cams. The size of the page (9 x 12 inches) permits the use of large drawings, but even with this size page it has been necessary to introduce one folding chart, being the cam chart of the chain-making machine. Altogether, we can recommend the book as being a first-class work on a technical subject in general little understood.

NEW TRADE LITERATURE.

Fitchburg Machine Works, Fitchburg, Mass. Supplementary booklet on the Lo-swing Lathe, giving some details about the machine and instructions for its operation.

Atlas Engine Works, Indianapolis, Ind. Bulletin No. 132 describing medium speed automatic four-valve engines and their various parts and giving tables of specifications for the different classes.

Crocker-Wheeler Co., Ampere, N. J. Bulletins 66 and 67, taking for their subjects Form I-F Variable Speed Motors and W Motors for Rolling Mills, respectively. The usual description, illustrations and tables of specifications are included.

Modern Tool Co., Erie, Pa. Catalogue describing and illustrating their various tools—chucks, tapping attachments, dies, grinders, etc. Tables of U. S. Standard bolts and nuts, drills for U. S. S., V., and Whitworth thread and decimal equivalents of nominal sizes of drills are also included.

The Bickford Drill & Tool Co., Cincinnati, Ohio. Radial Drill catalogue for 1906. Halftone illustrations show the complete line of radial drills and descriptions of the various parts and general specifications for the different styles complete the data.

Newton Machine Tool Works, Inc., Philadelphia, Pa. Catalogue No. 44—Keyseat Milling Machines, illustrates and describes the two sizes of this machine, and enlarged illustrations make clear the method of operation. A special machine for locomotive axles is shown and a new design of machine used for heavier and longer shafts is also illustrated.

Quincy, Manchester Sargent Co., 114 Liberty Street, New York City, have issued a new catalogue with adjustable leather cover fastened by screws, by means of which new leaves may be inserted as they are issued. The book contains illustrations and brief descriptions of the standard tools of the company, attention being called to the more important points only.

The P. L. Abbey Co., Kalamazoo, Mich. Circular describing emergency accident cabinets for individuals, shops or stores and manufacturing plants. The $7.00 size, designed for the manufacturing plant, comprises an emergency outfit, for accidents, that no shop should be without, as its presence may often save loss of life or serious consequences due to an accident not being properly attended to in time.

National Association of Manufacturers, 170 Broadway. Proceedings of the 11th annual convention, 1906, held at New York, May 14-16. The proceedings are given in full, including addresses of welcome, committee reports, etc. The proceedings are well worth study by those interested in discussions of the labor problem, strikes, metric system, railroad rate legislation and general commercial problems affecting manufacturers and their products.

Association of Licensed Automobile Manufacturers, New York. Bulletin No. 18, containing standard for hexagon head screws, castle and plain nuts adopted by the Association of Licensed Automobile Manufacturers. It has been found that the Sellers, or U. S. Standard screws, do not meet the requirements of automobile construction satisfactorily, the pitches being too coarse. Tables showing the dimensions, pitches, etc., will be given in a later issue.

J. H. Wagenhorst & Co., Youngstown, Ohio. Leaflet giving in concise form a description of the electric blueprinting machine manufactured by them; also testimonials from satisfied customers. The leaflet includes prices for various sizes of the machine. An important feature is the roller curtain which makes the placing of a tracing and sensitized paper an easily-accomplished operation. It also permits the printing to be examined at any time without the danger of disarranging the relative position of the tracing and paper.

The Gisholt Machine Co., Madison, Wis. Leaflet descriptive of the Gisholt turret lathe equipment for railroad shops showing tools designed for finishing crossheads, eccentrics, pistons and bull-rings. This equipment is of particular interest because it was thought, not long ago, that turret lathes could not be used economically on such parts on account of the comparatively small number made at one time. This equipment, however, is of such simplicity of construction that it is quickly set up and used economically on a few pieces as well as on a large number.

The Board of Trade, of Columbus, Ohio, has issued an attractively illustrated pamphlet on Columbus, showing the principal buildings, streets, manufacturing industries, etc. It tells of the advantages of Columbus for manufacturing industries and as a place of residence. Situated in central Ohio, a radius of 500 miles reaches all the principal parts of Eastern United States, thus indicating that the city is located in a strategic position as regards the distribution of products throughout this part of the country. A map graphically illustrates this fact.

Joseph Dixon Crucible Co., Jersey City, N. J. General catalogue giving description and illustrations of the principal graphite productions of the company. Prices are not included but are given in the form of a special price list, which will be sent free upon request. "Graphite Lubricants" is a booklet setting forth the important facts together with the prices of Dixon's lubricating graphites and graphite lubricants. A little pamphlet on Dixon's Graphite Brushes describes the use of same and gives the results of tests made upon these brushes by Prof. Albert F. Ganz of Stevens Institute.

Drexel Institute, Philadelphia, Pa. Circular offering the following classes in engineering subjects during the coming season: 1, Engineering Drawing; 2, Mechanics and Heat; 3, Elements of Chemistry; 4, Engineering Electricity; 5, Advanced Engineering Electricity; 6, Strength of Materials and Machine Design; 7, Advanced Strength of Materials and Machine Design; 8, Thermodynamics and Steam Engineering; 9, Plane Surveying; 10, Advanced Surveying. Although stated separately, the foregoing subjects may be grouped in courses in electrical, mechanical or civil engineering, the exact combinations being dependent upon individual needs.

Geo. V. Cresson Co., Philadelphia, Pa. Catalogue of cast iron pulleys. The three standard types of pulleys—whole, parting, and clamp-hub—and special pulleys made for use on electrical machines are described and illustrated. In the back of the catalogue is given a report of the tests made by R. C. Carpenter, of Cornell University, to determine the efficiency of the para-pneumatic pulley as compared with the smooth-faced pulley. The results show a decided superiority of the para-pneumatic pulley over the common, plain pulley in transmitting power for the same width of belt and under the same conditions of loading. The tables accompanying the tests give full details of data and results.

Chas. H. Besley & Co., Chicago, Ill. Catalogue of Besley spiral disk grinders, Besley band grinders and polishing machines, Helmet spiral circles, etc. Attention is called to four new machines, these being No. 11, for patternmaking and light metal grinding; No. 12, for heavy metal grinding; No. 14, with lever feed; and No. 6, model 1906, double disk grinder. A feature of the catalogue is the tables of Helmet spiral paper circles numbered for various materials, such as cast iron, brass, soft steel, hard steel, malleable iron, general grinding, hard rubber, wood, etc. About 12 numbers of abrasive are available for each of the various classes of substances. The numbers mostly used are identified by bold-faced type. Books containing sample sections of the various grades of abrasive disks used are supplied to dealers for the convenience of customers in selection.

The Western Tube Co., Kewanee, Ill. Pamphlet describing "high duty" metal, a new bronze mixture which shows a loss of tensile strength when subjected to a temperature of 407 degrees F. of only 5.6 per cent. This metal has been developed after an extensive series of tests of known bronze mixtures. The best of these, the United States Government mixture, consisting of 88 parts copper, 10 tin, and 2 of zinc, was found to be as little affected by high temperature as any developed heretofore. The decrease in strength at 407 degrees F. was a drop of 9 per cent from the cold tensile strength of 33,633 pounds per square inch. "High duty" metal, however, shows a strength of 31,627 pounds per square inch at 407 degrees F. as against 30,675 pounds for United States Government metal. Its wearing qualities are good and the alloy is tough, thus resisting shock due to water-hammer, etc.

MANUFACTURERS' NOTES.

Eberhardt Bros. Machine Co., Newark, N. J., are building an addition to their assembling room which will enable them to handle about double the present output.

Burke Machinery Co., of Cleveland, Ohio, manufacturers of oil furnaces and bench machinery, have recently moved to their new factory, corner Perkins Avenue and 35th Street.

The Morse Chain Co., formerly of Trumansburg, N. Y., have moved their general offices and shops to Ithaca, N. Y., where a new plant of the best modern construction has been erected.

The Armstrong Bros. Tool Co., Chicago, Ill., have installed additional machinery so as to keep up with their orders and get some finished stock ahead. The sales of Armstrong cutting-off and grinding machines are increasing steadily.

Chas. H. Besley & Co., 15 South Clinton Street, Chicago, Ill., will exhibit their Besley Spiral Grooved Steel Disc Grinder and their Helmet Spiral Paper and Cloth Circles at the Olympia, London, England, Exposition to be held from September 15 to October 17, 1906.

The Cleveland Twist Drill Co., Cleveland, Ohio, have recently completed an addition to their factory that will enable them to increase their capacity 25 per cent. They have also built a new power plant containing a 1,250 H. P. engine and 1,600 H. P. in new boilers.

The Jacobs Mfg. Co., of Hartford, Conn., makers of the Jacob improved drill chucks, have been forced to move into a larger and more convenient factory. They are installing additional machinery and hope in the near future to be able to take care of their rapidly-increasing business.

J. H. Wagenhorst & Co., Youngstown, Ohio, report the following recent sales of electric blue printers: Eugene Dietzgen Co., New York; Wisconsin Telephone Co., Milwaukee, Wis.; Calumet & Hecla Mining Co.; Carnegie Steel Co.; Swift & Co., Chicago, Ill.; the A. O. Smith Co., Milwaukee, Wis.

The Lyon Metallic Mfg. Co., formerly of Chicago, Ill., are now located at Aurora, Ill., where they have erected a large factory, giving them a capacity of over four times the old plant. They will manufacture on a large scale lockers, steel tool boxes, tote pans, oil cans, steel shelving, portable tool racks and all kinds of metal machine shop furnishings.

Armstrong Bros. Tool Co., "The Tool Holder People" of Chicago, have just shipped two orders received recently from the Isthmian Canal Commission, aggregating almost one thousand Armstrong tool-holders, many heavy sizes being included. They have also received recently an order for universal ratchets for use in the Canal Zone. Many smaller shipments have preceded these later orders.

The New Era Mfg. Co., Kalamazoo, Mich., manufacturers of metallic phosphoro (phosphor tin improved), white bronze, babbitt metals and special alloys, are now occupying their new quarters at the corner of Cobb Avenue and the S. H. Branch of the Michigan Central Railroad, and are thoroughly equipped and prepared to take care of any quantity of business in their line.

John MacGregor formerly superintendent of the Pope Manufacturing Co., Hartford, Conn., is now manager of MacGregor's Engineering and Employment Agency, Springfield, Mass. This is a newly organized concern developed on the basis of an old agency which was bought out. It is the intention to conduct a first-class agency for employment by men who have been "through the mill" and know something of the actual requirements of employers and who are personally able to judge of the abilities of employees.

The Goldschmidt Thermit Co., 43-49 Exchange Place, New York, are about to vacate their present manufacturing premises at 179 Christopher St., New York, as they are insufficient for their largely increasing business. They have bought ground at the corner of Cornelison and Bishop Sts., Jersey City, N. J., and have there erected a large factory building 75 x 165 feet. This location is within easy reach of their down-town offices. They intend removing the manufacturing plant from its present location to the new plant on or about October 1st.

The Carborundum Co., Niagara Falls, N. Y., have started building a large branch plant in Germany. They are the sole American manufacturers of carborundum in the various forms used for grinding purposes and the demands of their European trade make the establishment of branch works of carborundum on the continent an absolute necessity. The German company has been formed under the title of "Deutsche Carborundum Werke, G. m. b. h.," and is located at Reisholz, a manufacturing suburb of Dusseldorf-on-the-Rhine. The new works, which will embody all the latest and improved machinery for the manufacture of abrasive materials, is expected to be in operation about January 1, 1907.

The International Correspondence Schools, Scranton, Pa., will celebrate the fifteenth anniversary of the schools at Scranton, Pa., October 16. The schools were started by Mr. Thomas J. Foster, then editor of a newspaper in Shenandoah, Pa. He introduced a method of teaching through the mails by means of special home study text books and a system of direction and correction of student's work, the object of which was to enable the coal miners of Pennsylvania to pass the required examination for mine foremen. It was little dreamed that this was the beginning of a new educational system which would eventually turn the whole world into a vast school room and offer the means by which men in almost every trade or occupation could improve their education and consequently their money-earning power. The school now has 200 courses of instruction, covering almost every branch of the well-known trades and professions. Up to the present time 85,000 students have either completed the course for which they enrolled or a substantial portion thereof; 225,000 other students have completed the study of mathematical, physical and drawing subjects. These figures seem the more impressive when it is known that the largest number of students graduated by any one American school is 28,000, this being the record of Harvard University, an institution more than 200 years old.

RAILWAY MACHINERY.

A special edition of MACHINERY devoted to Locomotive and Car Equipment and Mechanics.

November, 1906.

THE LEHIGH VALLEY RAILROAD SHOPS, SAYRE, PA.

The principal repair shops of the Lehigh Valley Railroad are at Sayre, Pa. As at present constituted, the locomotive and car repair shops cover nearly 55 acres, and the layout is shown in Fig. 5. The buildings belonging to that part of the plant known as "the new shop," built in 1904, are the power house, main locomotive shop, blacksmith stores, scrap dock and various other small buildings in the immediate vicinity.

Beneath the gallery are located the various gangs for doing special work, including those working on the air brakes, spring rigging, brake rigging, rod and motion work, steam pipes, and painters, tinsmiths, and pipe fitters. The toolroom is located under the gallery.

The various shops and bays are served by thirteen electric traveling cranes located as follows: One 120-ton crane in the east erecting bay; one 120-ton crane in the west erecting bay; one 15-ton crane in the east erecting bay; one 15-ton crane in the west erecting bay; two 15-ton cranes in the east covered yard; two 15-ton cranes in the west covered yard; two 15-ton cranes in the east machine shop; two 12-ton cranes in the west machine shop; and one 30-ton crane in the boiler shop for the gap riveter.

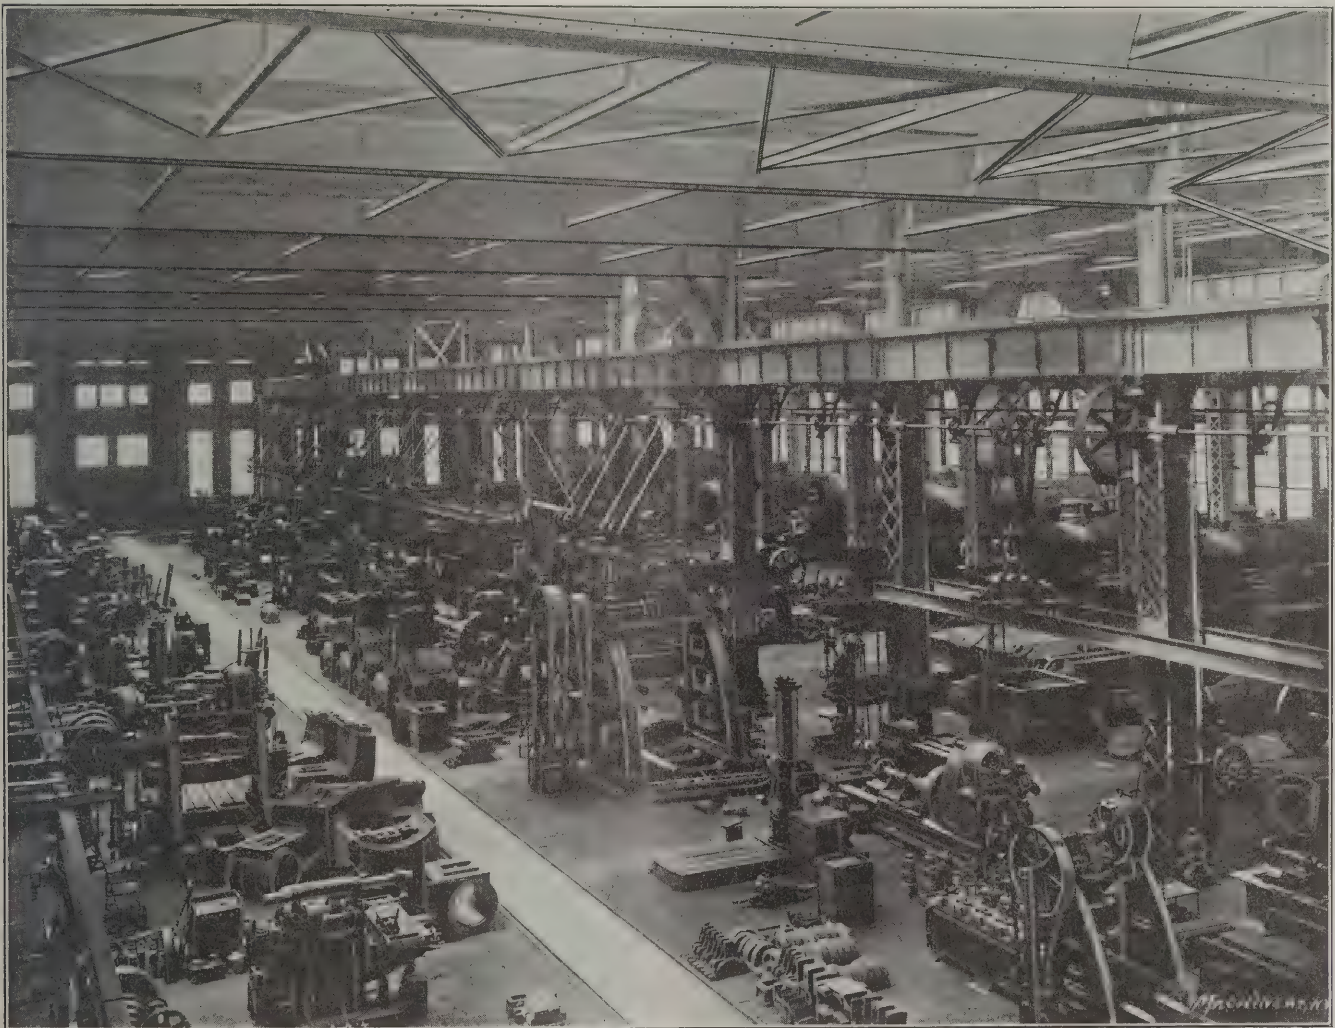


Fig. 1. View from Gallery of the East Machine Shop, showing North End of Bay.

The boiler shop and locomotive shop with which this brief description has principally to deal are under the same roof and are of large size, being 360 feet wide and 750 feet long. The boiler shop occupies a space 120 x 360 feet at the south end of the building, a view of one part of which is shown in Fig. 11. The main locomotive shop has a floor space 360 x 630 feet and a gallery of 36 x 630 feet, where are located the heaters, lavatories, toilets, locker rooms, belt room, etc. The locomotive shop is divided into two main departments, known as the east and west shops, respectively. Both are of the transverse track type and have accommodations for forty-eight engines, which number may be increased to fifty-two by utilizing, when necessary, the two main cross tracks. The shop is in all essentials a double shop, there being on each side an erecting shop, covered yard, and machine shop, with a gallery in the center.

Figs. 1 and 2 show general views in the east machine shop and are taken from the gallery near the middle of the shop. The row of locomotive pits on the side are shown in the background in each case. The views shown in Figs. 3 and 4 give an idea of the length of the shop; Fig. 3 is taken on the ground level in the west machine shop, showing nearly the full length.

The floors are built of 2-inch hemlock plank laid diagonally on 5 x 8-inch timbers, which latter are imbedded in concrete in a natural gravel bed. Over the plank is laid 7-inch maple

flooring 3 inches wide. The floors are laid first and then the outline of the various machine foundations are in most cases cut out by a portable saw with an electric motor. This machine is illustrated in Fig. 13 and is one of the greatest laborsavers for the purpose devised that can well be imagined. It consists essentially of an electric motor mounted on a frame which is pivoted on top of a four-wheel truck. The chines may seem at first thought like a rather wasteful process, it was the most practical method to follow in this case, and perhaps was the most economical from all points of view. The laying of the flooring was, of course, greatly simplified by having no machine foundations to work upon, and with the portable machine the cutting out to the exact shape required was a very simple and expeditious process. The saw

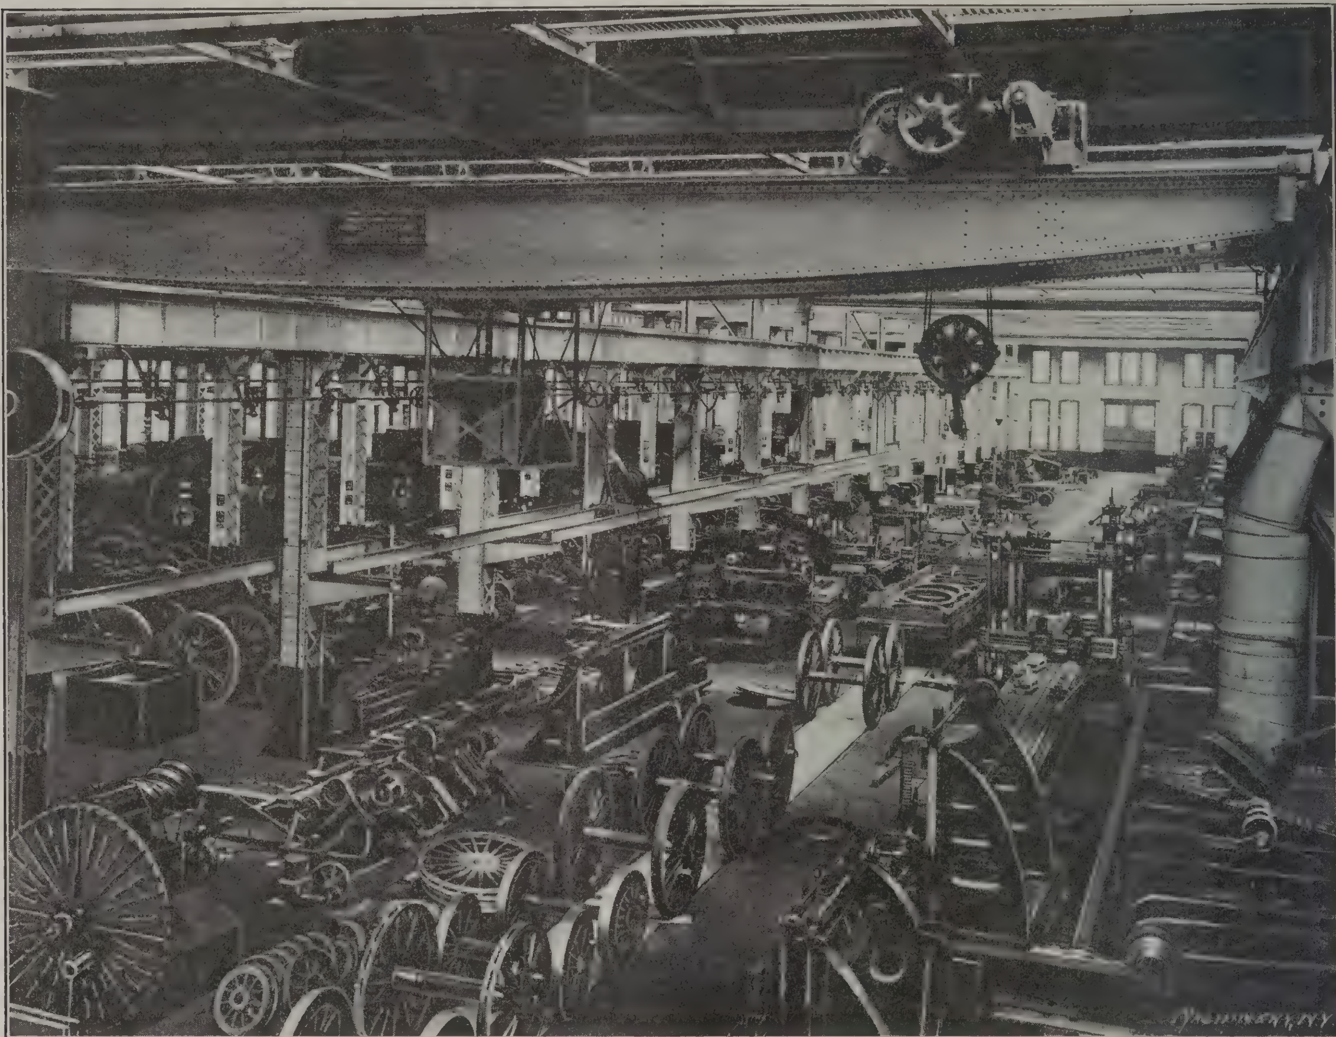

Fig. 2. View from Gallery of East Machine Shop, showing South End of Bay.

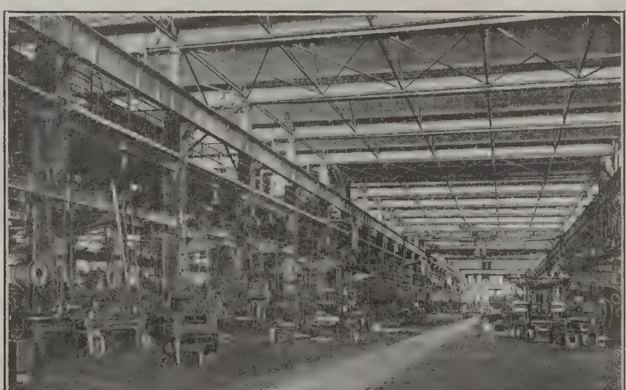

Fig. 3. View of nearly the Entire Length of the West Machine Shop Bay, looking South.

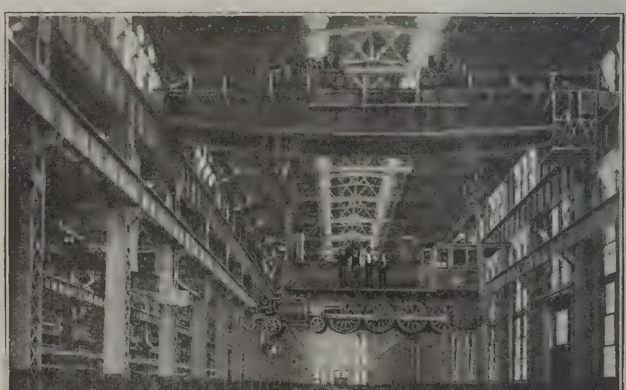

Fig. 4. View from South End of East Erecting Shop Bay.

motor is belted to a saw and a hand-wheel is provided by which the frame carrying the motor and saw can be tilted so as to cut into the flooring. The wheels are guided into temporary trucks while sawing and the feed motion is by hand.

While the plan of laying the floor over this immense area without breaks and then cutting out the places for the ma- cuts through wood, nails and concrete with cheerful indiscrimination and did in a comparatively few hours what would have been a tremendous job if performed by hand labor. It was really necessary to lay the flooring first, as in many cases the floor plans of the machines could not be obtained at the time the floor had to be laid.

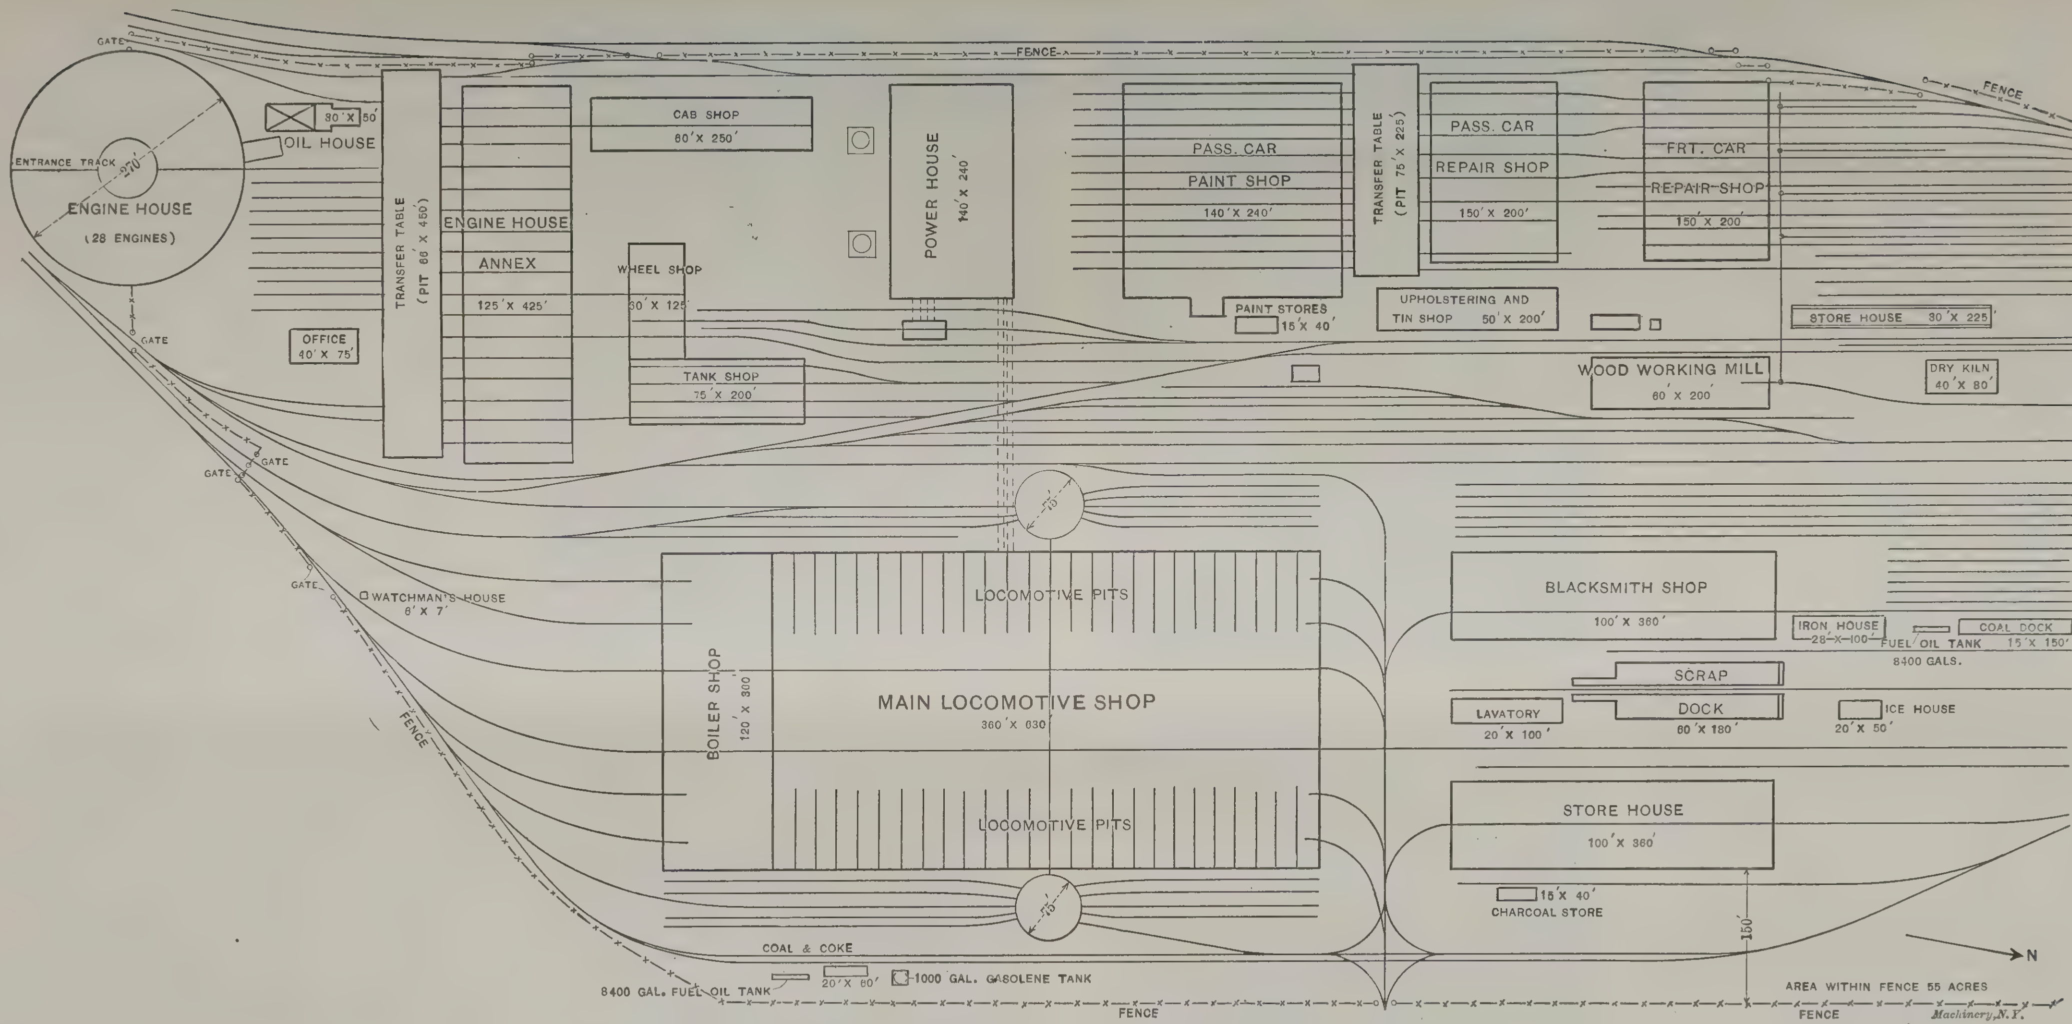

Fig. 5. Locomotive and Car Repair Shop Yards, Lehigh Valley Railroad, Sayre, Pa.

JOY VALVE GEAR NOT EXPERIMENTED WITH BY THE PENNSYLVANIA RAILROAD.

An erroneous statement was made in the October issue in the report of the discussion on the paper "Walschaerts vs. Stephenson Valve Gear," read at the New York Railroad Club in September. We inferred from the discussion that some years ago the Pennsylvania R. R. had experimented with a locomotive equipped with the Joy valve gear, but such is not the case; Mr. A. W. Gibbs' (General Superintendent of Motive Power, Pennsylvania R. R.) experience with the Joy gear was obtained on a Southern railway and not on the Pennsylvania R. R.

RYERSON FLUE CLEANING MACHINE.

An interesting flue cleaning machine for locomotive shops, which is quite a radical departure in principle from the usual type of cleaner, is made by Jos. T. Ryerson & Sons, Chicago. The flues are loaded on a car having a short cradle and are run under a gallows frame which stands over a concrete pit partially filled with water. Two wide faced endless chains mounted on sprocket wheels on the gallows frame are slipped over the ends of the flues and the car is then backed off the pit. The machinery is so adjusted that the chain loops are then lengthened sufficiently to immerse the flues in the water where they are turned over and over by the chain loops, running on the sprockets which are driven by an electric motor. The new process is advantageous not only in saving labor in handling flues but is nearly noiseless, the flues being entirely immersed in water during the operation. Five hundred flues may be handled at one time, the cost, it is claimed, being less than four cents per hundred flues. A model showing the complete operation was exhibited at the Master Mechanics' Convention at Atlantic City last June.

THE DESIGNING OF A LOCOMOTIVE.—18.

THE TRUCKS.

GEO. L. FOWLER and CARL J. MELLIN.

The truck is an essentially American characteristic of the locomotive. For many years European locomotives, especially those used in freight service, were built without any truck, and the guiding of the engine was done by the flanges of the front pair of wheels. In this country, however, the truck has always been used upon road engines and has been considered an essential detail in their safe and satisfactory operation.

Broadly speaking, the engine truck proper, or the one located at the front end, may be divided into two classes, the two- and four-wheeled types. The four-wheeled truck is the one that has been universally used on locomotives intended for passenger service, while the two-wheeled has been applied to freight engines, or those that are used, for the most part, in freight service, with an occasional assignment to passenger work. The exclusion of the two-wheeled truck from engines designed for passenger service has been due to the necessity of using a large boiler and so increasing the total weight of the engine beyond the requirements of adhesion represented by the tractive power that it was desired to develop. Under these circumstances the extra weight, beyond that needed for adhesion, could be carried on four wheels to better advantage than on two. As for safety, there is no difference of opinion that the two-wheeled truck is quite up to all the demands of the most exacting service.

In the designing of the trucks there is little else to be done than to secure ample strength to carry the load imposed and arrange for axles and boxes of sufficient bearing surface to do the work required without heating. At the same time care must be taken that sufficient weight is put upon the truck to hold it down, and cause it to keep the rails upon the sharpest curves to be encountered, and thus prevent the flanges of the wheels from climbing the rail and causing a derailment when called upon to guide the direction of motion of the machine from a straight line to a curve and through the latter.

In the case of the consolidation engine under consideration, as well as upon those of the mogul class, the two-wheeled pony or Bissel truck is used.

The plan of framing this type of truck is shown in Fig. 86 and the details of the working parts in Fig. 87. From these drawings, as well as from a comparison with Fig. 82, it will be seen that the truck is pivoted at the center between the wheels. As this would not hold them in place on the rails, but would allow them to swing into a position approximately longitudinal to the track, if any obstruction were to check the motion of one, a radius bar, A, is added that reaches to a point beneath the engine, where it is pivoted on the center point. This point is carried back far enough to insure stability of the wheels upon the rails, and, at the same time, permit of sufficient side motion to allow the truck to swing out of line with the center of the engine when entering and passing over a curve.

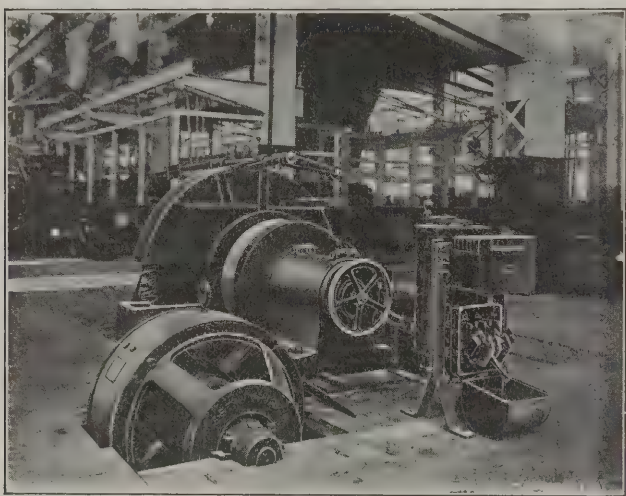

Fig 6. Forty-five-inch Car-wheel Lathe.

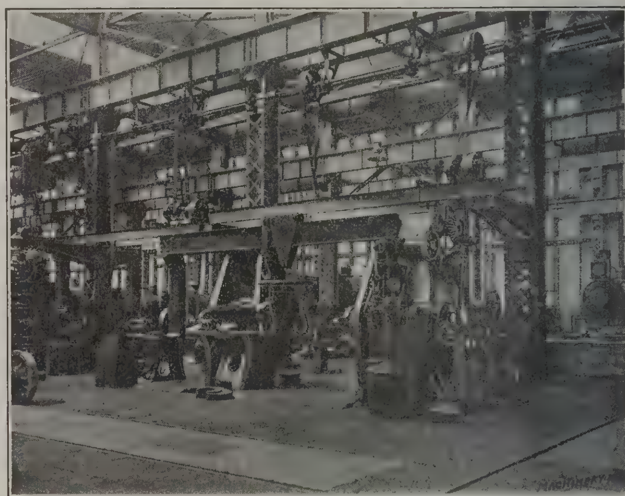

Fig. 7. Five-hundred-ton Wheel Press.

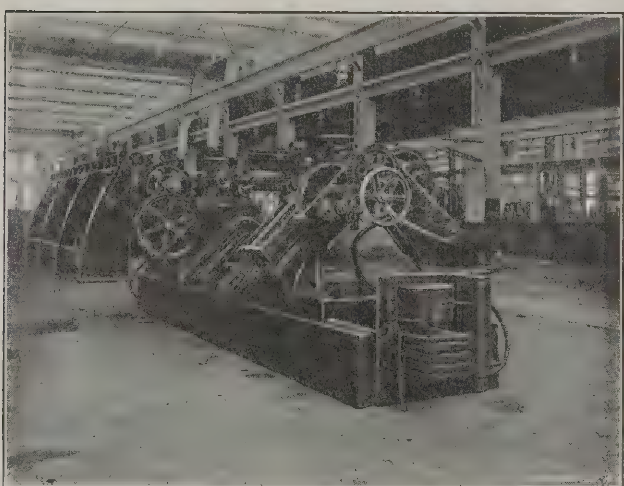

Fig. 8. Ninety-inch Quartering Machine.

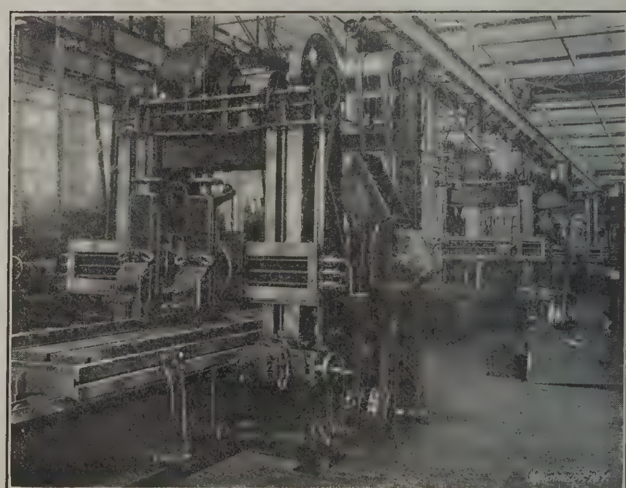

Fig. 9. Motor-driven 36-inch Planer in Foreground.

The formula used for calculating the length of the radius bar is as follows:

$$R = \frac{A \times B}{A + B} \times 0.85 \qquad (75)$$

in which

R = the length of the radius bar;

A = the total wheel-base for consolidation and mogul locomotives;

B = the distance from the front driving wheel to the truck wheel.

In the case of the consolidation locomotive under consideration, $A = 314$ inches and $B = 124$ inches. The formula (75) therefore becomes:

$$R = \frac{38,936}{438} \times 0.85 = 75.56 \text{ inches.}$$

This, then, may be taken as the distance from the pivotal point of the radius bar to the center of the truck axle, which in this case is made 6 feet 3½ inches for constructional reasons.

As the radius bar has no load to sustain and the only stress to which it is subjected is that of holding the wheels on the track, it is usually made of a flat bar of steel about 5 inches by 1¼ inch laid flat and stiffened by round braces rising diagonally from the foot of the pedestals and bolted to the horizontal portion of the bar itself at a convenient distance back of the truck frame.

In the case of the truck under consideration, the frame is carried by two helical springs at each side, and these, in turn, rest on seats attached to yokes that set on top of the axle boxes.

We have already noted that the weight on the truck of this engine is to be about 21,000 pounds, or 10,500 pounds on each wheel. In order to carry this load an axle 6 inches in diameter is provided with a journal 9⅞ inches long. This gives a load of about 177 pounds per square inch of projected area, or somewhat less than the 180 pounds that was allowed for the driving axles of freight locomotives.

The ordinary four-wheeled front truck of locomotives used on the eight-wheeled, ten-wheeled and Atlantic types calls for little or no calculation that is of value other than the determination of the strength of the equalizing bars from which the semi-elliptic springs, upon which the frame rests, are suspended. The front end of the engine rests, through a center

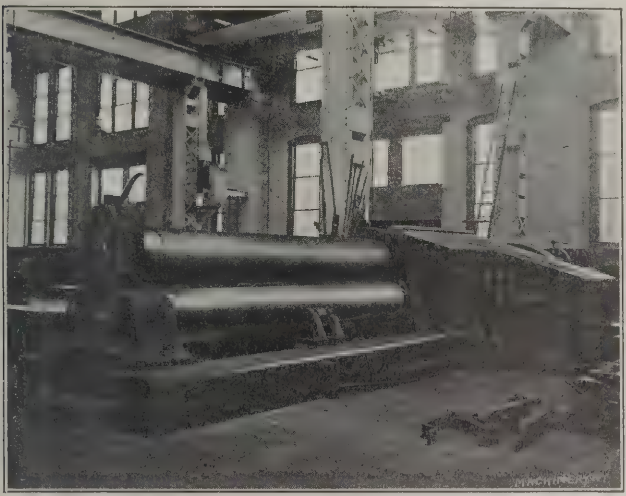

Fig. 10. Large Bending Rolls.

Fig. 11. Flange Fire Layout in the Boiler Shop.

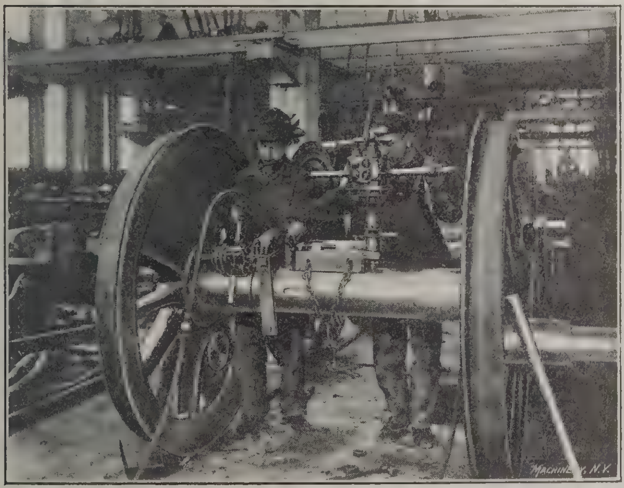

Fig. 12. Use of Air Tools Drilling Holes for Hub Liner Studs and Milling Keyways for Eccentrics.

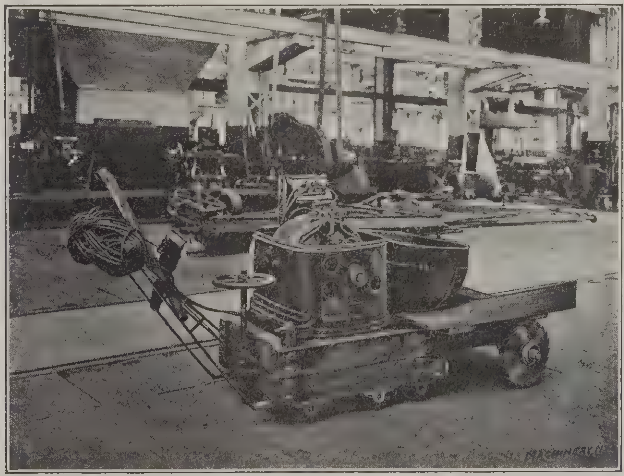

Fig. 13. Portable Routing Saw for Cutting Out Floors for Machine Foundations.

The design of frame, as shown in Fig. 87, may be taken as typical of that in use upon mogul and consolidation locomotives in the United States, and is of an exceedingly simple construction.

The weight of the front end of the engine is carried on the center plate, and this in turn is suspended by the center plate hangers from the transoms that reach across from side to side. These hangers are spread a small amount at the bottom so as to increase the tendency of the truck to return to the central position when coming back to a straight line from a curve. As the center plate and the pivot pin of the radius bar are normally located in the center line of the truck, it would be merely an extension of the rigid wheel base if no lateral flexibility were given to the wheels. It is this lateral flexibility, and the pull on the center plate by the hangers that tends to guide the front of the engine out of a straight line and around a curve.

plate on the saddle, upon the center plate of the truck. In the particular track, illustrated in Fig. 88, the center plate is suspended from the transoms by hangers in the same manner as in the case of the pony truck for the consolidation locomotive. There is a difference in the form of the hangers, however, in that, in this case, the hangers have two bearings at the top, arranged so that the two on either side act as inclined hangers, and yet remain parallel to each other and this tends to keep the center plate in a horizontal position.

In the calculations of the weight to be given to this Atlantic type locomotive, the total is 168,000 pounds, of which 80,000 pounds are upon the driving wheels. Of the balance, about 48,000 pounds will be upon the front truck and 40,000 pounds upon the rear. This puts a load of 12,000 pounds on each of the four forward wheels, with which a 5¾-inch axle is used having journals 12 inches long. This gives a pressure of somewhat less than 170 pounds per square inch of projected area,

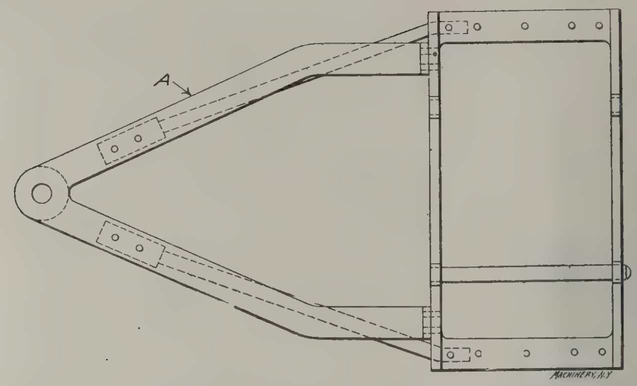

Fig. 86. Outline Plan of Pony Truck Frame for Consolidation Locomotive.

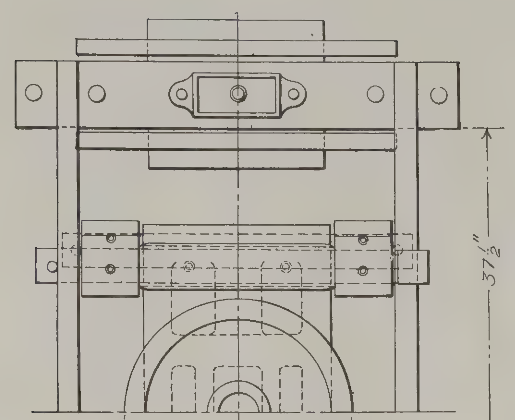

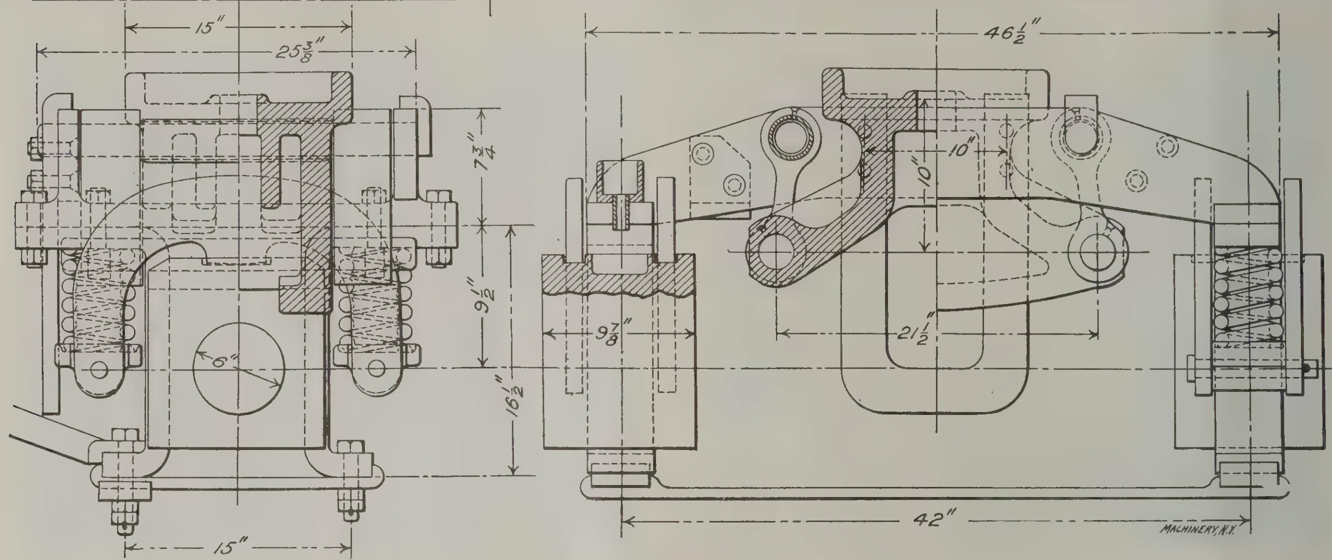

Fig. 87. Pony Truck Frame for Consolidation Locomotive.

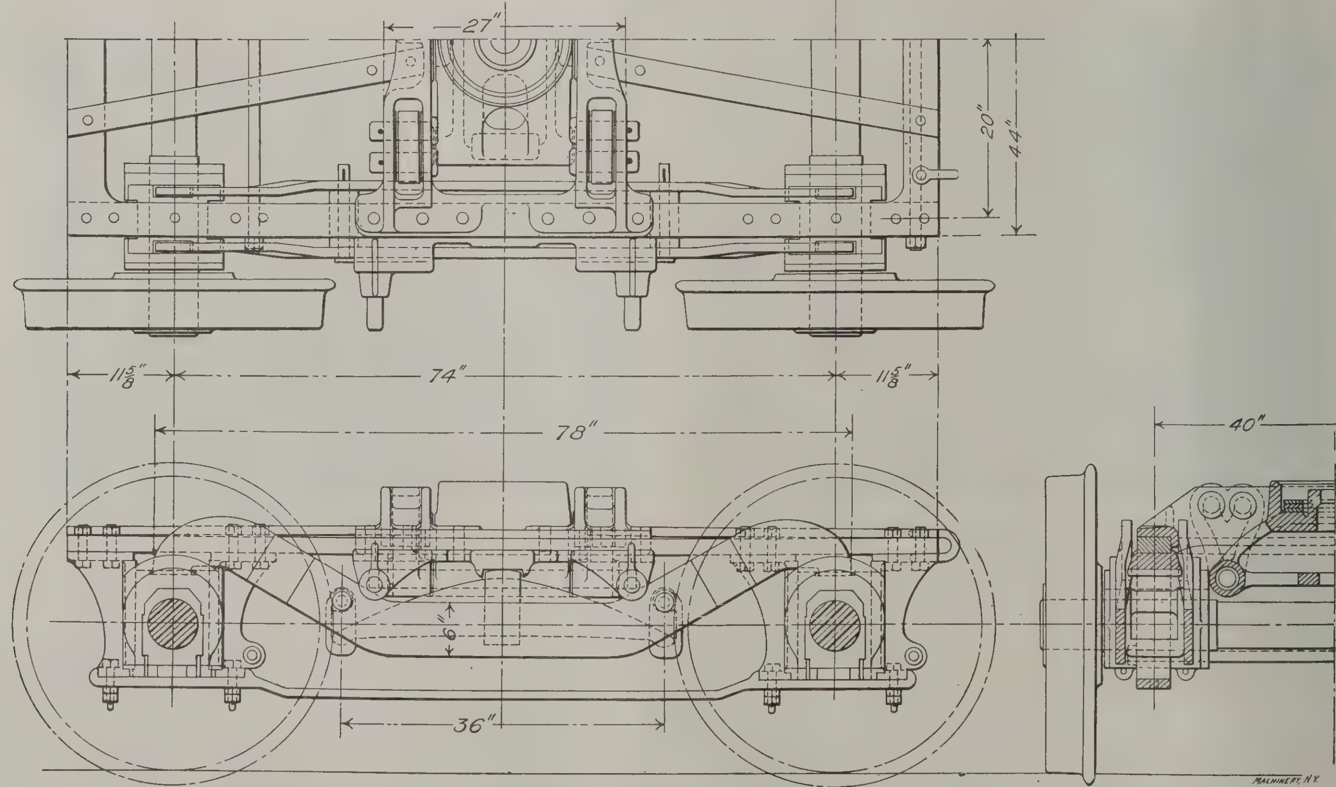

Fig. 88. Four-wheeled Forward Truck for Atlantic Locomotive

when allowance is made for the weight of the wheels, or about the amount allowable on the driving journals of a passenger locomotive. The wheel base of these four-wheeled trucks averages from 6 feet to 6 feet 6 inches. This is a matter that is subject to change due to local conditions, such as the diameter and arrangement of the cylinders, the position of the forward pair of drivers, the proportion of weight that is to be carried on the truck, and other items for which no rule can be laid down, and for which the designer must depend upon his own experience and knowledge of the fitness of things.

The rear truck of the Atlantic locomotive is of special design and varies with the builder. This type of locomotive has led to several designs of trucks for this point, most of which have been patented by the locomotive builders or individuals connected with the railroad service.

It is essential that the wheels should have a lateral flexi-

bility of movement, as in the case of the pony truck of a consolidation locomotive, in order that the virtual length of the rigid wheel base may be kept down to the actual length, or the distance between the driving wheel centers. It is also desirable that the center line of the axle shall remain as near radial to the curve of the truck as possible.

The trucks used in this place are designed with such an end in view.

As in the case of the other trucks, no formulas can be given for the determination of the dimensions of the several parts, other than the ordinary ones in use for beams and similar structures.

In the truck, illustrated in Fig. 89, the axle is 8 inches in diameter with a journal 14 inches long. As this has to carry a load of approximately 20,000 pounds at each end the load per square inch of projected area is less than the 170 pounds allowable on passenger driving axles when due allowance is made for the weight of the wheels.

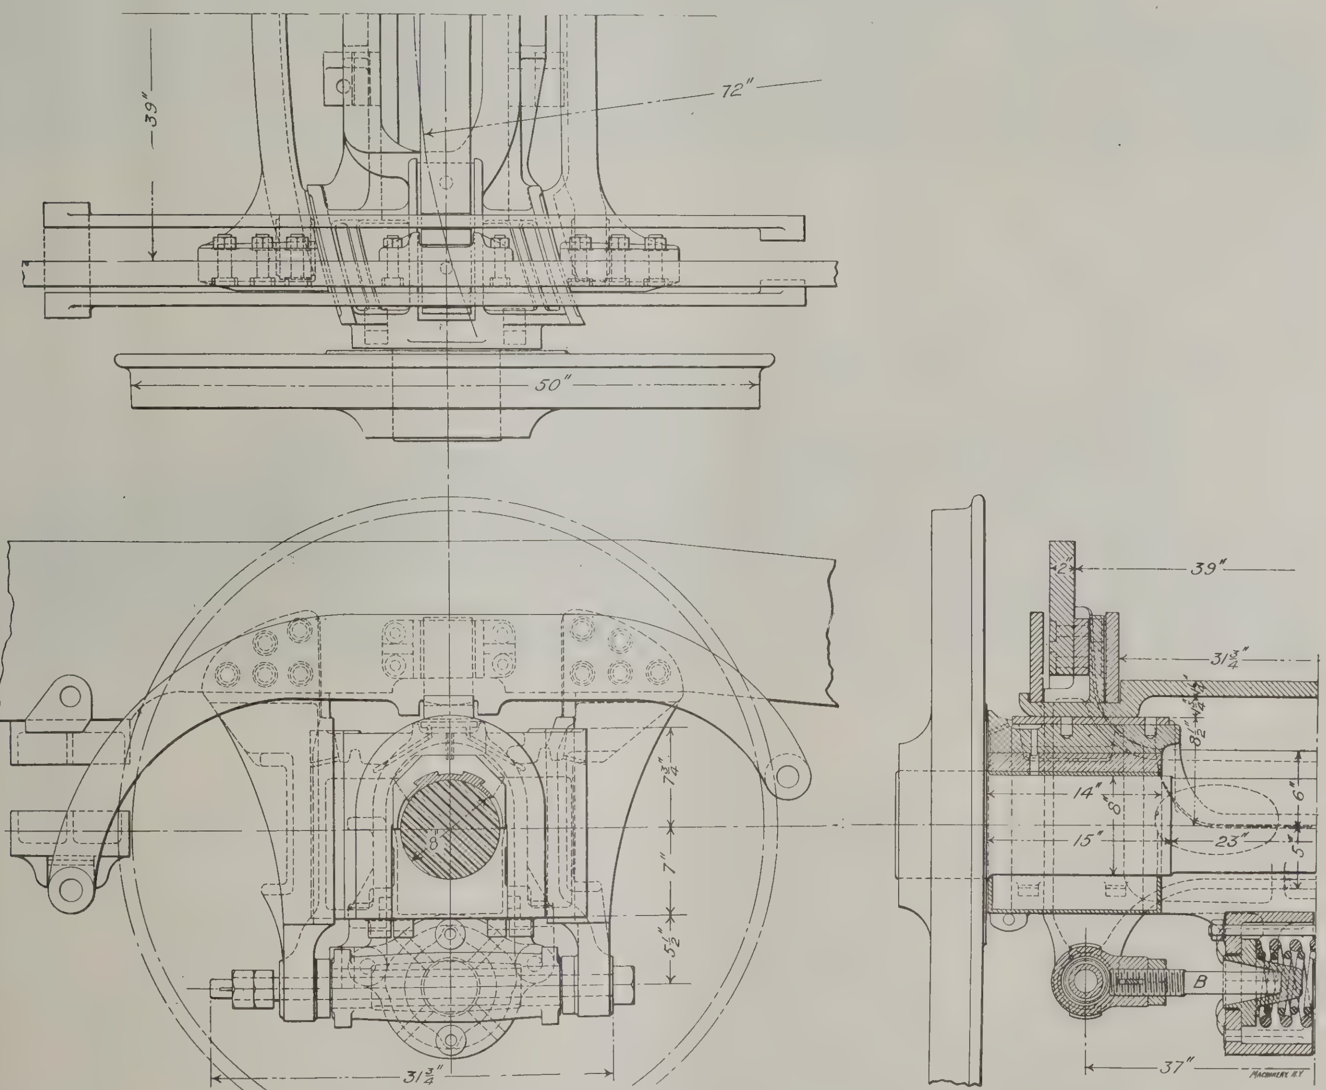

Fig. 89. Radial Trailing Truck for Atlantic Locomotive.

The axle is, of course, straight; but the boxes, instead of having their wearing surfaces parallel to its center line, are set in pedestal jaws that are cut at an angle and on a radius of 6 feet.

Hence, the transverse movement of the wheels is the same as though they were swinging through the arc of a circle whose center is at the center of curvature of the faces of the pedestals. This holds the wheels at an approximation to a truly radial position, but not exactly.

The swing of the overhang of the engine beyond the rigid wheel base throws these wheels out of center and the return of the frame to its central position on a straight track would restore the normal condition of things, but assistance is rendered in overcoming the resistance of the boxes to this movement by a centering spring placed beneath the axle. The pedestals are, of course, rigid transversely with the main frame of the engine and carry the push bars *B*, that bear against followers that are set in castings that move laterally with the boxes. Any movement of the latter, in either direction, compresses the intermediate spring, which thus has a constant tendency to restore the truck to its central position.

It will thus be seen that very little of a guiding nature can be said regarding the designing of the trucks that are to be used under American locomotives. The general design of the pony and the four-wheeled truck has been established by such long usage that it is no longer a subject for discussion. Details are being constantly varied to meet the changing demands of weight, proportions and service, but with no essential change in the main features of the designs.

With the rear truck of the Atlantic, Pacific and Prairie types of locomotives, the case is somewhat different. These locomotives have not been in service long enough to have settled down to an established basis of construction in detail and it will probably be a number of years before this will be done. Meanwhile the general principle of the freedom of lateral movement for the wheels, with the approximation to the maintenance of a radial position for the axle has been accepted and acted upon, and beyond this the truck may be said to be in a process of development, though the engines to which it is applicable may be considered as among the standards of American railroad practice.

* * *

The New York *Times* says that Edison has at last perfected his famous storage battery; also that it wearies the imagination to speculate on what this means for the world. It also wearies the world to think how many times it has been "perfected." It is to be hoped that this "perfection" means that the public will soon be able to realize its advantages.

ISTHMIAN CANAL COMMISSION LOCOMOTIVES.

The accompanying half-tones show two mogul locomotives of which 120 have been ordered by the Isthmian Canal Commission for the Panama Canal construction. The locomotive shown in Fig. 1, road No. 205, has 19 x 24-inch cylinders, 48-inch drivers, and a total weight of 130,500 pounds. The tractive power is 27,650 pounds; the weight on drivers is 114,000 pounds. Of this type 100 were ordered.

Fig. 1. Isthmian Canal Commission Locomotive No. 205.

Fig. 2. Isthmian Canal Commission Locomotive No. 603.

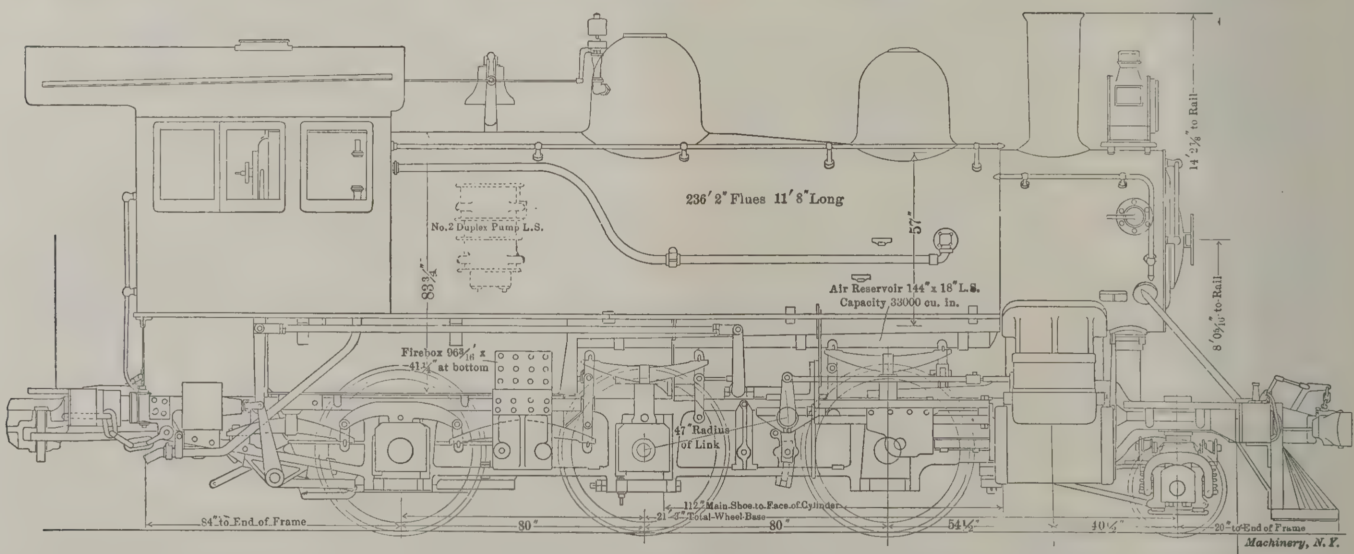

Fig. 3. Isthmian Canal Commission Lococomotive. General Dimensions, 19x24-inch Cylinder Class.

Fig. 2 shows a somewhat heavier design, road No. 603, the total weight being 147,500 pounds. The cylinder dimensions are 20 x 26 inches, the drivers 63 inches, and the tractive power is 25,250 pounds; the total weight on the drivers is 127,500. The total heating surface is 2,203 square feet, of which 174 square feet is in the firebox and the remainder 2,029 square feet, in the tubes. The boiler pressure is 180 pounds per square inch for both types. The gage is 5 feet.

These locomotives are of the ordinary mogul or 2-6-0 type and about the only peculiar feature of design worthy of note is unusually long and low tenders. The tenders are so designed to avoid any danger of their "turning turtle" because of the uneven and rough road bed over which they will ordinarily have to run.

* * *

The New York Central R. R. and its traffic manager, Mr. Frederick L. Pomeroy, have been found guilty of rebating on their freight rates in favor of the sugar trust, and October 19 Judge Holt fined the company $108,000 and Mr. Pomeroy $6,000 for the offense.

SPECIAL TOOLS FOR DRILLING HOLES IN TIME AND PERCUSSION FUSES AND FIRING RINGS.

W. R. BOWERS.

The accompanying cuts show some special jigs for drilling holes in fuse components. In this class of work there are two important features, firstly, the holes have to be very accurate both as to size and position and, secondly, interchangeable work has to be turned out at the lowest possible cost. It is essential that the degree of accuracy should be very high, as the whole result of the firing of both large and small guns depends upon the correct working of the fuse attached to the projectile. A defective fuse would probably not only fail to plosion until the gun is fired. It is, of course, necessary that the hole is of proper diameter and depth. The fuse body is dropped into the jig as shown in the sectional view, and located on the center bolt as shown. The center bolt is drilled, hardened and lapped, and acts as a position stop, and as a guide for the drill when drilling the flat bottomed hole. The jig is provided with a movable plate and a screw plunger, which are removed from the jig to allow the fuse to be put in and taken out. The screw only requires about one turn to fasten the fuse in position. The jig is also provided with two extracting levers which are necessary to extract the fuse after drilling, owing to the close fit of the fuse in the jig. The three holes are all of different dimensions, and as two drills are used for the flat-bottomed hole, the work is done on a

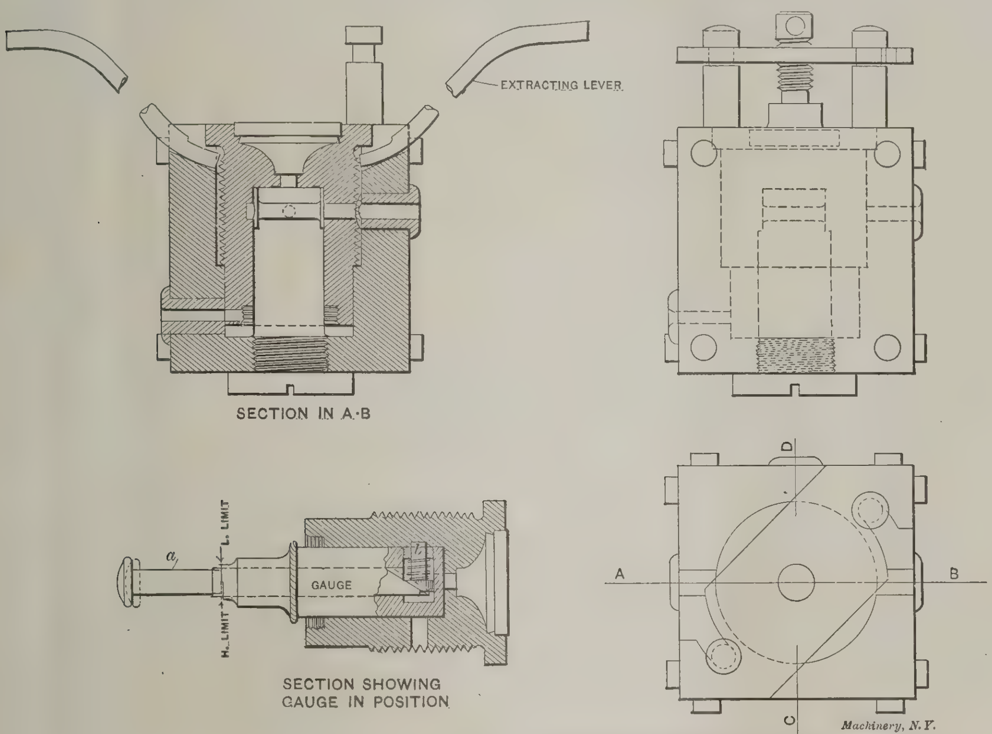

Fig. 1. Jig for Drilling Percussion Fuse, and Gage.

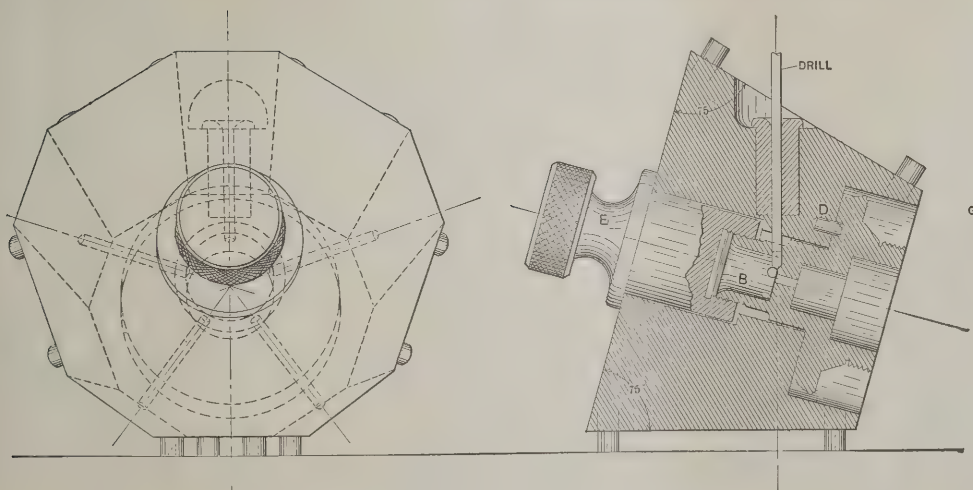

Fig. 2. Jig for Drilling Angular Holes in Percussion Fuse.

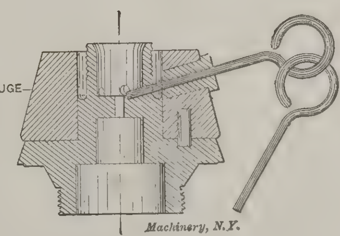

Fig. 3. Gage for Testing Angular Holes.

act at its destination, but would be liable to explode the shell either before it left the gun, or at so short a distance away from it that the operators themselves would be in danger of annihilation or the gun itself damaged to such an extent as to be of no further use. There is, therefore, a grave responsibility resting upon those engaged in the manufacture of this class of work. Fig. 1 is a plan, elevation and sectional view of a jig for drilling three holes in a percussion fuse, and as will be seen in the section showing the depth gage in position, one hole passes right through the wall and for a short distance into the other side of the fuse, forming a flat bottomed recess which acts as a locking chamber for a centrifugal bolt which renders it entirely safe from premature ex-

four-spindle drill press and all holes drilled at one setting, which ensures accuracy and speed. When the first hole is drilled a safety peg is pushed in to guard against any chance of the work moving during the drilling of the other holes. The method of gaging the flat-bottomed and most important hole will be readily understood from the cut. The plunger *a* is pressed down, pushing the plunger *b* forward, and if the hole is not of correct depth, it is immediately detected by the limit step on the body of the gage. If the hole is not at its correct distance from the bottom of the bore, which is very important, it is impossible for the plunger *b* to enter.

Fig. 2 shows a jig for drilling five holes in the stem of a time and percussion fuse at an angle of 75 degrees to the cen-

terline. The fuse body *B* is pushed into the jig from the front end and located by the position peg *D*, which serves the double purpose of locating the five holes in their proper position, and of preventing the fuse from turning during the drilling operation. The tightening bolt *E* is then screwed on the stem of the fuse and in conjunction with the position peg *D* holds the work perfectly secure. One of the five bushings in the jig is shown in section. The bushings are hardened and lapped, and are purposely made long, because when the drill breaks through the walls of the fuse body, it has to travel on a considerable distance to drill a half-round groove along the flat-bottomed cavity of the fuse stem. It is therefore desirable to have a good bearing to keep the drill up to the work. The method of gaging this operation is shown in Fig. 3. The gage is pushed on the fuse stem and has a position peg which fits a hole in the fuse; by the aid of two wire gages, the angle as well as the diameter of the holes are gaged.

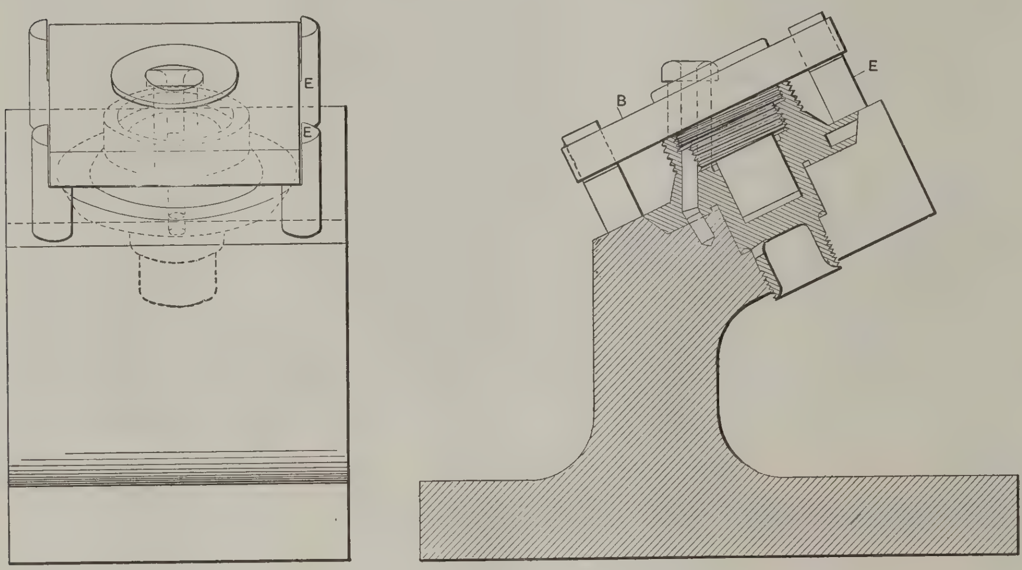

Fig. 4. Jig for Drilling Angular Hole in Percussion Fuse.

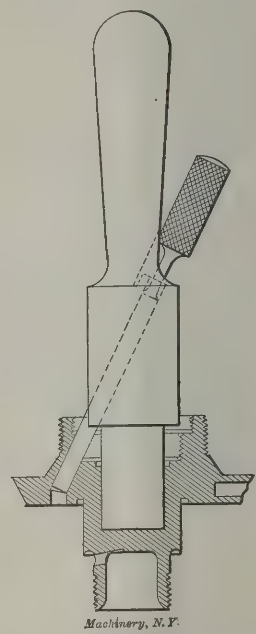

Fig. 5. Gage for Testing Angular Hole.

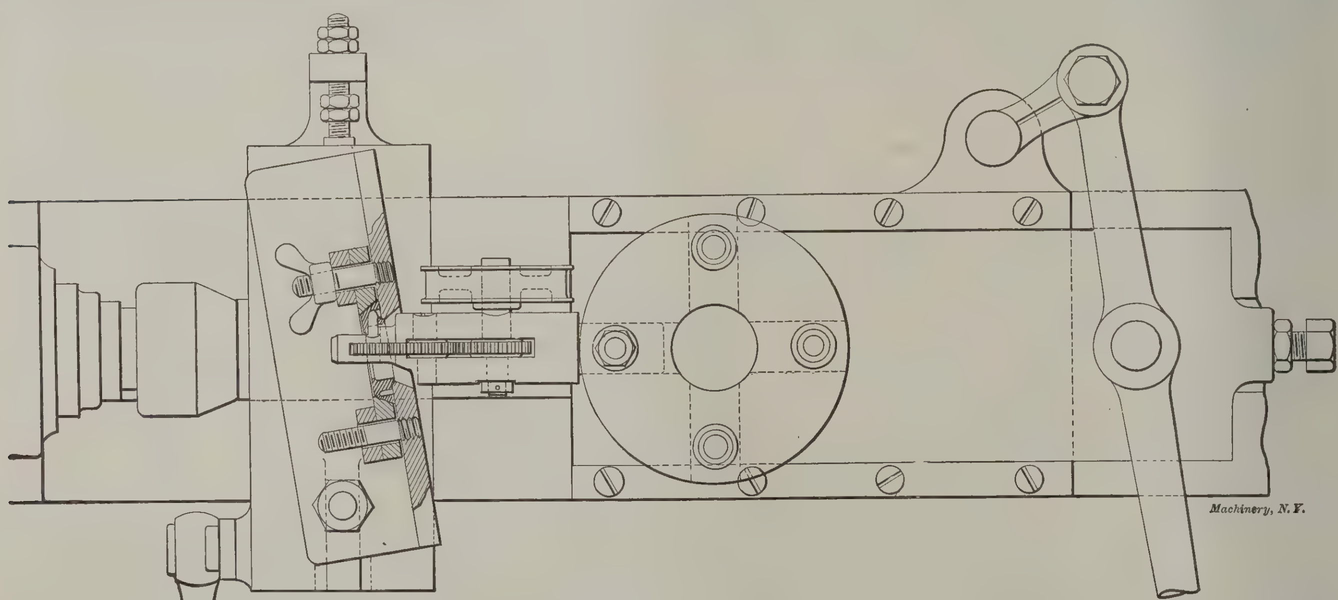

Fig. 6. Method of Drilling Firing Rings.

Fig. 4 shows another jig for drilling a hole in a time and percussion fuse at 25 degrees angle, and of a given depth to meet another hole running parallel to the axis of the fuse.

The fuse body is dropped into the jig and on to a position peg as shown, this being all that is required to keep the work in position. The drill bushing is mounted in a square plate *B*, which is held in position by the four upright standards *E* and provided with a stud entering the inside of the fuse body. The method of gaging the angle is shown in Fig. 5 and is a very severe test. In my experience (and I have been engaged in this class of work for years), I have never seen a jig which did better or quicker work than this one, and to those not engaged in this class of work, these special operations may be very interesting.

Fig. 6 shows a way of getting over what looks at first as a rather difficult job which had to be done in the shortest possible time, and without the aid of any expensive special machinery. The cut shows a firing ring for a time and percussion fuse fixed in position to have a hole drilled from its bore outwards at an angle of 81 degrees into the firing channel on the face of the ring. As the ring could not be drilled from the outside, I discarded any idea of using a drilling machine and jig for the purpose. I decided to use a screw machine with cross slide, and had a small fixture made to carry a train of gears to be driven from the countershaft above. I made the drill the axle for the smallest of the gears in the train, and by fixing a drum on the countershaft the belt was enabled to travel backward and forward and to follow the movement of the cross slide. The hole to be drilled was 0.157 inch diameter ± 0.002 inch. The drilling fixture had to be nicely fitted up and wearing parts hardened and ground to prevent backlash or poorly fitting surfaces. The fixture was mounted in one of the holes in the turret as shown in the cut. The holder for the firing ring was an angle plate bolted to the cross slide at the angle required, viz., 81 degrees. The firing ring being

cone shaped on the outside, I had the plate *A*, Fig. 7, made with a hole bored out to drop over and slide on to the ring, and a packing piece *B*, Fig. 7, to drop on and take up the space that the plate *A* required to slide back to clear the ring. This saved a lot of time inasmuch as it obviated the necessity of a lot of screwing up and unscrewing every time a ring was drilled. With these plates one half turn of the wing nuts was sufficient to loosen the plates so that the finished firing ring could be removed. When the firing ring was

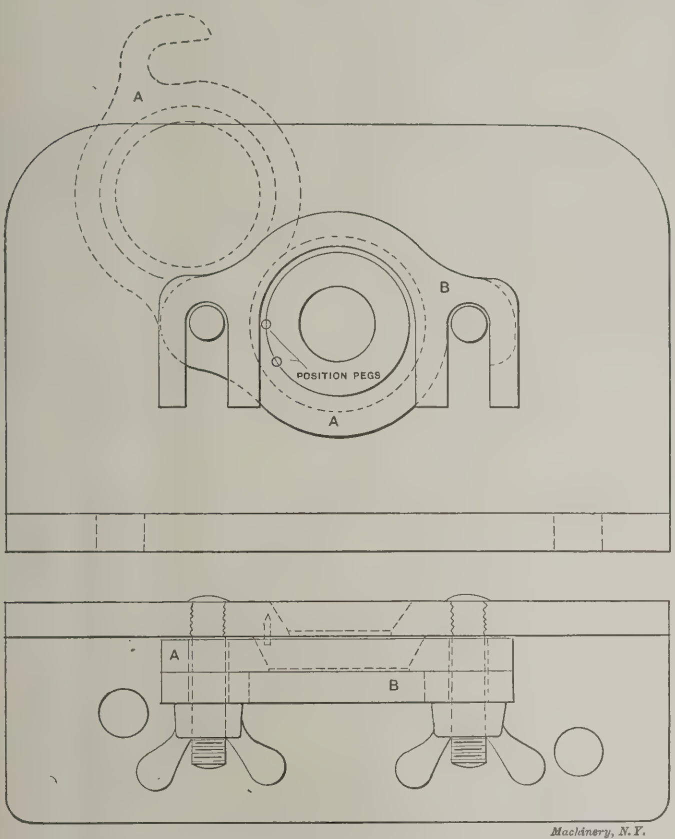

Fig. 7. Detail of Holding Device for Drilling Firing Rings.

fixed into position the operator had simply to move the cross slide back to its stop with his left hand, and, holding it there while he moved the turret slide forward to its stop with his right hand, he again moved the cross slide forward, bringing the work toward the drill until it reached its forward stop. He then simply reversed the movements and the job was done.

The countershaft was operated with the foot so that the drill was not running while change of work was going on, which

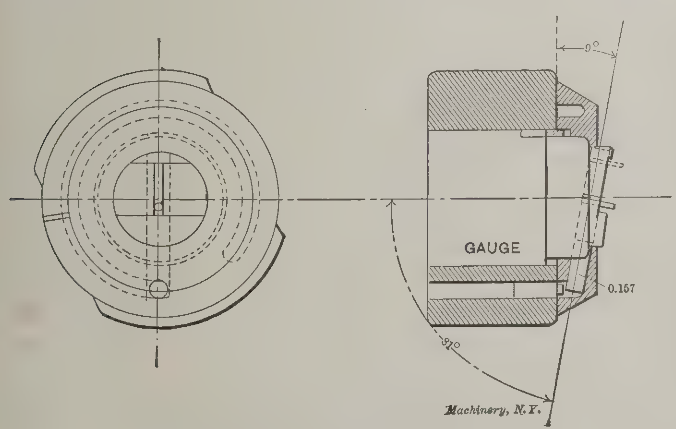

Fig. 8. Gage for Testing Hole in Firing Ring.

obviated a lot of unnecessary wear. The work came out with the greatest accuracy, the fixture gave no trouble, and one operator was able to drill 3,000 of these firing rings per day with comfort. Fig. 8 shows the method of gaging the angle of the hole, and it will be seen that if the work was not correct, the gage would very soon find it out. The diameter of the hole was gaged with a hook gage with maximum and minimum diameters on respective ends.

TRACING, LETTERING AND MOUNTING.—3.

I. G. BAYLEY.

Mounting.

Mounting Tracing Paper.—Tracings likely to be in hand a long time should be mounted to the drawing board, for several reasons. They will be protected from getting torn and will not shift on account of the sudden change of temperature of the room which may take place; they can also be cleaned more safely than if held by a few tacks.

The paper should be cut large enough to allow for sticking the edges to the board and should it be intended to color the tracing with liquid colors, twice the allowance should be made as the paper will be cut after the tracing is made, and mounted the second time.

The drawing to be traced should be laid down square with the board, perfectly flat and level, then thoroughly dusted down to remove all obstructions, as these cannot be removed after the tracing paper is mounted.

A long, flat straightedge with a couple of weights for each end is needed. Having cut the paper, dampen it slightly with a wet sponge, going over it very evenly and working quickly, so that it may be attached to the board before quite dry. The damp side must be up. The straightedge is placed an inch outside of the cutting-off line and the weights put on, one at each end. Turn up the edge of the tracing paper as shown in Fig. 22 and apply the mucilage or paste brush, pressing the edge down firmly with a straight-edged ruler or paper knife. The opposite side of the tracing paper is treated in the same way, and then the two remaining sides, care being taken to stretch the paper carefully by pulling the edge of the paper gently with the tips of the fingers, before the weights are put on the straightedge.

Any superfluous water may be removed with a blotter. The whole operation, as before stated, should be done very quickly, as in a warm room the paper soon dries.

Mounting Paper for Coloring.—Should there be any wash coloring to be done after the tracing is made, it is usually done on the back. The tracing is therefore taken up, cutting close to the pasted edge, so as to leave as much margin as possible for the second mounting. The drawing paper is also

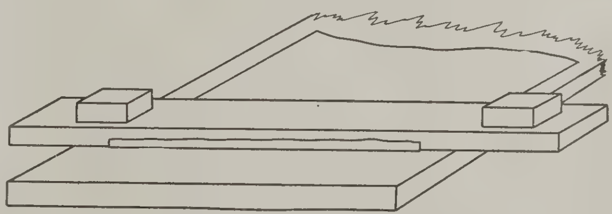

Fig. 22. Mounting Tracing Paper.

taken off the board and a clean white sheet not so large put in place of it. The tracing paper, being turned over, is again mounted to the board as previously described, care being taken to get no paste inside the cutting-off line, which should have been distinctly marked. While the paper is drying the colors can be mixed. Allow the coloring to thoroughly dry before cutting off the tracing, which should be done with a sharp knife, following the cutting-off line very carefully.

Mounting Cloth for Tracing or Coloring.—The process described above is for paper tracings only. Cloth can be mounted in the same way except that on no account should a damp sponge touch it, but it may be stretched without damping it at all, though not so satisfactorily. If the tracing cloth is put in a cold or slightly damp place over night it can be stretched very nicely, using a thin glue instead of paste. When one edge is firmly fixed, the other should be pulled very tight and extra weights put on the straightedge to hold it in place while applying the glue brush. Mounting for coloring is done the same way, it being, of course, understood that the coloring is done only on the dull side of the cloth.

Very satisfactory results can be obtained by not mounting tracing cloth at all, but simply using a number of iron tacks driven with a magnetized hammer elsewhere described.

Mounting Blueprints, Maps, etc.—Blueprints, maps, draw

ings, old tracings, etc., are often mounted on linen or cotton to preserve them. The linen or cotton should be cut larger by several inches than the blueprint and a drawing board about the same size used. Soak the linen well in water, rinsing it out between the hands until all the superfluous water is squeezed out, when it should be unfolded and shaken out. Lay it across the board and commence tacking one edge, beginning at the center and pulling gently; place a tack about every two inches along the edge of the board, as shown in Fig. 23. The other half of the same edge must be done in the same manner. The opposite edge is done next, stretching the linen well each time before a tack is driven; commence at the middle as before and work toward each end. The two remaining edges are done in exactly the same manner, and all is now ready for the paste, which should be prepared for use before the linen is stretched. The paste can be made either of starch or flour. A sufficient quantity is mixed in cold water to about the thickness of cream. Hot water is then poured over it, gently stirring it meanwhile; the whole is then put back into the saucepan and stirred until it begins to boil over, when it is lifted from the fire, poured back again into the basin, and is ready for use. An apron of some kind is fastened around the neck reaching to the knees to protect the clothes from getting soiled. Taking some of the paste in the hand, slap it over the board, rubbing it well into the linen with both hands, using more paste if required until the whole surface is covered. Now, commencing at the lower edge and at the left-hand end, holding the tips of the fingers close together push the superfluous paste along to the center of the board as you travel along from left to right. Go to the opposite side of the board and do the same thing, forming a ridge of paste along the middle of the board, which is scraped off with

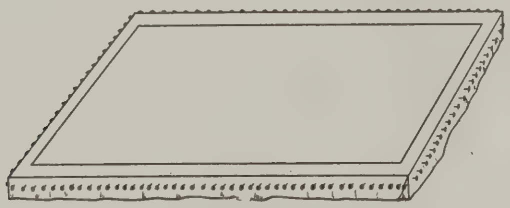

Fig. 23. Mounting Blueprints and Maps on Linen.

the hand into the basin. With both hands go all over the board again until the paste is nice and evenly spread all over the linen.

An assistant is now required. The blueprint is dampened on the back with a sponge and placed gently in correct position on the linen. One half is to be pasted at a time. The assistant holds it up by the two corners at an angle of about 30 degrees while with a large blotter in one hand held to the print you rub gently but firmly over it, the assistant letting the print gently yield to the pressure you bring to bear upon it. Passing over to the other half, it is lifted from the board and then treated in the same way. Wherever an air bubble appears it can be pricked with a needle, and the blotting pad placed over it, while with a circular sweep of the other hand you press it firmly to the board. Should any obstruction unfortunately have been left between the print and the linen a slit can be made in the former and the obstruction removed when it is again pressed to the board.

The whole should thoroughly dry before any attempt is made to tear it from the board. Often this is not done till the following day. Cut through the print and linen with a sharp knife along the cutting-off line all around the board. Then, lifting the corner, pull gently but firmly in a slanting direction. The tacks and trimmings are then removed and the board cleared away.

The case of a blueprint has been taken. Maps, drawings, etc., are done in precisely the same manner.

Before the print is taken up a coat or two of clear copal varnish is sometimes applied to preserve it still more.

Mounting Paper to Drawing Board.—A quick and very satisfactory way of mounting drawing paper to the board instead of using tacks is resorted to by many draftsmen in the following manner:

The paper is laid flat on the board, right side up. A moderate sized sponge filled with water is wiped all over the surface of the paper within an inch or so of the edge all around. The superfluous moisture is mopped up with the sponge and the edges then dampened.

One half of the sheet is turned precisely over the other half, edge for edge. With a well-filled mucilage brush go quickly around the three edges of the upturned half of sheet, and turning it over again, press the edges firmly to the board with thumb or a flat, thin stick. Turn the other half of the sheet over the first and proceed in the same way. When thoroughly dry the paper will stretch very satisfactorily.

Still another way of mounting paper is to lay the sheet down *wrong side up* and with a small glue brush dipped in liquid glue go all around the edge of the paper at once. Quickly sponge all over the surface with plenty of water, keeping clear of the glued edge. Having mopped up the superfluous moisture with a dry sponge, turn the paper completely over and stretch it to the board by going over the surface with the flat of the hand or a clean, dry duster, working from the center to the edges, pressing the latter all around firmly to the board with the flat of the thumb or a thin, flat stick or ruler.

Either of these methods has been successfully used in many offices, especially architects, but for important work the method described under the head of "Mounting Tracing Paper" and illustrated in Fig. 22 should be resorted to.

* * *

THE APPLICATION OF FOUNDRY BLOWERS.

The general application of a pressure blower of the fan type to a cupola is too well known to require description; but certain features which relate to its efficiency often escape attention. The proportions of a pressure blower wheel should theoretically be such that its capacity area or square inches of blast shall be practically equal to the free area through the fuel and iron in the cupola, less the influence of the resistances of piping, tuyere boxes, fuel and iron. These resistances are evidently the equivalent of just so much reduction in area, and must therefore enter into any consideration. But it is manifestly true that differences in the length and arrangement of piping in different plants, and of size, quantity and character of the charges in the same plant, introduce such variable conditions that it is impossible to design a blower of any type that shall at all times be just *exactly* proprotioned to the work to be done. For this reason the exact power required to operate any given blower cannot be given as an absolute quantity, but can only be determined when all of the conditions are known.

It is, or at least it should be, customary in specifying the pressure required to operate a cupola, to refer to that in the windbox. On the other hand, the table of blower speeds presented in the authoritative catalogues published by the B. F. Sturtevant Co. gives the number of revolutions necessary to produce the given pressure at *the fan outlet* when its area is within the capacity of the blower. Owing to losses due to transmission, this pressure cannot be maintained at any more or less distant point, such as the windbox of the cupola, unless the speed of the fan is increased sufficiently to produce an excess of pressure equal to the transmission loss.

It is the failure, on the part of the purchaser, to comprehend this fact, and to make due allowance for transmission losses, that sometimes results in too low a pressure at the cupola, and in unjust charge against the blower. Large, straight and short connections from blower to cupola are always imperative if waste of power is to be avoided. If changes in the direction of the piping are necessary, they should be made with as large a radius of curvature as possible. It should be distinctly understood that the power required to operate a fan blower is proportional to the area of discharge. If this area be reduced to zero, by the closing of the blast gate, the power will be reduced to merely that due to friction of the machine and the air confined within the case. Too often it is claimed, by those who ought to know better, that closing the pipe increases the power; but, as power is expended only when air is moved, the fallacy of this statement is evident.

SHOP PHOTOGRAPHY.

H. P. FAIRFIELD.

One of the most valuable and interesting phases of picture-making with the camera is what is commonly termed "shop photography"; that is to say, pictures of machinery either in operation or under construction. Where a machine is photographed for catalogue purposes it is usually painted and posed for the occasion and can be put in a selected light. Such work as this does not properly come under the head of shop photography, but is true machine portraiture.

Technical publications, such as MACHINERY, are making an increased use of shop photographs, and no small part of their popularity is due to the willingness to use camera results. How firmly a picture fixes a result in your mind! Take for example a "Weak Steam Fitting," shown on page 486 in MACHINERY for May, 1906. The eye catches this at once, and it is doubtful if the reader can ever forget the result of a use such as described. Besides this, it has called his attention to what he may expect under like conditions. Along this same line may be noted perhaps hundreds of similar cases where the camera has fixed for the readers a record of some device or called attention to some happening of general interest and value. As an example of what the camera has done for the manufacturer, consider the advertising matter of, say, the Cincinnati Milling Machine Co. In such cases as this the photographs represent the manufacturers' own practice and only what may be viewed direct by a visit to his works, if this were possible.

In machine construction of certain kinds, the camera tells the story of progress to those interested as no other means can, and many firms use such records on work being built or erected or going forward away from their immediate view. The Brown Hoisting Mchy. Co., of Cleveland, Ohio, are a notable example of this use of "shop" or "record of fact" photography.

The writer's use of the camera began about fifteen years ago with the taking of several views of a wreck due to a flywheel explosion in a wire mill, and has continued with increasing interest till the present time. Photographs have been sought wherever anything novel occurred, where machines were in use, and, in fact, whenever a record of fact was desired. Examples of old and interesting machines have been sought and recorded, and in this manner the progress of the designer's art is shown.

To the readers of MACHINERY it is probable that shop photography is most interesting from the aspect of its application.

First: For purposes of illustration and explanation relative to what may be expected under actual working conditions.

Second: Progress of construction or erection. To achieve satisfactory results in either field requires a good outfit and much careful, painstaking work.

In no other line of camera work will conditions relative to a proper lighting of the subject be worse than are often found in shops, when one considers that the exposures must be made just as things are found. However, satisfactory results can be obtained under any and all conditions by the exercise of good judgment and a knowledge of all the ins-and-outs of photography.

The pages of technical publications show that nothing is too difficult if the object is worth attainment. Pictures are seen which have been made with the camera set on the cylinder of a steam engine, on the running board of a locomotive traveling at high speed, under mills with the camera set on thin ice; in fact, no place is too hot or too cold for the ambitious worker—"the man behind the gun"—if he is provided with a suitable outfit.

A camera that will produce negatives of a size ranging between 5 x 7 inches and 8 x 10 inches is suitable for this work and should have a bellows draw that will permit the use of lenses with a length of focus equal to twice the *long* side of the plate used. For this purpose the writer prefers to use two cameras, one of 5 x 7-inch size and one 8 x 10 inches. The use of wide angle lenses must also be considered when the camera is purchased, as it should be possible to use lenses with a length of focus equal to or less than the *short* side of the plate used.

While the camera box is important, it is to the lens that we must look for the picture, and a good set of lenses is indispensable. A Zeiss Convertible VII. A. set is an excellent lens for the purpose, as the doublets are made up of two single combinations that are corrected for astigmatism, spherical abberation, and are rectilinear and practically perfect lenses each, when used alone. When used as a doublet the length of focus should approximate the long side of the plate they are used on and the single combinations should have a length of focus equal to one and one-half and two times the length of the long side of the plate. In addition to these, a doublet with a length of focus equal to, or less than, the short side of the plate should be provided. These should all be fitted to interchange in a good "between the lenses" shutter, provided with a bulb and tube sufficiently long to permit standing a convenient distance from the camera while making the exposure.

The picture depends, to a great extent, upon the viewpoint from which it is taken, and the length of focus of the lens used. If the machine is taken broadside on, the effect is usually grotesque, and the same may be said of strictly end views; however, as the operation or construction to be photographed will seldom admit of a choice of views, it becomes largely a question of which lens to use. To this end, bear in mind that the shorter the focus of the lens used on a particular plate, the more the perspective is magnified, and *vice versa*, the longer the focus the more nearly correct is the perspective.

Little can be done relative to lighting, as the light must usually be taken as found; however, at times, a choice is possible, and something may be said on this point. Bear in mind when setting up the camera: *a*. That the light should not come from the front, but from behind. Strong light in front *must* be screened off. *b*. Strong light from any point is to be avoided, as it begets heavy shadows, and a dull or rainy day is to be preferred to brilliant sunshine, unless some means for screening the windows is provided. *c*. That the light which enters the lens should be reflected light coming from the surfaces photographed, and that the dark surfaces and shadowed portions reflect but little actinic light. Use double-coated, non-halation plates, expose for the shadows and develop with a pyro developer, at least until you become an expert operator. Study your negatives and prints for the lighting, the effect of the perspective, the length of exposure given, and the development. Keep at this until you know a good negative when you see it, also how to produce such a one; study the picture upon the ground glass when selecting the view point and lens to use, as that represents the way the lens sees it.

As a short summing up, the description of an outfit that has been in use for four years and was bought after considerable experience with various combinations, may place the subject before the reader most clearly. The camera box is known as a 5 x 7-inch, and has all the usual adjustments, with a bellows sufficiently long for any of the lenses of a No. 8 Zeiss convertible lens ground by the Bausch & Lomb Co. Used as a doublet, the focus is 7 inches; front combination, 14 inches; back combination, 11½ inches; which interchange in a Bausch & Lomb shutter lens of 4¾-inch focus. The tripod is of the single-slide type, heavy enough to be rigid and stable under severe conditions, even when used to carry an 8 x 10-inch box. This outfit is practically duplicated in the 8 x 10 size, as a 10-inch focus lens is used upon an 8 x 10-inch plate and a 19-inch focus wherever the conditions will permit. A study of camera catalogues will teach the user that there are many helps in the line of simplifying his labors if his means will allow of their purchase. For instance, a flash-lamp outfit is a great help in dark situations, but it needs to be used with good judgment and a knowledge of its limitations or the results will be grotesque. Do not buy an advertised help until you know something of it, and then only when you can see its value in your own work. Study up on lighting, chemistry of the developing and printing processes, the design, construction, and physics of photographic lenses and ever stand ready to honestly compare your work with that of other workers, aiming at improvement always.

PORTABLE TOOLS FROM EUROPE.

Portable tools have been brought to a high state of development in Europe and are widely used for general manufacturing. Advantage has been taken of the electrical drive in many ways, for various purposes and with the leading idea to reverse the ordinary practice; instead of carrying heavy work to the machine tools, where it has to be set up and fastened for machining and removed again after the work is done, effective tools working with utmost precision are brought to the piece and attached to same, the machining is done with or without jigs in one setting. This always saves time and in a great many cases operations can be performed with these tools that would otherwise require special and costly machines.

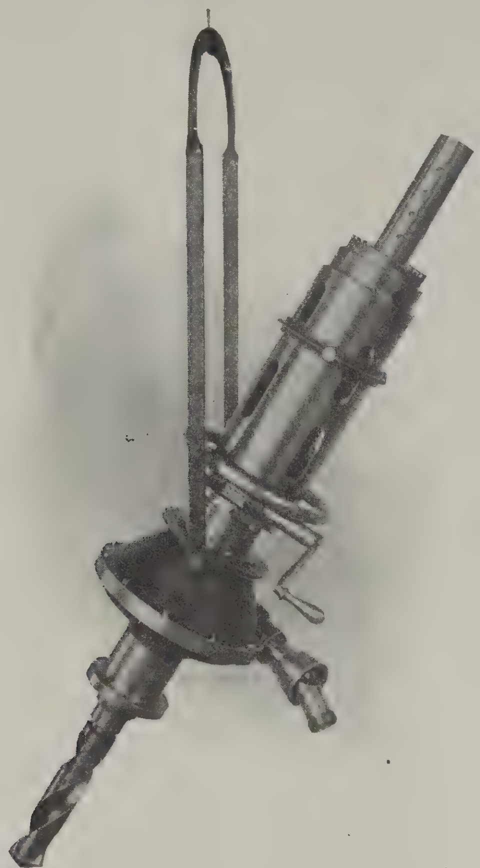

Fig. 1. Drilling Spindle without Base.

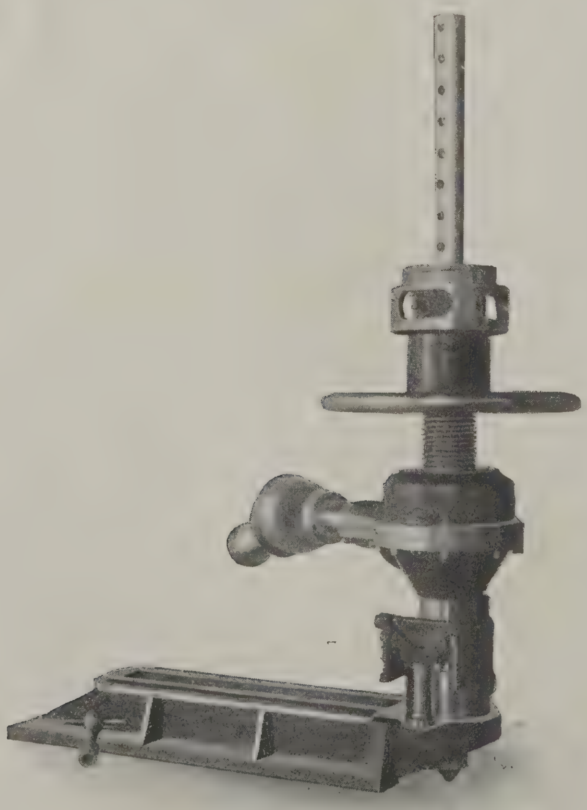

Fig. 2. Drilling Spindle Clamped to Slotted Base and provided with Extensible Drill Spindle.

It was the general custom to use portable tools only in places where no other means were available, where a bracket or similar part had to be attached which was not provided for on the drawing and in other such instances. With the European tools it is different, they count just as much in the process of manufacture as any stationary machine with the only difference that they are more adaptable.

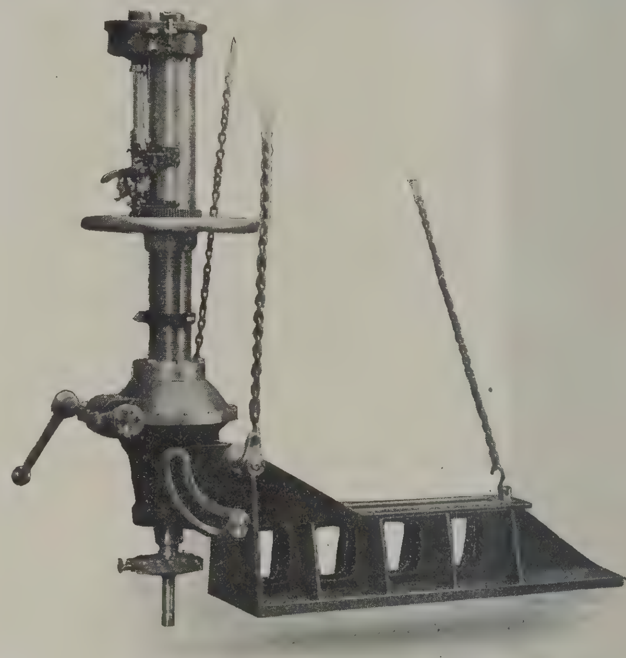

Fig. 3. Capitaine large size Portable Milling and Drilling Tool.

The milling and drilling tools illustrated consist mainly of a work spindle, driven by means of a telescopic shaft from a portable electric motor. This spindle may be clamped to a jig or to the work itself by means of a very simple device. Fig. 1 shows a drilling spindle suspended; Fig. 2 a drill spindle clamped to a slotted base. A series of holes is drilled into a flat plate, by clamping the base *A*, Fig. 4, to the plate by means of a screw-clamp *c* and after one hole is drilled this is used to hold the base with a bolt. From the illustrations can be seen that the drill is guided by a suitable bushing *i*, close to the hole, which in combination with the flat base *A* insures a perfectly true and accurate drilling. The same cut shows in the upper view how bosses inside of side frames may be finished with the same appar-

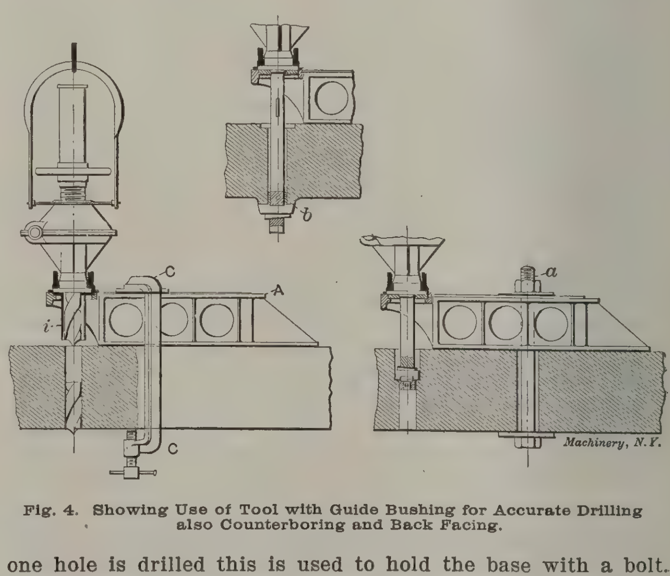

Fig. 4. Showing Use of Tool with Guide Bushing for Accurate Drilling also Counterboring and Back Facing.

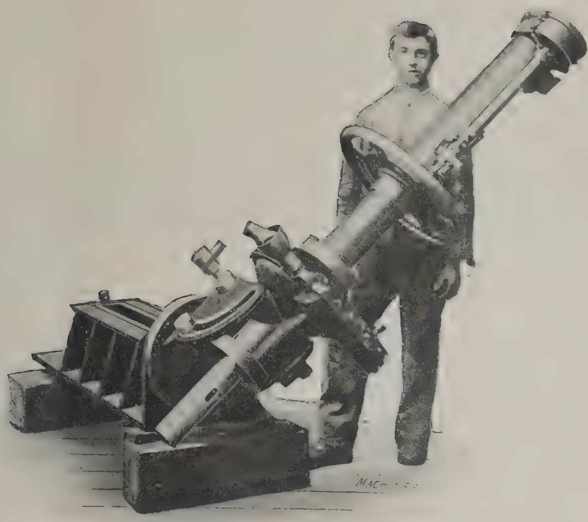

Fig. 5. Large Size Portable Milling and Drilling Tool.

atus. When very deep holes are to be drilled, or the hole, which is to be drilled is some distance away from a suitable place for clamping the base, the drill spindle can be lengthened indefinitely, by moving a pin in its upper end from hole to hole, as may be seen from Figs. 1 and 2. The larger portable spindles are provided with automatic feed and stop, which permits drilling or milling under any angle. Figs 5 and 5*a*, which illustrate this, also illustrate to what large dimensions these tools are built. Fig. 6 is the same tool at work drilling a big dynamo frame. These large sizes are suspended and balanced, but the smaller ones can easily be lifted by one man.

A few more illustrations will show the general adaptability of the system. A special base with slide-rest is provided for milling seats with toothed or other milling cutters, Fig. 7, and clamping one of the larger spindles to it. By providing two upright posts on a floorplate, Fig. 8, it serves as an efficient horizontal boring machine. Fig. 9 shows a portable spindle clamped to a jig, *c*, for drilling the holes *b* and milling the valve seats *a* in one operation.

Another application of this system of portable tools is the boring of large cylinders. The boring bar of Fig. 11 is principally used for boring locomotive cylinders in place; it may be used for any length of cylinder as the spindle length is unlimited. The feed and stop are automatic, by means of two rollers pressing against opposite sides of the boring bar;

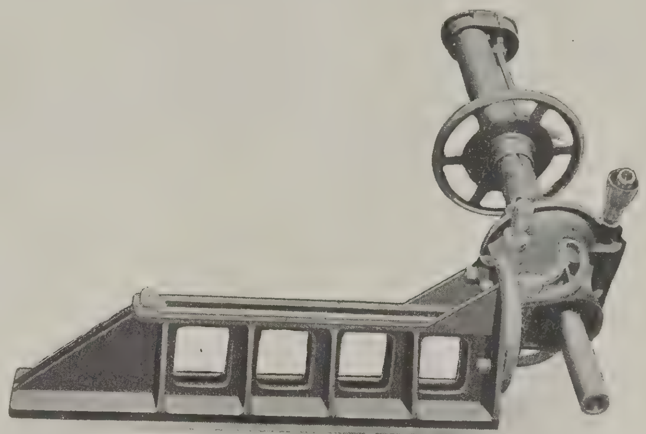

Fig. 5a. Large Size Portable Milling and Drilling Tool.

these are driven by a worm gear. Figs. 10 and 12 show a similar tool for boring and facing gas engine cylinders.

A special tool for milling steam ports in Corliss engine valve chests and which also is driven by a telescopic shaft and electric motor, is illustrated in Figs. 13 and 14. The

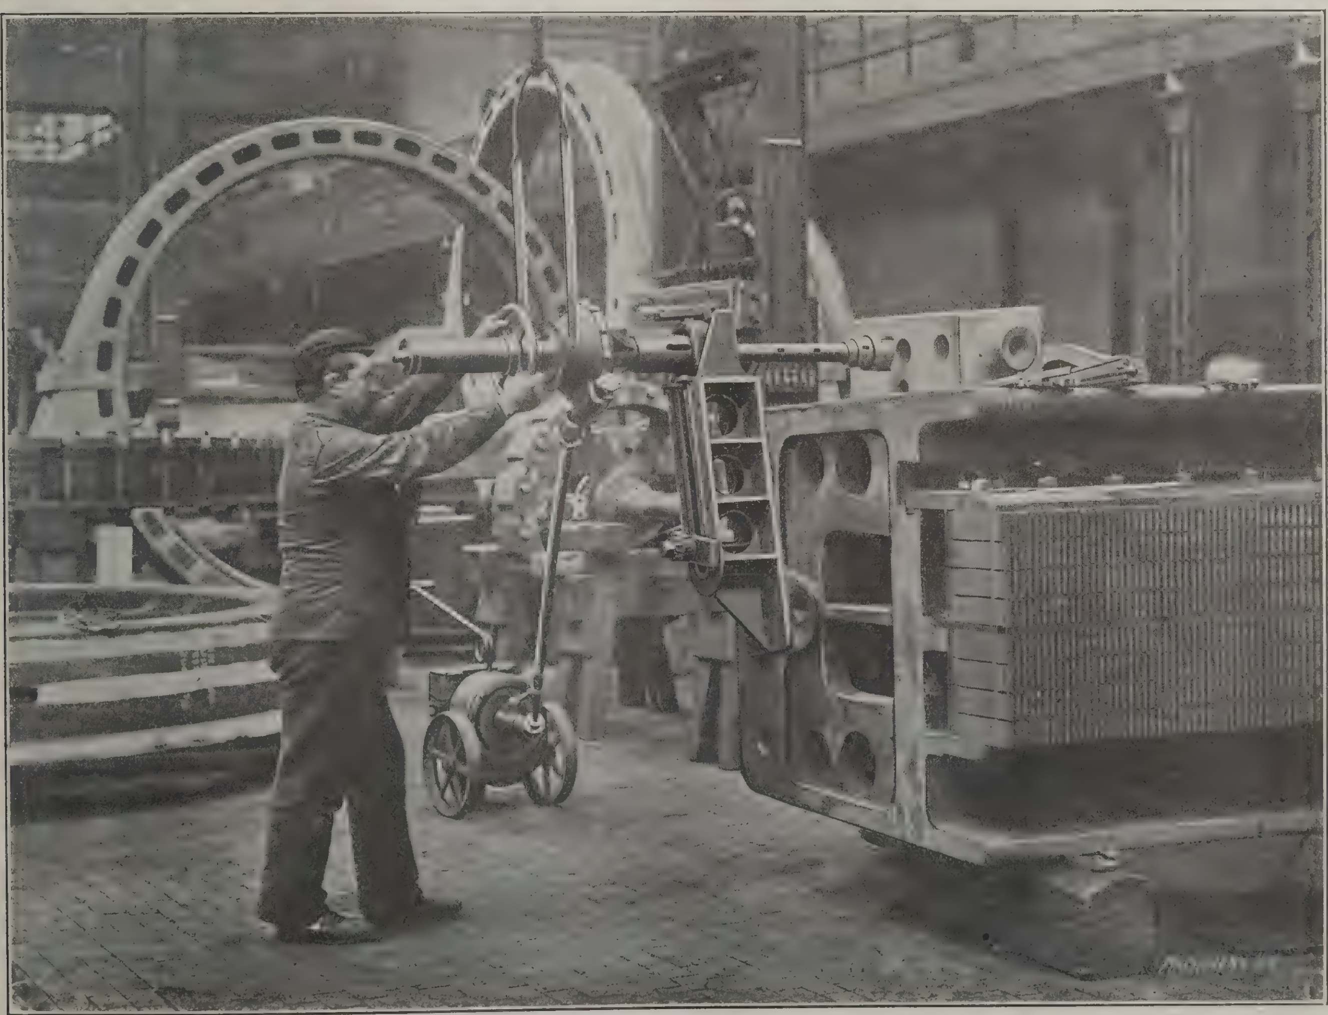

Fig. 6. In Use Boring Holes in a Large Dynamo Frame.

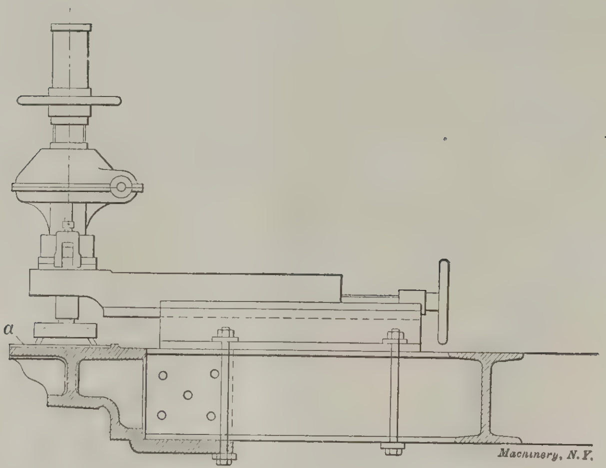

Fig. 7. Milling Tool provided with Slide-rest.

carriage *B* moves in the groove of the tube *A* automatically, being driven by spindle *D* and a sliding helical wheel which meshes into the pinion on the milling spindle *C*. The transverse adjustment is accomplished by a long wrench *p* from the outside, turning shaft *o*, which transmits its motion by a worm and wheel to the adjusting screws *c* and *e*. The parallel milling of the ports is secured by two eccentric discs *E*, which fit into the bore of the valve chests.

There are many more applications of these tools for special purposes, of which we have shown a few. The designers and builders of these tools are Messrs. Emil Capitaine & Co., Frankfort-on-the-Main, Germany, and Mr. M. Joachimson, 14 Church Street, New York, is their American representative. The De La Vergne Machine Co. recently installed a number of these tools in their shops and others are in preparation.

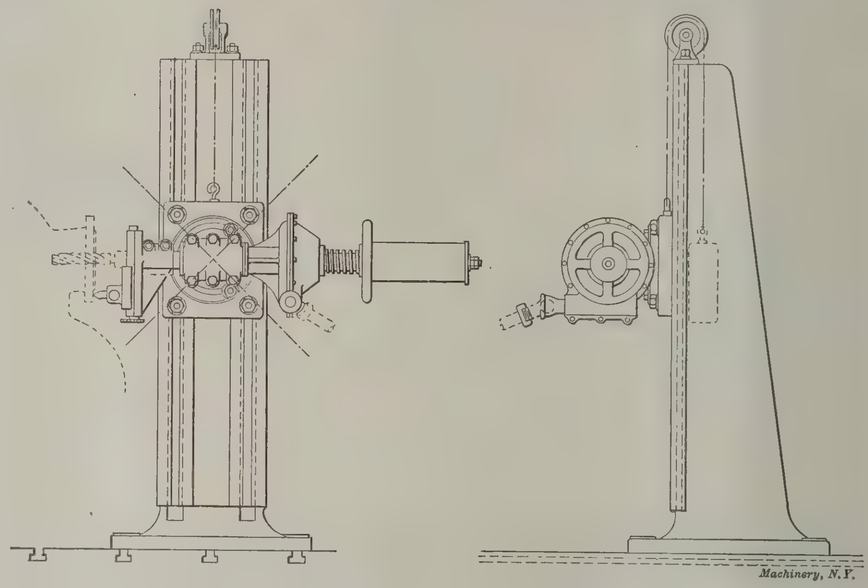

Fig. 8. Use of Portable Tool as a Boring Machine.

* * *

A new bridge of imposing dimensions will be built across the St. Lawrence river at Montreal in the immediate future. It will be a cantilever bridge with a main span 1,500 feet long, 150 feet above the water. The bridge will have accommodation for railway and trolley tracks, as well as for horse and passenger traffic. From end to end the bridge will be two and a half miles in length.

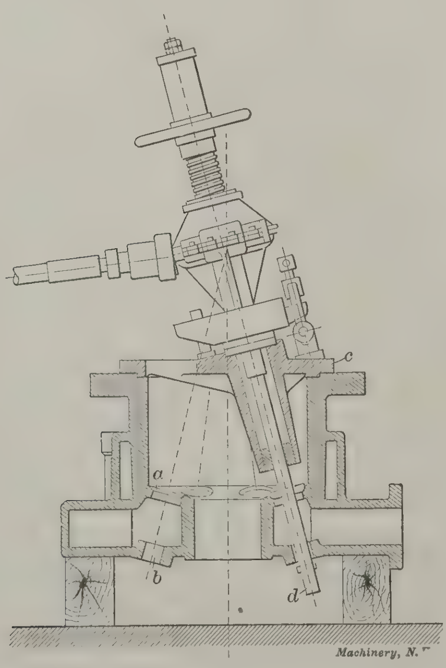

Fig. 9. In Use in a Jig, Boring and Milling Valve Seats at an Angle.

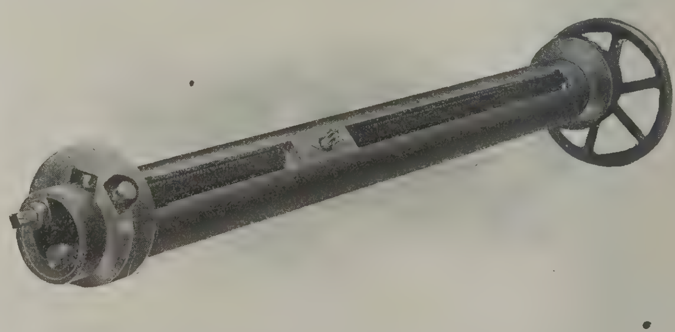

Fig. 13. Portable Tool for Milling the Ports of Corliss Engine Cylinders.

TECHNICAL EDUCATION IN EUROPE.

In his article "An Experiment in Industrial Engineering," in the September issue of MACHINERY (Engineering Edition), Mr. Alexander expresses the belief that the efforts which the General Electric Co. and other concerns are putting forth to train boys in various trades, must be considered "as experiments only, highly important as an immediate remedy; but these are experiments which the state ought to watch with a deep interest, in order to draw therefrom proper conclusions as a foundation on which to build the right system of industrial education." He expresses his belief that the public school system should adapt itself to modern industrial conditions by at least starting boys, who are to work with their hands for a living, in the way of gaining familiarity and efficiency in the handling of the tools which they are to employ when they leave the school and enter the factory. The extent to which this idea has been carried in some continental countries is a matter of record. We were given a fresh and vivid impression of this condition, however, in a recent conversation with Mr. Arthur Williston, the director of the Department of Science and Technology in Pratt Insitute. Mr. Williston has just returned from an extended visit to the various trade and technical schools of Europe.

The population of Switzerland, for instance, is 3,315,000; that of Massachusetts is slightly over 3,000,000. Switzerland, which we are accustomed to think of as primarily a land of wild mountains and unfertile soil, with the fleecing of tourists as its chief industry, has within its boundaries over 300 technical schools of various grades. The data for the number in Massachusetts are not at hand for the moment, but whoever is at all acquainted with this most highly developed of our manufacturing commonwealths would hesitate to put the number at more than 10 or 15 per cent of that given for its European rival. The figures given for Switzerland include, of course, institutions of all grades—trade schools, elementary and higher technical schools, and engineering colleges. One of these latter, the Polytechnikum of Zurich, compares in equipment and number of students with our

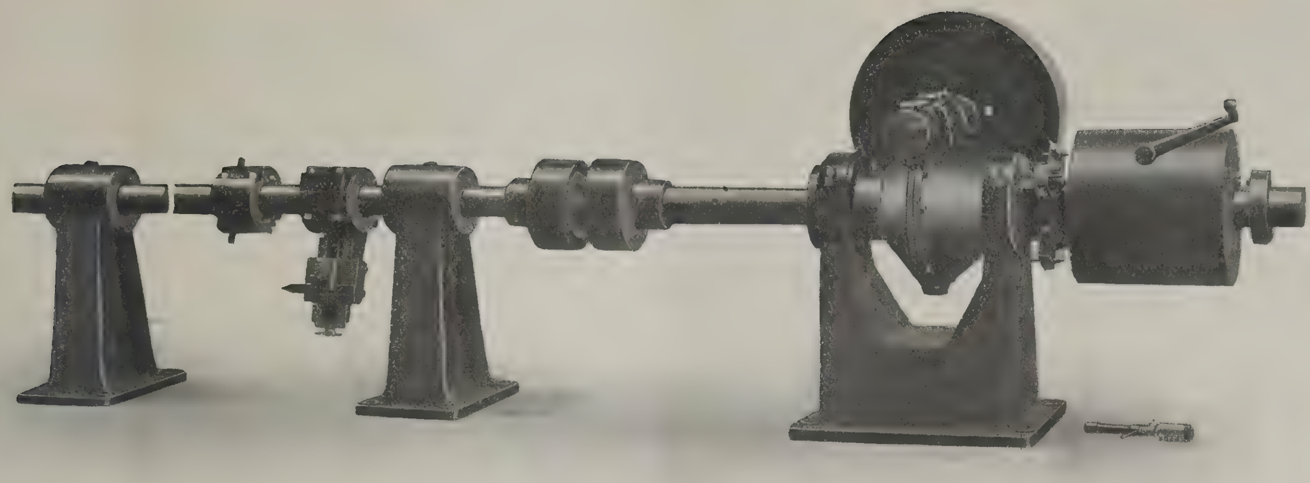

Fig. 10. Portable Boring Machine for Engine Cylinders.

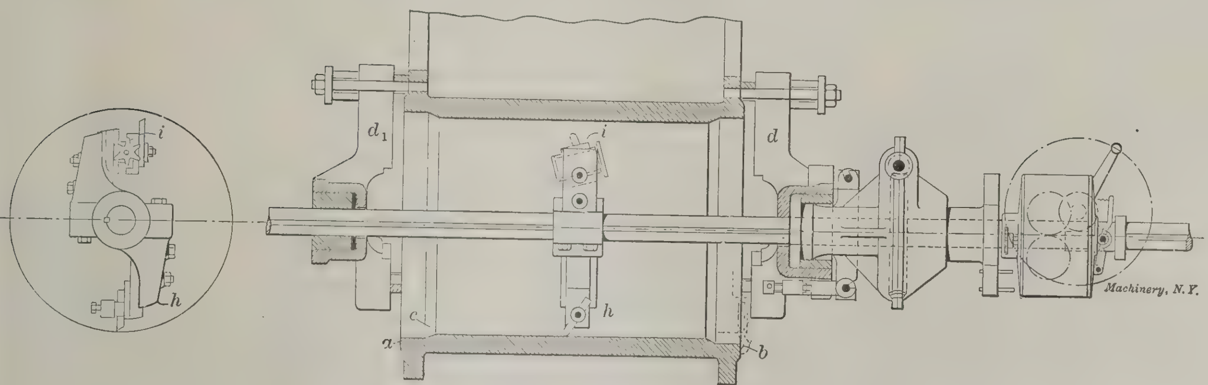

Fig. 11. Capitaine Portable Boring Machines

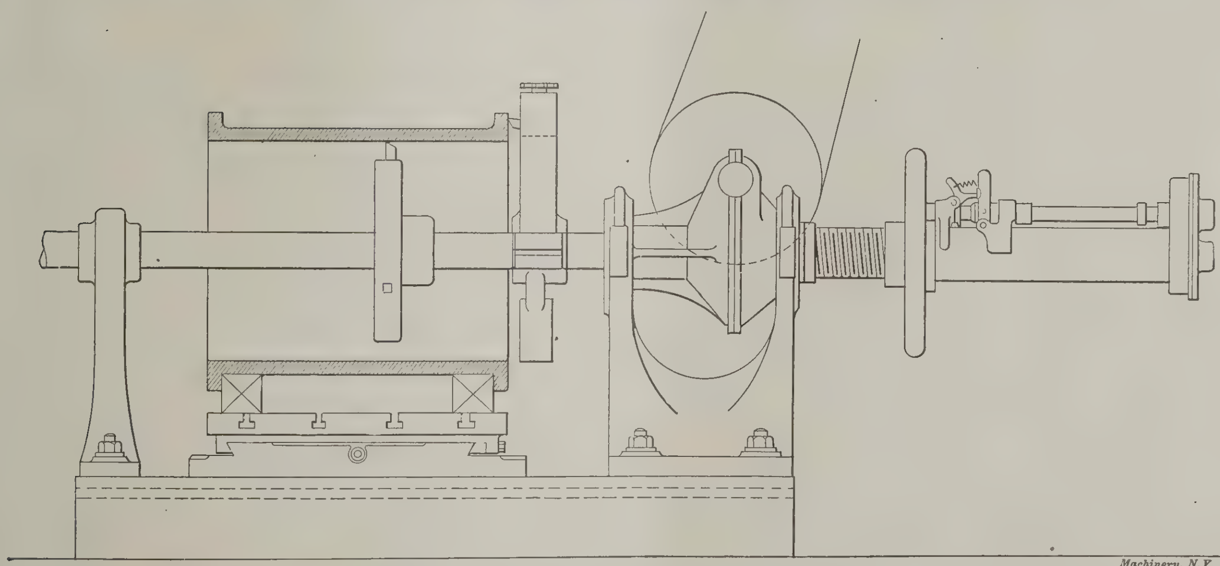

Fig. 12. Portable Boring Machine for Engine Cylinders.

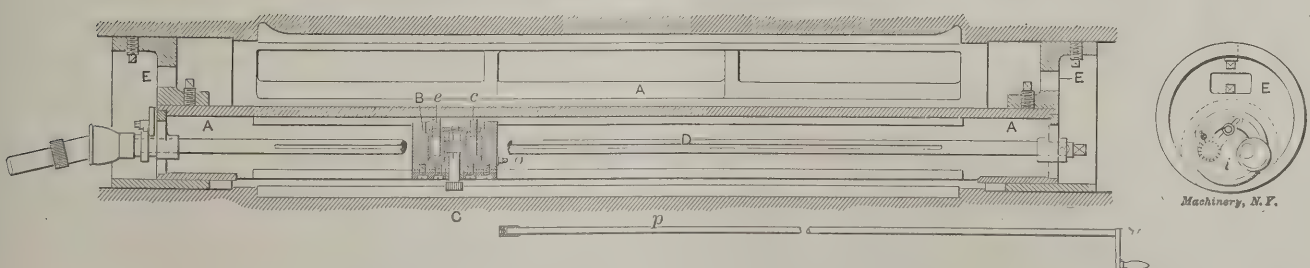

Fig. 14. Detail of Portable Tool for Milling Corliss Engine Cylinders.

great engineering schools, and ranks with the Massachusetts Institute of Technology in the excellence of its work. With this as the culminating point, the list, widening as it descends, embraces schools of various characters of the grade that Mr. Williston calls "technical schools," of which Pratt Institute and a few others are the only representatives in this country. Of these Switzerland has many; they prepare men for foremanships, positions as mechanical and architectural draftsmen, etc. Below this rank come the elementary technical schools and the trade schools. Some of these are of great size and

wide reputation, while others teach but a single trade and have perhaps only a single instructor, being located in the midst of the district employing the class of labor which the school is intended to furnish. One of those visited, a cabinet-maker's school, had only one instructor and twenty-five or thirty boys, but the artistic quality and finish of the work turned out, most of which was designed as well as executed by the students, was really marvelous. Institutions of this kind are almost unknown in this country; except for the small horological schools which are to be found in some of the watchmaking centers, we cannot call to mind an American parallel. Descending to the lowest grade, the elementary trade or industrial schools are found everywhere. Boys in the towns learn to use tools with the same facility that American children are taught to reckon interest on promissory notes, and this is done without sacrificing much of what we consider necessary to the boy's education.

The still more highly developed German system of instruction provides for the "continuation school." When the boy is graduated from what corresponds to the grammer school he has two paths open. He may, if he possesses the inclination and the moderate means necessary, continue his education in the higher technical schools with the idea of becoming an engineer; or he may leave school and go to work in a factory, serving an apprenticeship in some trade. If he chooses the latter course, however, he is not by any means through with his education. He is required by law to attend this "continuation school' held evenings for six days in the week, usually, with five hours on Sunday. This lasts from two to four years longer. His time is largely taken up with subjects having some bearing on his business during the day, so it all makes toward his efficiency as a workman. The result of this completeness of education might possibly be somewhat disquieting to an American young man, arousing in him ambitions which there would be no opportunity to fulfill. Whether this would be so here, or not, in Germany with German workman it is fast bringing that country to the premier position in industrial competition. All the work which these engineers, draftsmen and mechanics are doing has to be done under any circumstances, and the question is, shall it be done by men who know merely the barest superficial rudiments of the business they are engaged in, or shall it be done by men intelligently educated, even over-educated, for the work they have to do. In Germany they have chosen the latter alternative and they seem to have chosen wisely.

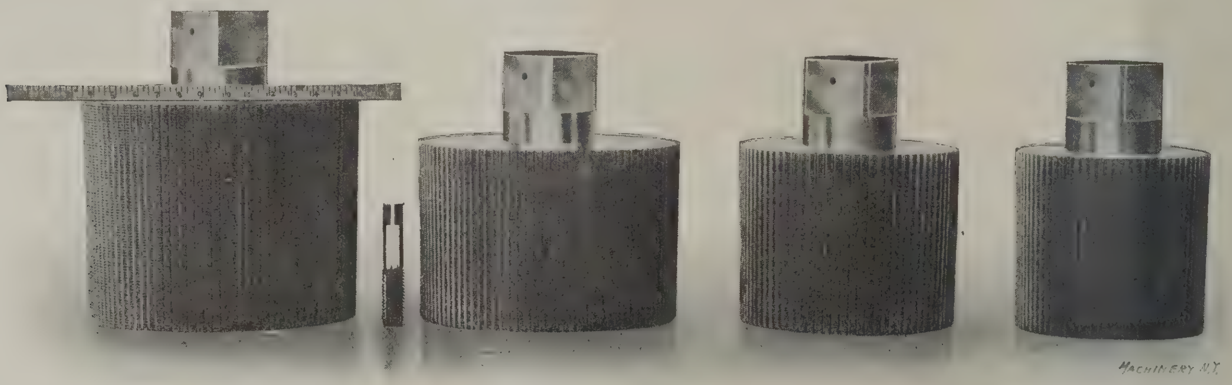
LARGE HOB TAPS.

The accompanying halftone shows a series of taps which in all probability are the largest hob taps ever manufactured. These taps were recently made by the Pratt & Whitney Co., Hartford, Conn., and are to be used for oil well casings. The two largest taps in the series measure 12 and 12¾ inches in diameter, respectively. The threaded portion of the largest hob tap is 10 inches long, and has eight threads to the inch. This tap is provided with 104 flutes, the land and the flute being each about 3-16 inch wide, and if the tap were forced entirely through a piece of metal, it would thus present to the work more than 8,000 cutting edges. The total weight of this tap is 357 pounds. For comparison, a 1-inch hob tap is shown on the side of the largest tap.

The manufacturing of these taps presented, of course, no new principles, but that difficulties were encountered, particularly when hardening these large pieces of tool steel, is easily apprehended. The successful performance of the hardening operation is indicative of the efficiency of the methods employed in the manufacture of "small" tools on a large scale. In this connection it may be appropriate to mention that during the last few years the size of "small tools" has increased decidedly, and that many a time the name does not seem to suit the object. Inserted blade milling cutters, 30 inches in diameter and even larger, and gangs of interlocked cutters with 40 inches width of face are frequently encountered. The introduction of large size milling machines has made the requirements for a different type of milling cutters than those used only a few years ago imperative, and in almost all the branches of the small tool manufacture there is a tendency to increase the sizes of the tools used above the limits of former years.



Large Hob Taps.

THE ULTIMATE DEVELOPMENT OF THE AUTOMATIC MACHINE.

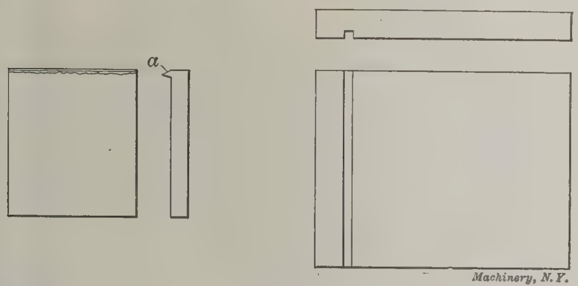
When describing a visit to a typewriter factory, a cotton mill, or any other place where automatic machinery is in evidence, the magazine writer always speaks of it as possessing "an intelligence almost human." What the possibilities are in the development of these machines toward the point where they will think for themselves, it is hard to say; even now they may be arranged to perform selective functions, guiding their action in accordance with the momentary condition of the materials they are working on. Many years ago Bulwer Lytton, in his book, "The Coming Race," suggested the possibility of the time when the problem of social inequality would be solved by the employment of automatons as servants, these mechanisms being guided by the telepathic communication to them of the desires of their masters. Perhaps this is an idle dream, but the writer lays claim to having discovered in an automatic machine an approach to one, at least, of the attributes of a human being—conscience. Each evening in returning home from the office he is confronted by a penny-in-the-slot chewing gum machine which has tempted him more than once to try the result of inserting a coin in the opening, with the hope of obtaining value received for what he has given up. He has been invariably disappointed in this experiment. The other evening as he stood glowering at the machine, soured by the memory of past misfortunes, his imagination could almost conceive that it was writhing under the withering scrutiny. Giving the plunger a vindictive jab, merely to express his feelings, without putting in the cent as on former occasions, what was his surprise to see the panic-stricken machine shoot a chocolate caramel out at him through the opening, and then—O, culmination of wonders! Two metallic tinkles, one after the other, announced the giving up of two of the numerous cent pieces which had been unavailingly surrendered to it from time to time. "Thus conscience doth make cowards of us all." May be the time is coming when this will apply to machines as well as to men.

DRILL JIGS.—1.

E. R. MARKHAM.

Drill jigs are used in drilling holes which must be accurately located, both in relation to each other and to certain working surfaces and points; the location of the holes is governed by holes in the jig through which the drill passes. The drill must fit the hole in the jig to insure accuracy of location. When the jig is to be used in drilling many holes, the steel around the holes is hardened to prevent wear. If extreme accuracy is essential, or the jig is to be used as a permanent equipment, bushings made of steel and hardened are used to guide the drills.

The design of a jig should depend altogether on the character of the work to be done, the number of pieces to be drilled, and the degree of accuracy necessary in order that pieces drilled may answer the purpose for which they are intended. When jigs are to be turned over and moved around on the drill press table they should be designed to insure ease and comfort to the operator when handling, and should be made as light as is consistent with the strength and stiffness necessary. Yet, we should never attempt to save a few ounces of iron, and thereby render the jig unfit for the purpose we intend to use it. The designer should see that the jig is planned so that work may be easily and quickly placed in and taken out, and that it can be easily and accurately located in order to prevent eventual mistakes. As it is necessary to fasten work in the jig in order that it may maintain its correct position, fastening devices are used; these should allow rapid manipulation, and yet hold the work securely to prevent a change of location. Yet, while it is necessary to hold

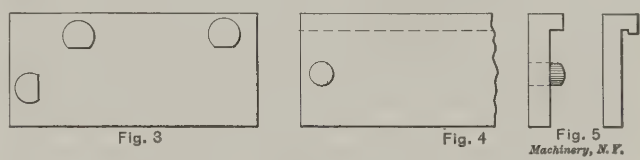


Figs. 1 and 2. Work with Burr and Grooved Part of Jig to correspond.

work securely, we should not use fastening devices which spring the work, or the holes will be not only improperly located, but they will not be true with our working surfaces or with each other. When finishing the surfaces of drill jigs and similar devices used in machine shops, the character of the finish depends entirely on the custom in the shop; for while in some shops it is customary to finish these tools very nicely, removing every scratch, and producing highly finished surfaces, in other shops it is not required, neither is it allowed, as it is considered a waste of time and an unnecessary item of cost.

When making drill jigs we must discriminate between measurements that must be *exact*, and those not requiring extreme accuracy; it is not generally allowed to spend the amount of time necessary to locate a hole within a limit of variation of 0.0001 inch or even closer, if a variation of 1-16 inch is insignificant. But if the holes must be located *exact* as to measurements, it is necessary to work as accurately as possible, and time cannot be considered a factor, provided a man improves every minute. Yet the fact that extreme accuracy must be observed does not warrant a jigmaker *wasting time*.

Before starting to work on tools of this character, the workman should first carefully look over his drawing, making himself thoroughly familiar with the construction, and making sure that the measurements given are correct; if in doubt about anything, consult the foreman, or the draftsman—according to the custom in the shop—in order that every detail may be thoroughly understood, or that any mistake made in the drawing may be rectified. A very poor policy is carried out in some shops. The drawing department and the shop seem to be at "loggerheads" with each other, and are constantly on the lookout for points on which to trip each other. This condition should not be allowed, as both departments are paid by the company to work for the interest of the firm, and not to hunt for chance to harm each other; and if best results are to be attained, there must be a correlation of departments, which condition cannot exist where there is jealousy or a desire to harm one another. The draftsman should always be ready to give any information wanted in the shop, and should also gladly correct any errors his attention is called to. I remember at one time a draftsman's attention being called to an apparent error in a drawing; instead of explaining matters to the toolmaker he informed him that his only concern lay in making the piece he was working on exactly as the drawing called for, and if it proved wrong it was none of his—the workman's—affairs; he was paid simply to follow instructions, and it was the business of the drawing room to give the necessary instructions. In making



Figs. 3, 4 and 5. Means for Locating Work in Jigs.

the drawing the draftsman had, in order to save time, shown several screws as being without threads; they were made of the proper size and length, with slotted heads, yet without threads, the draftsman knowing that the toolmaker would know what was wanted. The latter, however, was offended, and in order to get square for his recent snub he made the "screws" as represented on the drawing, fitted them to the holes and drove them home. When it was discovered, and he was questioned about it, he told what the draftsman had said to him, and said he had followed his instructions implicitly. I need not tell you that he was discharged, and think every fair-minded man will agree that he should have been; but I think the draftsman should have been made to go with him for creating a feeling of antagonism rather than of good will toward himself. Many times one draftsman is puzzled to understand a drawing made by an equally good man, especially so if the work is foreign to him; and a shop man who may not be very well versed in reading drawings—yet be an excellent workman—may easily get puzzled when he attempts to read a drawing of work he is not familiar with.

While the above does not relate to toolmaking in the strict sense of the term, yet it seems advisable to speak of it, as the condition is altogether too common.

It is necessary when designing tools of any character, whether they be cutting tools or fixtures for holding work while machined, to make provision for the chips. These are

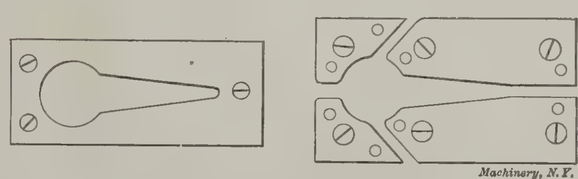


Fig. 6. Method of Locating Work in Jigs.

liable to get into drill jigs, and despite ordinary care get under the work or between it and the locating points. In order to do away, so far as possible, with this tendency, it is advisable to cut away as much of the seating surface as can be spared, and to locate stops away from the seating surface if possible. The seating surface should be smooth enough so that chips will not adhere to it, and so that waste will not stick to it, but it should not be a polished surface, as we would in all probability get it out of true if we attempted to polish it. If chips are allowed to get under the work it will not be drilled true; that is, the holes will not be at the proper angle with the working surface, and consequently the piece will be unfit for most purposes.

Many operations of machining are almost sure to throw a burr on one side of the piece, and in shops where quantities of work of the same kind are machined, men or boys are kept

busy removing these burrs in order that they may not interfere with the proper seating of the pieces during the succeeding operations. While the operation of removing the burr on a single piece of work may not incur great cost, yet when thousands of pieces are machined each day, the aggregate cost constitutes quite an item of expense, and the successful manager is he who so far as possible eliminates the small items of expense, knowing that many small items of expense amount to a large item in the aggregate. Not only is the operation of burring expensive, but as the class of help usually employed to do this work is unskilled, surfaces are many times left in a condition anything but satisfactory. As a consequence, the surfaces of jigs, milling machine fixtures, etc., are many times cut away to receive these burrs, thus doing away with the necessity of burring, and it many times happens that subsequent operations remove the burrs. In Fig. 1 is shown a piece of work having a burr thrown out at *a*, while Fig. 2 represents a surface cut away to receive the burr.

When we wish to drill two holes a given distance apart, the location of the holes is obtained by means of a pair of dividers set to a scale. The location is obtained and prick punched, after which the holes are drilled. This method answers nicely when one piece is to be drilled, and precise measurements need not be observed. If it is necessary to drill ten thousand pieces, then this becomes a costly method and the work can be done more cheaply if a jig is made to hold the pieces. The jig must, of course, have holes the size of the drill, which are properly located. By the use of the jig the cost of drilling is but a fraction of what it would be if the holes were located by dividers, and the surface prick punched as described.

A factor which must be considered is the cost of the jig. If the cost of the jig plus the cost of drilling would exceed the cost if the pieces were first prick punched and drilled as formerly described, then the making of the jig would not be considered unless a greater degree of accuracy was necessary than would be liable to be the result of the method mentioned. When a jig is to become a permanent part of the equipment of a shop, its first cost is not so much a matter of consideration as when only a limited number of pieces are to be drilled. Yet no unnecessary expense should ever be allowed.

Many times when only two pieces are to be drilled which must be exactly alike as regards location of holes, it is cheaper to make a simple jig than to attempt to drill them by any of the methods commonly used in machine shops. In such a case the jig may be made from a piece of cast iron or other material which may happen to be on hand, the holes being carefully laid off and drilled. This jig makes it possible to drill the holes in both pieces exactly alike as to location. When using a jig of this description it is possible to locate the holes near enough for most work by ordinary measurement. If many pieces were to be drilled, it would be necessary to provide locating points so that the pieces could be placed in the jig, and the essential surfaces brought against these. The means of locating may be pins, as shown in Fig. 3, or a shoulder and a pin, as in Fig. 4. If pins are used, they should be so located that the bearing surfaces may be worked flat, as shown, to prevent wear, and also to do away with a tendency to press into the surfaces of the work. If flat shoulders are used they should be cut away, as shown in Fig. 5, to do away so far as possible with a liability of dirt or chips getting between them and the work. Then, again, if the working edges of the pieces of work are not exactly true, it would be impossible to properly locate by pressing them against true locating surfaces which extend the whole length.

When work is of irregular contour that could not be properly located by bringing it against two locating surfaces it is possible to provide a locating device which bears against all the surfaces, as shown in Fig. 6. This method, however, is hardly to be advocated for most work, as it necessitates exactness of measurement and shape on all the bearing surfaces. Then, again, the shape makes it extremely difficult to clean, and a chip under any portion of the work will cause it to stand at an angle with the seating surface of the jig.

THE EXPERIENCE OF BEAUREGARD NAPOLEON FREDERICKSON WITH THE PROFIT-SHARING SYSTEM.

"THE HIRED MAN."

Beauregard Napoleon Frederickson called by his host of friends "Gardie Fredericks" in loving abbreviation, was, and is, one of the best fellows that ever laced a belt; this does not mean that he spent the money that should have been spent for his wife and babies in "setting them up" in bar rooms for his host of friends, nor on the other hand does it mean that he was afflicted with "the deadly dullness of the merely virtuous."

Gardie was a good mechanic, and alas! an inventor also; all of which wouldn't have been so bad, but he was, in addition to all these things, a sucker. How could he be a good fellow and a sucker, too? Why, bless your heart, I don't mean a sucker from a shop standpoint, but one of the kind that some classical writer has assured us is born every minute. So, being an inventor, he brought forth his celebrated "whirlwind whirligig" with a sort of "dusky diamond attachment," and having been born at the psychological moment aforesaid, it wasn't long before he was soon collared by Charlemont Worsley Hornswoggler, who, having been born at a

"* * * * all the profits made on the selling end of the business * * * * unable to figure any profit at all for the factory."

different minute from the subject of our sketch, could not only see through a hole in a ladder, but knew a good whirligig when he saw it. The result was that Mr. Beauregard Napoleon Frederickson assigned all his right, title, etc., in the whirligig to Mr. Charlemont Worsley Hornswoggler and to his heirs and assigns forever; in return for which Hornswoggler was to furnish a factory and machinery and other capital necessary to manufacture the whirligig, and give B. N. Frederickson a stated salary for running the factory and a share of the profits. (As Artemus Ward would say: "The printer must put some stars here.") * * * *

What is the use of going on? We have now reached what corresponds to the end of the third act of a play in a theater, and everybody can see how the last act will end. But as people usually stay to see the last act, and as the editor will probably refuse to give me the large check he has bribed me with to get this story, unless the story is finished, here it goes! When the things got to moving in good shape, and it seemed there ought to be a pretty good sized wad to spare, our hero borrowed a plug hat and went over to the city office to look it up. Mr. Hornswoggler told him that he had carefully figured the thing out, and found that, while there had been considerable money made, it had all been made on the *selling end* of the business, and that he had been *unable to figure any profit at all for the factory.*

THE VALUE OF "NON-PRODUCERS" IN MANUFACTURING PLANTS.

H. K. HATHAWAY.

The greatest fallacy that exists to-day in the minds of most proprietors and managers of manufacturing plants is the idea that if they keep down the proportion of so-called "non-producers" they are necessarily saving money; but in considering the subject of non-productive expense, they are so alarmed by the thought of spending money from which they can see no immediate tangible return, that they do not look beyond the surface; and thus they deceive themselves in the belief that they are acting wisely in curtailing the number of "non-producers," whereas, if the subject were thoroughly investigated, the opposite course would often prove the one to be followed. The object of this article is to represent the matter in its true light, and to show that mere "non-producers," if their efforts are properly directed and utilized, are in most cases, not only profitable but essential to economical production.

The term "non-producer" is generally applied to clerks, foremen, inspectors, helpers, and others, whose labor is not directly expended in transforming raw material into product to be sold; while those whose labor is so expended are classed as "producers."

A few years ago the writer was superintendent of a plant whose principal product was automatic steam engines; this concern employed about one hundred and twenty-five men, and had started in a small way about fifty years ago. It prospered and grew for about forty years, and then, for no apparent reason, began to slowly retrograde until finally it failed completely. To the end the product was of the same high standard of workmanship and design that had contributed to the early prosperity of the plant, having been improved from year to year to keep pace with the demand for something better, and to compare favorably with the goods put on the market by competitors. The business policy was unchanged, and the same methods of manufacture and management that had prevailed in the period of prosperity were still adhered to.

In this plant there was only one foreman, who kept track of all the work in progress, looked after the quality of the work, the discipline, and all other details connected with the operation of the plant. Each workman ground his own tools, and had them dressed when necessary; repaired his own belts, and took care of the appliances used by him. Only two or three laborers or helpers were required, as the men helped each other in getting work to and in and out of their machines; and only one clerk, besides the bookkeeper, was necessary to keep the men's time and make up the pay-roll. Thus the number of employees classed as non-producers was remarkably small; the manager saw to that, and impressed upon the writer the stern necessity for keeping it down, and reducing it further if possible. The item of "non-productive" expense was so carefully watched and guarded against that the workmens' daily time cards showed that almost the entire time of every man was spent on productive work.

This, however, while apparently representing a very desirable state of affairs, was not indicative of the true conditions, which were something quite different, as will be shown by a more thorough analysis. In reality, only about 50 per cent, or less, of the time was spent in actually producing, the balance being consumed in preparing to do the work, that is, in doing things that should have been done in advance by "non-producers," the rate of pay of most of whom would have been less than that paid to the "producer." To illustrate this point, we will consider that the workman has just finished a job. He then hunts up the foreman to learn what he is to do next; the foreman, after considering, tells him, and the workman finds the job and moves it to his machine. He then goes after the drawing, which may be anywhere in the shop, after which, unless he is perfectly familiar with the job from having done it before, he will again hunt up the foreman for some explanation of what is to be done. The next thing is to set the job in the machine. His clamps are often missing or not suitable, his bolts are not the right length and have no nuts or washers on them, or the threads are in such bad condition that the nuts have to be forced on with a wrench. The writer has seen cases where men have spent as much time looking for a bolt or a clamp with which to hold a job as was required to do the work. After the job has been set the workman looks up his tools, which have to be ground; so he takes his place at the grindstone, which is usually worn out of shape, and waits his turn with the two or three others who are always there.

He has now completed his preparations. The time consumed in making them is charged to the job and considered as productive labor, although in this time neither the man nor the machine have produced anything. All of these preparations, except the actual setting of the job, could have been made by "non-producers" before the workman had finished his preceding job, and the machine could have been producing continuously. The state of affairs here outlined is one which exists, in a greater or less degree, in almost every shop, the management being blinded to it through having its attention taken up by matters of seemingly greater importance, or regarding it as an unfortunate condition of affairs for which it can see no help.

After the writer was thrown out of employment by the failure of the concern referred to, he had the good fortune to become connected with another plant, of about the same size and producing a line of work not differing essentially from that of the first one. This concern had been run for years upon much the same lines as were followed by the firm that failed, but the management had realized in time the necessity for taking some action to avert a similar fate, which had begun to cast its shadow before it; so with this object in view they had started to install the "Taylor System of Works Management."

During the past year the output of this plant has increased more than 100 per cent, with no increase in the pay-roll; and the most interesting thing about it is that, in effecting this result, it was necessary to increase the "non-productive" force from a total of six or eight men to twenty-five men, and to make a corresponding reduction in the number of so-called "producers." In this plant the "Taylor System" provides for having all the preparations made in advance for the workmen; and it is in carrying out the system that the "non-producers" referred to are employed. The nature of their work is outlined in the ensuing paragraphs.

When it is decided to manufacture certain machines or parts, either to fill specific orders for customers or for goods to be carried in stock, a manufacturing order is issued, which passes in turn through the hands of a number of clerks in the "planning department," whose duty it is to plan and arrange for furnishing the tools, materials and appliances to be used in manufacturing the articles called for on the order, and prescribe the methods to be followed in doing the work in the quickest possible time, and in a manner to meet the requirements as to quality.

The first of these "non-producers," called the route clerk, must be a man with practical shop experience, and it is his duty to determine what operations must be performed on each part, and to prepare the route sheets, which indicate these operations and show in what machines they are to be done. He must specify how much of each material is required, specify the number of castings, and must furnish the necessary orders on the storekeeper for the materials. If the articles called for on the manufacturing order consist of a number of parts to be assembled, as in the case of complete machines, the route clerk must plan out the method to be followed in assembling, and so arrange the parts into groups or divisions as to enable the assembling to be done with the least delay; certain groups are thus assembled while the parts for others are still being machined. He must prepare a chart, or working diagram, showing this arrangement of the parts, and giving detailed instructions for the guidance of the assemblers.

The relation of the parts to each other is kept in mind in getting the castings into the shop and in doing the machine work, so as to insure that all the parts of each group shall be delivered to the assemblers as nearly simultaneously as possible. For example, in building a steam engine, if the cylinder, flywheel, and connecting-rod boxes arrived on the assembling floor together, it is obvious that nothing could be done toward erecting the engine; whereas, if the cylinder,

piston, cylinder heads, valve, and steam chest cover arrive together, it is possible to proceed with the work at once.

The manufacturing order next goes to a clerk, who keeps a running balance of all raw and worked materials carried in stock, and subtracts the materials called for from the quantities shown to be available. This clerk is also responsible for issuing orders for replenishing stock, as soon as the quantity available falls to a certain minimum. The foundry clerk orders any castings required that are not regularly carried in stock, specifying the dates on which they must be delivered, and following them up regularly by means of a "tickler."

Instruction cards are next prepared for each operation on each part, giving in detail the method to be followed in setting the job, the tools to be used, the feeds, speeds, and cuts to be used, and the time allowed to do the work. The clerks who make up these instructions must be practical shop men, possessing considerable experience and good judgment. The time allowed for a job is based on "elementary time study," such as Mr. Taylor has described in his papers on works management. Barth's slide rules are used in setting the feeds and speeds at the proper figures. The various orders for performing the operations, for moving the work to another machine after the completion of an operation, for inspecting the work as required, etc., are then written, and the work is begun on the order in the shop.

There are, in the planning department, in addition to the clerks mentioned, the timekeeper, cost clerk, and several messengers, and besides these, the production clerk, the order of work clerk, and the recording clerk. The production clerk sees that orders go through the planning department without delay, and watches the progress of the work through the shop to see that goods are finished and ready for shipment when due. The order of work clerk plans ahead the work to be done by each workman, and arranges the order of work ready to be done by each machine, in accordance with the "Order of Work" or schedule given him by the production clerk; he sees, also, that plenty of work is kept ahead of each workman. The recording clerk enters on the route sheets the progress of the work as it moves through the shop.

In the shop where there was formerly but one foreman there are now several, each of whom has a certain function to look after. The gang boss has charge of the work when the machines are not cutting, and it is his duty to look after the setting up of the work, and the preparations for doing it in accordance with the instruction card. The speed boss has charge of the work while it is being actually machined, and sees that the tools, feeds, speeds, and depth of cuts used, are as specified on the instruction card, and that the workman operates his machine to the best advantage. The inspector is solely concerned with the quality of the work, and it is his duty to see that the work done is up to the required standard of finish and accuracy. The repair boss looks after the repairs and maintenance of the machines, shafting, and belts.

The moving of materials is done by special laborers, and is controlled by the recording clerk in the planning department, nothing being moved except upon a written order issued by him. After a job has been moved to a machine where an operation is to be done on it, the order of work clerk issues the order for doing that operation, and the drawing and the instruction card are delivered to the workman. All tools required to do the work are brought in a "tote box" to the machine by a messenger, tools and appliances of all kinds being kept in the tool room in constant readiness for use. The gang bosses are required to see that these preparations are at all times made for at least three jobs ahead for each workman.

When a workman starts a job, an order is at once sent to the inspector, notifying him to that effect, and requiring him to immediately see that the workman thoroughly understands what is required, and to inspect the first piece finished. This inspection at the start of a job is for the purpose of preventing mistakes being repeated on the entire lot of parts, and is most effective in reducing bad work to a minimum. Upon completion of the entire lot of parts, they are again finally inspected, before being moved to the machine that is to perform the next operation.

With the work thus planned and prepared for in advance, and with the various "functional foremen" not only directing the men, but assisting them to perform a definite task in a definite time, it has been demonstrated that each workman, by actually doing productive work all of the time, can turn out from one to three hundred per cent more work than he is able to do in a shop run as many are, where the planning and preparations are left to be looked after by the one "overworked foreman" and the workman, no matter how competent either of them may be.

In concluding, the writer wishes to call attention to the fact that the "non-producers" in the planning department and in the shop are doing nothing but what had to be done by somebody under the old form of management, with the difference that, under the "Taylor System," each thing is done in a systematic manner by men qualified by training in that particular thing, whereas formerly it was done much less efficiently in the shop, and charged against the job as productive work. The fact that it is being done by a man who should have been producing, but whose machine was standing idle, does not make it productive labor. It does not matter whether the wages for "non-productive" labor are 10 per cent of the total pay-roll or 60 per cent of the total pay-roll, the only sound basis of judgment being a comparison of goods produced per dollar expended. On this basis it has been clearly shown, as in the case of the second plant described, that it is a mistake to fight shy of "non-producers," provided, as before stated, that their efforts are properly directed and utilized. The proportion of "non-producers" required to obtain the best results, depends upon the nature of the product and the quantities handled.

* * *

THE GROWTH OF THE CEMENT INDUSTRY.

The Portland cement industry in this country presents one of the most marvelous instances of growth on record. The use of cement for all forms of construction—for railroad, dock and harbor work, great office buildings, factories, hotels, dwellings, and a thousand and one other things—has occasioned the amazing increase in the output in the United States from 42,000 barrels in 1880, to 35,000,000 barrels in 1905, or over 800 times as much; whereas in pig-iron production the output in 1905 was only about six times that of 1880. This marvelous growth of the cement industry, however, has in no way interfered with the growth of the iron industry. To the contrary, cement has come as an auxiliary to help maintain the vast building activity, preventing an iron and steel famine, which would have upset all building operations throughout the country. As concrete has supplemented iron so has it helped the lumber situation through its use in many forms of construction where timber would otherwise have been essential. The scarcity of timber is growing to an alarming extent. Experts have placed the limit of supply at 35 years. The advent of the cement industry is therefore important in helping to save the American forests from complete destruction. The manufacture of all this cement requires a vast amount of machinery. Many plants have sprung up within the last few years in various parts of this country, whose capacities run up into thousands of barrels daily. Contracts for cement-making machinery calling for an expenditure of hundreds of thousands of dollars are of frequent occurrence to the large cement machinery manufacturers. What is said to constitute the largest individual order ever placed for tube mills for the grinding of cement clinker is one recently placed by the United States Steel Corporation. This order calls for forty-seven tube mills, 5 feet in diameter by 22 feet in length. Twenty of these are to be installed in the plant of the Carnegie Steel Company at Homestead, Pa., and twenty-seven are for an extension to the immense modern cement plant of the Illinois Steel Company at Buffington, Ind. This entire order was awarded to the Power and Mining Machinery Company, Cudahy, Wis.

* * *

The production of gold which has of late commanded so much attention, is still continuing to increase. August returns from the Rand mines in South Africa show that the output is nearly 20 per cent in excess of the output during August last year.

COUNTERBORES WITH INTERCHANGEABLE BODIES AND GUIDES.

ERIK OBERG.

The efforts constantly made by progressive manufacturers to decrease the cost of tools without impairing their efficiency have resulted in the design of a number of holders for cutting tools which permit a cheaper grade of material to be used in the holder proper, while the best quality steel can be used for the cutting tool itself. A further impetus to these efforts has been given by the extensive use of high-speed steel, the price of which is so high as to make its use for many purposes prohibitive, if the whole tool should be manufactured throughout of this material. Many tools which only a few years ago were almost invariably made solid are therefore to-day made up in several parts, the portion which performs the cutting being the only one made out of high grade material. Incidentally another advantage is also gained. Inasmuch as the cutting portion of a tool is the only one which, in general, when worn, has caused the tool to be discarded, it is now possible to retain all the other parts and replace the cutting portion only.

The accompanying cuts show a number of counterbores with interchangeable bodies and guides. In the case of counterbores the interchangeability is even of a greater advantage than in many other tools, inasmuch as here a number of guides can be used with the same body, and *vice versa*, thus making it possible to replace a very large collection of solid counterbores with a single holder and a few bodies and guides.

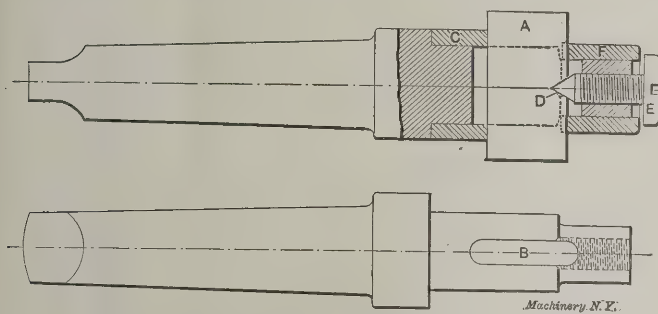

Fig. 1. Counterbore with Interchangeable Blade and Guide.

Fig. 1 shows a counterbore where the body consists simply of a blade *A*, inserted in a slot *B* in the holder. The blade rests upon a hardened tool steel collar *C*, which is driven in place. A slot is milled across the blade in the center at *D*, and a setscrew *E* serves the double purpose of binding the blade against the collar *C* and holding it central. The guide bushing *F* is provided with a small slot fitting over the blade to prevent it from turning, and is kept in place by the head of the screw *E*. There is, however, a slight allowance for play between the guide bushing and the head of the screw, in order to insure that the screw will bind the blade in the slot *D*, and not tighten down upon the bushing before binding the blade. By simply removing the screw the counterbore can be provided with any size blade and guide within certain limits. This class of counterbores is manufactured by the Pratt & Whitney Co.

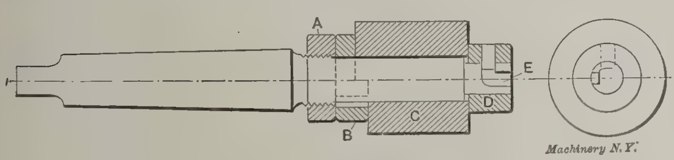

Fig. 2. Counterbore with Interchangeable Body and Guide.

Fig. 2 shows a counterbore of a different type. The collar *B* is keyed to the holder, and is provided with a step as shown in the cut by means of which the counterbore-body *C* is driven. The collar is movable in the longitudinal direction of the holder, being pressed down toward the counterbore by means of the nut *A*. The thrust when binding is taken by the guide bushing *D*, which is provided with a pin sliding in a slot in the guide pin *E*. This slot is milled in the longitudinal direction of the holder about one-half of the length of the guide pin, and is then milled in form of a circular groove about one quarter of a revolution. When the guide bushing with its pin is pushed over the guide pin and given a quarter of a turn, the nut *A* can be screwed down until it holds the body of the counterbore firmly in place. The advantage of this type is that the bushing and body can be very quickly changed and are simple to duplicate.

Fig. 3 shows a counterbore of a somewhat similar type. Here the driving collar *A* is fastened to the holder by a taper pin, and provided with a key freely fitting a slot in the body *B*. The guide *C* is screwed into the holder, and binds the counterbore-body against the driving collar. The guide is provided with a screw slot to facilitate its being screwed in and out. A portion, *D*, on the stem of the guide should be plain and a good fit in a plain hole in the holder, in order to insure that the guide will be concentric with the body of the counterbore. The thread must, of course, in such a case fit very freely.

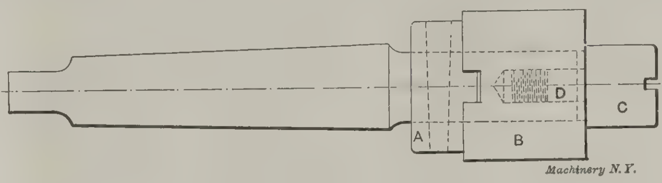

Fig. 3. Counterbore with Interchangeable Body and Guide.

The variations possible are evidently many, but the types represented involve the principles upon which interchangeable body and guide counterbores are designed. The body and the guide should be easy to duplicate, there should be means insuring that they will always remain concentric in relation to one another, and all details, needing fitting when made, should be contained in the holder itself in order to prevent difficulties arising when placing new bodies or guides on old holders.

* * *

There is a large class of persons totally unfamiliar with machine shop operations and who have but the vaguest ideas of the methods and machines employed for reducing forgings and castings to shape required for machine construction. A not uncommon idea of the tyro is that a faced part is done at say one sweep of a broad-face tool, and that cylindrical parts are turned in the same manner. *We*, of course, know that in the beginning the fundamental design of all machine tools was based on the holding of a narrow point tool and feeding it progressively as the work rotated or reciprocated. In this way a small portion of metal is attacked at once and successive furrows are made the same as in plowing a field. The width of the plow furrow is limited to the strength and endurance of the team, and the depth and width of a lathe cut is dependent on the rigidity and power of the machine. In time, as the design of machine tools increased in power and rigidity, the width of the cut was increased; the forming idea became more pronounced and the use of broad-faced tools which would actually sweep at one revolution a complete cylinder of definite length was an established fact. To-day this idea has been carried to an extent which would astonish those who are familiar only with the earlier types of machine tools. For example, a special machine has been built by one well-known concern for facing a certain part in three different places at one operation. Each of these three operations would have required at least twenty minutes if done in an ordinary 24-inch engine lathe of a generation ago. To-day, this special machine, which weighs as much, perhaps, as ten engine lathes, does the three operations in one-twentieth of the time. It literally "hogs" the metal off at say, two or three revolutions, followed with a finishing revolution, and the work is done. It seems hard to conceive of the development of machine tools being carried to a much greater extent than this. Any further improvements would mean the elimination of machining, and perhaps this in time may come when the molder succeeds in producing molds mechanically perfect and which are not destroyed for each casting. This, already done with alloy castings, does not, however, promise much for the more refractory metals like iron, steel and brass. Shrinkage must first be overcome, and this is a large job alone.

Entered at the Post-Office in New York City as Second-Class Mail Matter.

RAILWAY MACHINERY

A SPECIAL EDITION OF MACHINERY FOR THE RAILWAY SHOP, DEVOTED TO LOCOMOTIVE AND CAR EQUIPMENT AND MECHANICS.

Published monthly by

THE INDUSTRIAL PRESS,

66-70 WEST BROADWAY, NEW YORK CITY.

DOMESTIC SUBSCRIPTIONS, $2.00 A YEAR. FOREIGN, $3.00 A YEAR. SINGLE COPIES, TWENTY CENTS.

The receipt of a subscription is acknowledged by sending the current issue. Remittances should be made to THE INDUSTRIAL PRESS, and not to the Editors. Money enclosed in letters is at the risk of the sender. Changes of address must reach us by the 15th to take effect on the following month; give old address as well as new. Domestic trade is supplied by the American News Company or its branches.

We solicit communications from practical men on subjects pertaining to railway machine shop practice, for which the necessary illustrations will be made at our expense. All copy must reach us by the 5th of the month preceding publication.

NOVEMBER, 1906.

The Walschaerts valve gear of which we made mention in our October issue has again been discussed at a convention of railroad men, this time at the fourteenth annual convention of the Traveling Engineers' Association. A paper was read before the convention by Mr. O. H. Rehmeyer on the Walschaerts valve gear in which he briefly refers to the history of this type of gear and to its adoption for American locomotives, comparing some of its features with those of the Stephenson link motion. It was pointed out that the Walschaerts gear is superior from the standpoint of inspection on account of all parts liable to defect being in plain view and easily examined from the outside. In regard to the cost of maintenance of this gear compared with the Stephenson valve gear, the author believed it to be fully 25 per cent less and expressed the opinion that the Walschaerts gear will handle a train better at a slow rate of speed with very little slipping, while with the Stephenson motion there is a greater tendency to slip at slow speed, requiring a greater amount of sand to prevent it. The ensuing discussion evinced the Walschaerts valve gear to be in general favor, especially so in view of advantages gained by placing the motion on the outside and removing difficulties consequent upon the motion work of heavy engines being between the frames, and the Walschaerts gear was reported to be popular among engineers.

* * *

RAILWAY ACCIDENTS.

The frequency of serious accidents on American railways has made the general public so accustomed to these occurences as to class them amongst those which are nearly inevitable. It must be deeply regretted that such a condition should exist, because frequent railway accidents are by no means necessary, if proper regard is paid to the safety of passengers. The conditions on European railroads, where accidents are incomparably fewer than on American roads, vouch for this statement. Nor is it possible to argue that traffic on American roads is so much heavier, or speeds so much greater than on European roads, so as to make the chances for accidents more frequent. The traffic and the speed maintained on any of the great European thoroughfares compare with the traffic and the speed of our own railroads. It is difficult to give a valid reason why such an unfavorable condition should exist here, if it has been possible to eliminate accidents to a great extent elsewhere. For the sake of comparison with European experiences it is interesting as well as instructive to note that on the Swedish state railways, which at present carry more than 11,000,000 passengers a year, the total loss of life of passengers during the last forty years has been only eight. The number of passengers injured in railway accidents during the same period has been fifteen. While we do not have any record of the casualties of any American system carrying approximately the same number of passengers a year, it is too well known a fact that we could not find any record that would compare favorably in the slightest degree. It is time that there be a general demand for greater safety on our railroads, and the country as a whole will have taken a step forward in a direction which we have partly ignored during our general progress.

* * *

REGULATION OF INTERSTATE COMMERCE.

"Congress shall have power to regulate commerce with foreign nations and among the several States, and with the Indian tribes." Article 1, Section VIII.

The Constitution of the United States is justly regarded as a most remarkable document; the vision of its founders seems to have been prophetic, as it is adequate for conditions that otherwise could scarcely have been provided for at the time it was written. This applies with especial force to the part quoted and few of us at the present time realize the importance of this paragraph, or what developments will come from its liberal interpretation. Seemingly some of the mightiest movements of the present era will pivot on this interstate commerce clause. Not only is it to be used to compel equitable freight and passenger rates, but the regulation of railways in functions which have heretofore been regarded as strictly those of private corporations; it will be the lever by which the packing of pure food products will be assured to the people, and the manufacture of any product going beyond the bounds of the State may be regarded as coming under the scope of government authority because of this fortunate Constitutional provision. But stranger still is that it may be made a powerful lever for controlling and regulating swollen private fortunes, a menace which to-day looms with frowning front. Few indeed of the great fortunes which have been accumulated are restricted in the scope of their activities to one State. The moment they go out of the State they become subject to the interstate commerce law of the Constitution and hence are susceptible to government regulation. It appears that a liberal interpretation of this clause will be a much more effective lever for public weal than any government ownership scheme could possibly be.

* * *

CAR CLEANING.

The subject for discussion before the New York Railroad Club at the October 19 meeting was a paper on car cleaning read by Mr. B. P. Flory, mechanical engineer of the Central R. R. of New Jersey. It was descriptive of the vacuum system of car cleaning in use at the Jersey City terminal of this road. It is a somewhat curious fact that up to within a few years the improved method in general use for cleaning cars was the so-called pneumatic system, using compressed air for blowing the dust out of the cushions, carpets, etc. While the advantages of the "sucking" or vacuum system were obvious, no one seemed to have the courage to try it, chiefly on account of the difficulty of getting rid of the debris so that it could not be carried over into the vacuum pumps, etc. The compressed air system has the great disadvantage of merely displacing the dust, and if cleaning is carried on within a car the dirt simply changes position and settles on the other interior parts of the car. The advantage of the vacuum system is that the material is not only displaced, but is carried away through a hose and disposed of without any annoyance. It is not very much more rapid in operation, but obviously much more hygienic, all germs being whisked away where they can no longer be a source of trouble. Mr. Flory said that the plant installed at the Jersey City terminal for cleaning the cars and station has been in operation now about two years and the first cost was about $18,000. This includes the cost of two double-acting steam pumps of 20 H.P. each and a pipe system with distributing outlets in the coach cleaning yards, etc. A vacuum measured by about 14 inches of mercury is the usual working force. His conclusions are that the vacuum system is more economical of power; the cost for labor is reduced; all dust is absolutely removed from the seats, back, and carpets; the varnish is not injured by having particles of dust or cinders blown against it, it keeps the equipment in better shape; and the cars can be cleaned quicker and turned in less time than with compressed air.

AUTOMOBILE FINE SCREW THREADS.

We give publicity to the newly adopted thread standard of the Association of Licensed Automobile Manufacturers, the details of the standard forming the subject matter of the article on page 148 and of the current supplement. It will be noticed that the pitch of the threads of the various screw diameters is considerably finer than that of the Navy, United States or Sellers standard, as it is variably called. For example, the pitch for a ¾-inch screw is 16 threads per inch instead of 10, and about the same proportion holds with all the screws from ¼ inch to 1 inch diameter, inclusive; the number of threads per inch being increased by about 50 per cent on the average.

The needs of the automobile, especially that of the racing type, undoubtedly require a finer pitch screw than the present American screw standard. This feature is one thing that has made for the superiority of the foreign machines, their builders having generally used screws much finer than our standard pitches and thus much less likely to be jarred loose. The Association of Licensed Automobile Manufacturers recognized the condition and adopted the present standard which, in itself, is commendable but somewhat hasty. In giving publicity to it, we do not indorse it, except that we also recognize the need for the finer pitches, not only on automobile construction but certain other machinery as well. We believe it is unfortunate that this move should have been made without a more common indorsement which would have given it a better standing and have paved the way for its general adoption as another standard alongside of the present United States standard. The adoption of a new standard of screws should only have been made after careful consideration and consultation with men whose opinions have weight. How much of this was done we do not know, but it comes as a surprise to most people outside of the automobile business.

It might be said that we had just arrived at the stage of having standard screw threads. The general adoption of United States standard thread brought order out of chaos and was perhaps one of the greatest moves for advancement in machine construction ever made, as it tended toward interchangeability. Now, if the manufacturers of special products, such as automobiles, etc., are to feel free to adopt new standards which seem to them better suited to their peculiar requirements, it will be only a question of a few years when we shall again in a measure be in the confused state as regards screw threads that marked manufacturing before the present era.

The United States standard screw threads are admirably adapted to the needs of heavy work, such as bridges, buildings, cars, locomotives, etc., being easily manufactured and not readily bruised and damaged by rough handling. The needs of the automobile, of course, are quite different. Not only are the parts relatively smaller, but, being made of finer material, much stronger. Better workmanship permits the use of finer screw pitches, and the extreme vibration incident to high speeds undoubtedly requires a system different from that of the United States standard. While some agitation has already been made toward the adoption of a finer system of threads it has not materialized into anything definite. Perhaps this radical departure will bring matters to a focus and result in giving us an authoritative standard of finer pitches adapted to special machinery, either as an indorsement of the one in discussion or of some other—it does not matter particularly so long as it meets the wants and is generally recognized. It is to be hoped that something of this nature will be the result.

* * *

A GROWING OPPORTUNITY.

When the young man is casting about for a profitable and congenial business to which to devote himself for life, if his inclinations lead him toward the realm of engineering, he cannot but feel somewhat disheartened by the state of this profession at the present time. There are scores of engineering schools in the country attended by thousands of students, great numbers of whom are graduated each year. It is truly said that there is a great demand for these graduates on the part of engineering firms in various lines, but this demand is for young men who are willing to work for long hours at small wages for the sake of gaining "practical experience." The upward steps from these positions are difficult and the openings leading to the ascent are few. Besides, the salaries obtained by even the best engineers are not commensurate, so at least it seems to the young man, with the time and study and money which he has expended on his education. Especially is this so when compared with the harvest reaped by the financial managers and the members of the selling organization in great industrial undertakings. The expert in salesmanship, the man who obtains the big contracts and brings in business, is the one who up to this time has been the most valued member of the salaried organization.

It is not safe, however, to consider this as a permanent condition. While this field is an attractive one at present, the increasing growth of the idea of combination and community of interest is bound to lessen competition more and more as time goes on, and competition is the only factor which makes it possible for the selling agent to receive the abnormal rewards which he now enjoys. Considered from a purely abstract standpoint, indeed, this condition does not seem to be a stable one. The salesman's business is an economic waste, so far as the country at large is concerned, in the sense that he does not add to the wealth of the country an amount corresponding to the value he receives for closing his large contracts. He merely diverts business from one channel to another. The consumer is therefore compelled to pay something more than the intrinsic value of his purchase for the privilege of having his order subjected to the fierce rivalry which has hitherto characterized the industrial world.

With the partial decadence, at least, of the importance of the selling end of the business, more and more will appear the necessity for reducing the cost of production to the lowest possible point. Competition in the future will largely be waged in the work shop and factory instead of in the city offices of manufacturing firms. This condition is one that must, in the nature of things, call increasingly for men skilled in the art of production at a minimum cost, who can get the most possible out of men and machines without unduly distressing either. This is the most attractive opening for the intelligent, energetic young man of to-day. The steps that he should take to perfect himself in the art of management cannot be definitely laid down. Each one will have to search them out for himself. A technical education will be no hindrance and should be of great help, not only from the greater knowledge of scientific principles which it gives, but also in the training given in expressing one's ideas in handwriting and in speech and in the broadening influence of contact with numbers of other men with similar aims in life. But a technical training is not absolutely necessary. The works manager has to make large use of the brains of others when it comes to solving engineering problems, and will give up his own time mostly to questions of organization and administration. This can best be learned by actual practice in the art. The steps to be followed are the old-fashioned ones from the ranks of the workmen up through the petty foremanships to the higher positions of responsibility. He must consider, however, unlike the ordinary foreman, that he is studying and striving to master a definite and complicated science—a science of which something has been written and concerning which some experimental work has been done, but which is in the main a region whose prominences are unmapped and whose routes of travel are undetermined and unmarked.

The typical manager of the past, like the old-fashioned engineer, attained his eminence through unusual and fortuitous natural endowment. The efficient manager of the future, like the engineer of the present, will depend for his success on accurate analysis of the conditions with which he is confronted, and carefully considered and executed plans for accomplishing the results he desires. This is the field which to-day presents the most inviting opportunities in the mechanical world. As to how it shall be entered, each one must determine for himself. There are few places where one can serve a definite apprenticeship in the art, and no college has yet added the study of the science to its curriculum.

ENGINEERING REVIEW.

CURRENT EVENTS, TECHNICAL AND MECHANICAL—LEADING ARTICLES OF THE MONTH.

The Mechanical World states that a new alloy for turbine blades, containing 80 per cent copper and 20 per cent nickel, has been found to be the most satisfactory metal for the purpose as yet discovered. Of the alloys formerly used those containing zinc are said to be extremely unreliable at high temperatures, particularly when used with superheated steam.

A new German process of case hardening is claimed to give results superior to any hitherto obtained. It is said that a piece weighing 400 pounds can be hardened 0.040 inch deep, and so hard that no steel will cut it, though it may be welded. The work to be hardened is heated in bone dust powder to which is added ¾ pound of yellow prussiate, ½ pound of cyanide of potassium, and one pound of phosphorus. It is heated to a very high temperature in a closed box.

Lead wool, made in Germany, is used principally for caulking pipes, the joint being filled cold against a backing of hemp or tarred yarn. It is considered a good substitute for melted lead in making joints for hub and spigot cast iron gas mains. This "blei-wolle" is lead which has been shredded to about the size of heavy thread, collected into bundles of convenient length and of a size in proportion to the joint to be filled, twisted somewhat.—*Mining Reporter.*

Pure copper cannot be cast in sand without considerable difficulty; in fact, some deoxidizer is always used. For common copper castings from 2 to 5 per cent zinc is generally added to get sound castings; but for electrical work this is useless. The only way to get good electrical castings is to melt pure electrolytic copper in a plumbago crucible under a thick layer of charcoal. When thoroughly melted add 2 per cent silicon copper and stir it in with a stick and cast as soon as ready. Practical experience alone will show the correct temperature for casting copper in sand molds, and the proper temperature of the sand. It must not be cast boiling, but a fairly high temperature is necessary.—*Metal Industry.*

The *Maschinen- and Metallindustrie-Zeitung* has made calculations to the effect that a grown person receives through his food an amount of heat equivalent to about 12,000 or 14,000 B. T. U. a day. Only 1,200 B. T. U. are during an eight-hour day transformed into work, and the exertion of a man under these circumstances is equivalent to 0.08 H. P. Granting these figures to be correct, it is further stated that the efficiency of the steam-engine, the cost of its running being compared with the wages paid for labor, is 150 times greater than that of human exertion. No wonder then that we try to replace the brute force of man with motors of all descriptions wherever possible, and rather use the mental powers of man which no machine has as yet been able to replace.

A German manufacturer, Mr. Julius Pintsch, of Berlin, has made a number of experiments in order to ascertain the comparative durability of various metals when exposed to the heated exhaust gases from internal combustion engines. The experiments indicate that bronze and copper are least adapted to endure exposure; nickel and brass are possessed of more enduring qualities, while machine steel, nickel steel and cast iron show little depreciation from exposure. Cast iron stood the test far better when not finished, but even finished cast iron proved to be well suited for exposure of this character. The exhaust gases in the experiments referred to had a temperature of 700 degrees F. So high a temperature, of course, is not necessary for the exhaust gases if the machine is provided with a proper provision for cooling off the cylinder walls.

United States Consul Griffith, of Liverpool, has sent to Washington a brief note concerning an automatic train stop which has been in use at one or more places on the North Staffordshire Railway for two years. The apparatus, devised by Mr. T. E. R. Phillips, of Liverpool, consists of a "tripper" fixed on the sleepers between the rails which, when a signal is in the stop position, actuates a visual and an audible signal in the locomotive cab. The apparatus is also designed to apply the brakes. A great number of similar devices have been patented, but have not proved successful. One fault common to a large number is that the inventors have not considered the inertia of parts suddenly moved from a state of rest to a velocity of, say, 88 feet per second, and this is what happens to a "tripper" when struck by a train running a mile a minute.

The uses of bismuth are fairly numerous, and recently the German and French governments adopted this metal in place of lead for the cores of rifle bullets. The alloys of bismuth with lead and tin are well known for their easy fusibility and their property of expanding on solidification. Their fusibility can be increased by adding cadmium. Usually alloys contain from 20 to 50 per cent bismuth, 25 to 50 per cent lead, 4 to 20 per cent tin, and occasionally a little cadmium. There has been further research work on copper-bismuth alloys to determine their physical characteristics and to decide what percentage of each metal will make the best eutectic mixture. The structure of copper alloys containing 98 per cent or more bismuth resembles pure bismuth. Alloys generally are valued by the market conditions of their constituent metals.—*Mining Reporter.*

It appears that the Kjellin electric furnace for the production of steel has developed beyond the stage of mere experimenting, as this method is now reported to be far enough developed for utilization on a large scale in Sweden. The immense water power at Trollhattan will be utilized for this purpose and the Swedish government, which controls this water power, is expected to give the necessary permits to the exploiting company. The promoters expect to build a steel mill for producing at least 500,000 tons of steel annually, and at least one mill of the same size is expected to be erected in another part of the country. The extensive iron ore deposits in the northern part of the country will furnish all the raw material necessary. The Krupp Works are reported to have acquired the Kjellin patents for Germany and will erect large mills for their utilization.

William Marriott, an English civil engineer, makes a very interesting statement in the London *Times Supplement* regarding what has been called the "growth of iron." He asserts that during an experience of more than thirty years he has become convinced that iron increases in volume through continued heating and cooling. Mr. Marriott writes: "Rails that have fitted swing bridges with plenty of clearance have had to be shortened repeatedly year after year, and only recently I have known an instance of a swing bridge which had been open for half an hour that could not be put back until some of the ironwork had been reduced. The bridge had been built for some thirteen years and had been opened and closed during that time many hundreds of times. There is little doubt in my mind that iron heated and cooled alternately does permanently lengthen."

On September 30 the first run with a heavy electric train was made on the New York Central R.R. from Highbridge to the Grand Central Station. About November 10 it is expected to have electric engines running regularly between the Grand Central Station and Highbridge. The smoke nuisance in the tunnel will, however, not be fully eliminated for some months, as the electrification of the New York, New Haven & Hartford R.R. is not yet far enough advanced to permit steam to be abandoned on this line. Enough has already been accomplished, however, to remedy the disagreeable features of the entrance to New York by way of the tunnel, and to indicate that marked improvement in suburban traffic accommodations

will follow the completion of the undertaking. The first trip through the tunnel was made with open windows without annoyance, except from the small amount of gas left in the tunnel from preceding trains.

In establishments expecting to produce a uniformity in their output, estimating the heat of a piece of steel by the color is no more considered safe. No two men will agree as to the color of a piece in any one fire or bath. The same temperature will be differently estimated in different parts of the shop or at different times of the year or day, according to the light, and no two kinds of steel will show the same color for the same temperature. For these reasons the eye cannot be depended upon. There are, however, means for measuring temperatures used by manufacturers of fine porcelain which undoubtedly would be valuable to steel workers to enable them to ascertain with certainty the temperature in a furnace. The method consists in the use of porcelain or clay cones of various melting or softening points. Sixty different grades exist, each stamped with a number corresponding to the different temperatures at which the cones will collapse. The range of these temperatures is between 1,094 to 3,522 degrees F.—*Scientific American.*

According to the *English Mechanic and World of Science,* Messrs. Siemens and Halske, of Berlin, Germany, have recently patented an alloy which is especially suited for use as a bearing metal. They state that it is superior to the usual white metal in that it is very easily worked and particularly easily turned, that it fills up the mold completely when cast, that it possesses relatively great hardness, and, what is most important, that it has an extremely small coefficient of friction. The alloy is made by melting together approximately equal parts of cadmium and zinc, with an addition of a small proportion of antimony. The alloy can, for example, consist of 45-50 parts of cadmium, 45-50 parts of zinc, and up to 10 parts of antimony. The antimony added should not exceed 10 per cent, as otherwise the metal is too brittle. A very suitable proportion of antimony is 5 per cent. If the proportion of cadmium and zinc is considerably varied, the coefficient of friction increases, and the other good properties of the alloy are essentially prejudiced.

As a result of tests made on an experimental steel coach, the Pennsylvania Railroad has decided that all its future passenger equipment shall be made of steel. The necessity for providing non-collapsible and absolutely fireproof passenger cars for the Hudson River tunnel has led to this decision. The experimental car, it is stated, could stand any load or any collision. Its hidden frame is like a cantilever bridge, suspended on the trucks as piers, insuring safety against telescoping. The car weighs 103,550 pounds, against 84,500 pounds for the standard wooden coach; but it is found that the added weight very greatly reduces the vibration and adds to the comfort of the passengers. The decision now arrived at means that there must be rapidly constructed 1,000 fireproof cars, to be ready when the tunnel is completed. The Pullman Co. has also decided to build a steel sleeper which weighs some 25 per cent more than the standard wooden coach. The frame is of cantilever construction similar to a bridge and the flooring of the car and platform is of imitation stone spread on steel plates. Doors are of steel plate filled with cork to prevent noise, and the roof is of composite boards covered with copper sheathing, the inside lining being of composite boards covered with fireproof paint.

An explosive, which cost only one-tenth as much as dynamite, was experimented with at the Simplon tunnel, but had to be abandoned because of a peculiar disadvantage. As described by M. Jacquier, in the *Annales des Ponts et Chaussées,* it was made by soaking meal or powdered charcoal in liquid air or liquid oxygen, the powdered carbon being first packed into a case made of stout paper and covered with an asbestos wad, through which passed a paper tube to the bottom of the cartridge. Just before firing, the liquid air was poured in, and the firing was done by means of a fulminate cap as usual. Not over ten minutes should be allowed to elapse after filling before firing the cartridge, as the liquid air is gradually evaporating, and at the end of half an hour has completely disappeared. From this results one of the great advantages of the explosive, namely, that if it should miss fire, it is only necessary to wait awhile and there will be no danger whatever to the men. The dynamite used in the construction of this tunnel cost $27.50 per lineal yard of single tunnel; therefore this new explosive would have effected a great saving if it had been possible to use it. The reason why it could not be used was that it produced such great quantities of carbon monoxide (CO), that the atmosphere in the tunnel became very injurious to the workmen.—*English Mechanic and World of Science.*

ALCOHOL FROM CORNCOBS.

The Department of Agriculture is developing a new industry in the production of alcohol from corncobs, which, the department says, promises to be of much commercial value. Investigations are being made at Hoopeston, Ill., and have proved that the large quantities of corncobs which every year go to waste can be made to produce alcohol in sufficient quantities to justify the erection of a distilling plant in connection with a corn cannery. So far the department has succeeded by simple methods of fermentation in getting a yield of 11 gallons of alcohol from a ton of green cobs, and by similar methods in getting 6 gallons of alcohol from a ton of green cornstalks. A department official says that these tests show that there are 240 pounds of fermentable substance in a ton of green field cornstalks, which will yield about half of its weight in absolute alcohol. In round numbers a ton of stalks will produce 100 pounds of alcohol or 200 pounds of proof spirits. As a gallon of alcohol weighs nearly 7 pounds, there should be 15 gallons of alcohol in a ton of stalks. The addition of the corn on the cob adds further to the possibilities of alcohol obtainable from a ton of cobs, and will have its influence in bringing the quantity to a greater figure.—*Horseless Age.*

TURBO-BLOWERS.

In a paper recently presented at a meeting of the British Association for the Advancement of Science by Gerald Stoney, on the subject of "Recent Advances in Steam Turbines—Land and Marine," the author described the development of the steam turbine for driving rotary air compressors of the turbine type, which are now being used largely for blowing blast furnaces. The advantages gained are light weight, small foundation, small consumption of oil and above all, high economy of steam over the reciprocating types of blowing engines. The outfits described are generally for about 20,000 cubic feet of free air per minute, and a pressure of ten to fifteen pounds per square inch. A slightly different type is made for about 30,000 cubic feet per minute, at about one pound per square inch pressure. These blowing equipments are being used in several large iron works for dealing with the waste gases from furnaces and for driving these gases through the recovering plant, etc., an important feature being that they do not clog with tar and other matters. Since it is nearly impossible to use economically low-pressure steam at about atmospheric pressure in a reciprocating engine, the exhaust steam turbine becomes an important factor in those cases where there are non-condensing engines and other sources of exhaust steam.

WIND MOTOR FOR ELECTRIC LIGHT AND POWER STATION.

While wind power has never been very extensively used in this country (excepting in the prairie regions of the West), some European countries (and among them Holland in particular) have made use of this cheap power to a very great extent. The wind motor, however, has been used only for such purposes where a certain and constant amount of power was not a necessary condition, and where the variations in speed did not in any way interfere with the working of the driven machinery. In some cases there have been attempts made to provide the wind motors with devices which would

permit the driven machines to run at constant speeds no matter what be the speed of the wind motor itself. But even such devices could, of course, not eliminate the uncertainty of the amount of power. Of so much greater interest is therefore the report that a wind motor has been in successful operation for two years, furnishing the required power for an electric light and power plant in the small town Arkow, in Denmark. When using the wind motor for such a purpose some other kind of a motor must, of course, be kept in preparation for emergency cases. Even so, however, is the proposition of using the wind power a particularly economical one, as has been proven by this electric plant, which pays a net profit on the investment of 12.5 per cent. Regarding the efficiency of this particular motor the *Zeitschrift des Osterreichischen Ingenieur und Architekten-Vereines* states that with a wind velocity of 20 feet per second each 60 square feet of blade surface will generate 1 H. P., out of which 86 per cent will reach the electric generators.

HOLDING POWER OF RAILROAD SPIKES.

The Forest Service of the United States Department of Agriculture has completed a series of tests to determine the holding power of different forms of railroad spikes. The tests were made on ordinary commercial ties of loblolly pine, oak, chestnut, and other woods. The spikes used were of four kinds: common driven spikes, a driven spike which has about the same form as the common spike with a lengthwise channel on the side away from the rail; screw spikes of the American type; and screw spikes similar to those in use on European railroads, and differing from the American spike mainly in the manner of finishing the thread under the head.

The common and the channeled spikes were driven into the ties in the usual manner to the depth of five inches. A hole of the same diameter as the spike at the base of the thread was bored for the screw spikes, which were then screwed down to the same depth as the driven spikes. The ties were then placed in the testing machine and the force required to pull each spike was recorded.

The average force required to pull common spikes varies from 7,000 pounds in white oak, to 3,600 pounds in loblolly pine, and 3,000 pounds in chestnut. The holding power of the channeled spike is somewhat greater. For example, about 11 per cent more force, or 4,000 pounds is required to pull it from the loblolly pine tie. The two forms of screw spikes have about the same holding power, ranging from 13,000 pounds in white oak, to 9,400 pounds in chestnut, and 7,700 pounds in loblolly pine.

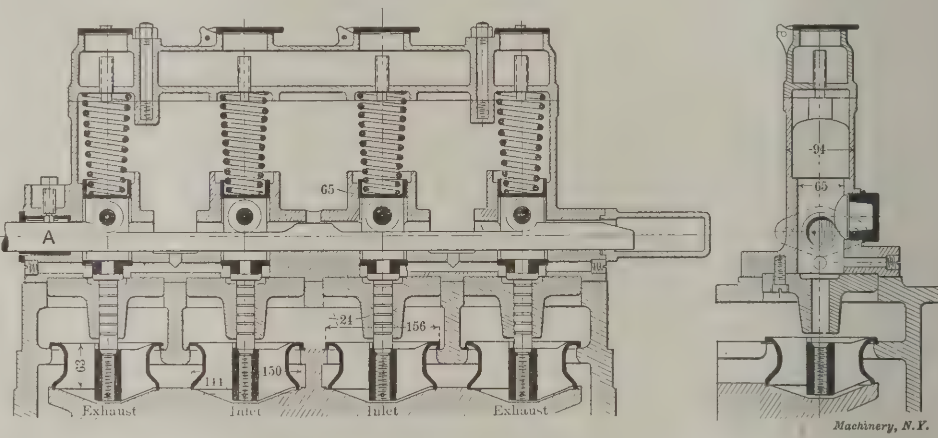
There is a marked difference between the behavior of driven and screwed spikes in knots and in clear wood. Knots are brittle and lack elasticity, so driven spikes do not hold as well in them as in clear wood. In the case of common spikes in loblolly pine the decrease of holding power in knots is as great as 25 per cent. On the other hand, screw spikes tend to pull out the whole knot which they penetrate. This increases the resistance so much that in lobololly pine the increase of holding power of screw spikes in knots is about 35 per cent over that for clear wood.

USE OF GRAPHITE TO PREVENT CREAKING.

Graphite has other lubricating uses besides its application to running journals. It is used with good results to overcome the fiendish propensity of car windows to stick, and according to *Graphite* it has been used with marked success to overcome the creaking and cracking noises made by poorly built cars when rounding curves and running over uneven track. An instance is given of a private car which had given much trouble from noise of this character. It was entirely rebuilt and all joints and seams were thoroughly covered with graphite before being put together. The result was that the creaking was entirely eliminated. Of course part of this might have been due to the improved condition of support and construction, but there is no doubt that graphite in places like this would allow the parts to move upon each other with greatly lessened friction and this means less noise and distress.

LOCOMOTIVES WITH POPPET VALVES.

The use of superheated steam in locomotives has not made any great headway owing to the fact that it does not work well with slide or piston valves. To overcome this difficulty, the Hanover Locomotive Works, in Hanover, Germany, about a year ago reconstructed a small engine that came into the works for repairs, equipping it with poppet valves of the Lentz type. The design of these valves is shown in the two sectional elevations taken at right angles to each other in the cut. The two center valves are for the inlet, and the outside ones for the exhaust. They are actuated by the end movement of rod *A*, which is made with elevations on one side to move the valves at the proper times. The valves are held closed by means of springs which do not have to be very stiff, as the valves only weigh about 8 pounds each. Tests made of this engine in comparison with another one of the same size equipped with slide valves showed a decided saving in water and fuel, 30 per cent and 19 per cent respectively, while the durability of the valves was well demonstrated by the fact that after running 11,000 miles they were in perfect running order. The operation of the poppet valves on this trial locomotive was so satisfactory that the Hanover works have constructed a larger engine of the same type.



Poppet Valves for Locomotives.

CAST-IRON WHEELS.

The Master Car Builders' Association has adopted by letter ballot the two recommendations of the committee on cast-iron wheels increasing the thickness of the flange one-eighth of an inch and changing the coning of the tread from 1 in 25 to 1 in 20. Increasing the thickness of the flange is not a new suggestion; it was first made several years ago and then dropped because it was considered impossible to run a thicker flange through the frogs and guard rails. The American Railway Association, after an investigation of the limiting conditions of modern track, has approved the change, and there are now no objections on the grounds of safety. How much strength and durability this ⅛ inch of metal will add to cast-iron wheels is yet to be determined by laboratory tests and actual service.

The committee report, in recommending the change in the taper of the tread from 1 in 25 to 1 in 20, says: "The reason for asking for the change in the taper is due to experiments that have recently been made which indicate less flange wear and a longer life to the wheel on this account."

The comments made on taper of wheel treads by Mr. M. N. Forney in his paper on the Relation of the Wheel to the Rail, presented to the Master Car Builders' Association in 1884, are pertinent:

"The relative advantages of coned and cylindrical treads of wheels have been in dispute ever since railroads were first built. Whatever advantage may accrue from the use of coned wheels is soon lost because the cone of the treads is rapidly worn away, and the wheels become either cylindrical in form or approximate thereto."

It may be, however, that the coning has more influence than

is usually accredited to it. In the topical discussion on the allowable variation in circumferences in mating wheels, it was said that if one wheel is made 1-32 inch larger in diameter than its mate, such a wheel will not run sharp. It is probable that a pair of new wheels will act on the rails like a barrel rolling on skids; that is, so adjust themselves that they will roll on points of equal diameter, and it is evident that this will be the more easily accomplished the sharper the cone of the tread. Hence, if they are brought to bear, when new, on points of equal diameter, they have the probable advantage of being liable to wear evenly and thus be of the same diameter when they are worn to the cylindrical tread. The change suggested by the committee is a reasonable one and may do something towards the elimination of sharp flanges, but the change is so small that complete relief cannot be hoped for.—*Railroad Gazette.*

REMOVING OIL FROM EXHAUST STEAM.

Abstract from a paper read by Albert A. Cary before the American Society of Refrigerating Engineers.

Separation of oil from condensed steam has been a problem of great moment, and many methods and devices have been used to effect its removal, all of which may be classified in six divisions in the first of which baffle plates or screens are used, the exhaust steam being thrown against these surfaces and allowed to pass, while moisture and free oil cling to the plates and are separated. In the second method, the steam delivered by the engine is sent through filters, generally composed of coke or some other loose material, while in the third process the steam is exhausted from the engine through a series of pipes having their lower ends immersed in water, which is supposed to wash out the oil and allow the steam to pass to its place of exhaust. A fourth method makes provision for the steam exhausted from the engines to be projected upon the surface of a large tank of water, where the oil attaches itself to the water surface, while the steam is allowed to pass on to its point of exhaust. The fifth method allows the steam with its charge of oil to be condensed and then carried to a skimming tank, where the oil is supposed to rise to the surface of the water and float off, while the cleared water is drawn from a point some distance below the surface. In the last of all the methods purification is effected by passing the oil-charged condensed steam through various filtering mediums, such as blankets, sponges, straws, excelsior, etc., and depending upon their oil-retaining properties to clear the water of its contained oil.

Recently a new process has been devised which provides for the introduction into the water of a small percentage of a special material, the nature of which is at present a secret, which has a great affinity for oil. As this material is stirred throughout the condensed steam, it takes up the oil in the same way that blotting paper takes up ink. Tests thus far made show that the separation of oil from water by this process is absolute and complete.

Oil is present in exhaust steam in three different forms: first, as a vapor; second, in finely subdivided particles of oil; third, in the form of a coating around the small particles of condensed water existing in exhaust steam. In all of the processes of oil separation, excepting the last described, it will be seen that it may be possible to ensnare and filter out the finely divided particles of oil floating in the steam and also the minute particles of water with their oil coating, but it is difficult to take care of the vaporous portion of the oil, which has proved most troublesome to the users of such devices. When oily steam is condensed, oil is found existing in the resulting water as a free oil, little clots of which, either separately or combined, float to the surface of the water. Conceiving the idea that a substance might be obtained which would have a greater attractive force for the oil than the surface of water, the inventor of the new process discovered the material already mentioned. So effective is this material that the quantity used for oil extraction is but one-twentieth of 1 per cent of the weight of the water itself, and after being introduced into the water, it has proved so light and feathery that a little stirring causes it to diffuse itself throughout the volume of oily water. This extreme lightness and ability to diffuse itself throughout the water soon causes the material to get in contact with all of the oil, which seems to leave the water suddenly and attach itself to the material. Thus, in a few minutes the water becomes cleared and all that is needed to produce a liquid as clear as crystal is a rapid filtration of the oil and water with its contained oil-absorbing material. Samples of water obtained from various power stations and subjected to this treatment have shown no trace of oil in the filtrate when analyzed by the most delicate chemical means. The material has such a capacity for oil that it can be used several times before a new charge is required, and, further, the cost of the original material is small.—*The Engineer.*

THE ROTARY GAS ENGINE.

W. L. Chambers, in The Engineer, October, 1906.

Much on the possibilities of the gas turbine is printed in engineering magazines of the day, and it must be admitted that there are certain advantages to be gained in the use of that form of motor. At the same time there are certain obstacles in the way of its successful operation which make the turbine impracticable, at least in almost every form yet devised. Chief of these difficulties is the inability to keep the temperature of the blades below the point of oxidation, which renders them brittle and useless. Several ways of overcoming this difficulty have been suggested, but no one so far seems to have been able to surmount the mechanical obstacles presented. A little study of the faults of the common reciprocating gas engine has led the writer to the belief that there is a greater chance of success in the field of the rotary gas engine of the explosion type than in the turbine. The rotary has no greater cooling problem than the reciprocating engine, and it is quite possible to get one, two, or even three explosions per revolution, instead of one every alternate revolution, or, at best, one each revolution, as in the ordinary four-cycle and two-cycle types.

If, in the reciprocating engine, two impulses are obtained per revolution, it must be in the two-cycle, double-acting type with pump and one cylinder or two-cylinder, two-cycle, single-acting crosshead type or four-cylinder, four-cycle type. Any of these have a great multiplicity of parts and the first two are open to the serious fault of all two-cycle engines, viz., that of imperfect scavenging, which allows a large amount of burned gases, varying with the back pressure of the exhaust, to be mixed with the incoming charge. This mixture of the gases is very liable to cause back firing. In the four-cycle type nearly a fixed amount of burned gas is left in the ports, explosion chamber, etc., which as in the two-cycle is mixed with the new charge. This amounts to from one-sixteenth to one-quarter of the entire volume of the cylinder, varying with the compression. If the compression is high, the amount is less in proportion, but increases rapidly as the compression is lowered. No such trouble would be encountered in the rotary, as it could be made to scavenge almost perfectly and obtain the full benefit of a clean charge.

Even more than the turbine the rotary would reduce the size per unit of power over the common type, due to the fact that the rotor of the turbine would of necessity have to be made large to keep down the angular velocity, while the rotary could be made as compact as possible. The greatest advantage, however, of the rotary over the reciprocating engine would be, that the power of each impulse is applied constantly on the tangent; hence, the turning moment would be always equal to the pressure at any point, while in the reciprocating type the turning moment varies for small close-connected engines approximately as given in the accompanying table:

	Pressure.
Beginning of stroke	0.00
⅛ of stroke	0.444
¼ of stroke	0.668
⅜ of stroke	0.84
½ of stroke	1.00
⅝ of stroke	0.75
¾ of stroke	0.60
⅞ of stroke	0.44
Full stroke	0.00

This variation is due to the imperfection of the crank and connecting rod as a means of power transmission. The above factors coupled with the constantly varying pressure, which

falls rapidly after the beginning of the stroke, make the average turning moment only about 0.45 of the average pressure on the piston. The rest of the pressure, about 0.55, is simply lost in strains and friction.

Another advantage of the rotary over the common type is its compactness, the rotary having something like 8 to 1 the advantage in cubical space occupied, and about 3 to 1 in floor space.

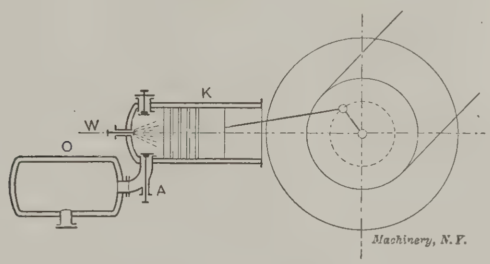
Owing to the comparatively small cylinder volumes to piston areas in some forms of rotaries, the volume of gas consumed would be, theoretically, nearly 40 per cent less than in its reciprocating competitor. In practice it would in all probability not more than equal the common types, owing to the difficulty of keeping rotary cylinders tight enough to prevent leakage without undue friction.

There is one thing in the rotary, however, that promises to be a little difficult, and this is its lubrication. But this is far from an impossible problem, although a somewhat complicated one owing to the number and location of places that require oil.

NITRIC ACID AS A GAS ENGINE BY-PRODUCT.

Cassier's Magazine, August, 1906.

One of the great chemical and economic problems is the discovery of a commercially profitable method of fixing the inert gas, nitrogen. This element is a valuable one, being used in various combinations in the arts, and having an especially broad field of usefulness as a plant food. The problem of obtaining it, however, in a form suitable for use is a very difficult one. Mr. F. E. Junge contributes to *Cassier's Magazine* a description of a process developed in Germany in which the gas engine is used as a medium for performing this highly valuable but difficult operation.



Nitric Acid as a Gas Engine By-product.

After discussing the various methods for the fixation of nitrogen it can be shown that the most available compound for this purpose is nitric oxide, which is composed of equal quantities of nitrogen and oxygen. This combination takes place at high temperature. After the gas is cooled to a low temperature it will absorb another atom of oxygen from the surrounding air, forming nitric dioxide and this will in turn dissolve in warm water to form nitric acid according to the formula:

$$2\,NO_2 + O + H_2O = 2\,HNO_3.$$

This last action is effected by spraying the water into the gaseous mixture in finely divided form. We thus, in this process, have a very simple means of making HNO_3 by the exclusive employment of water and air, both of which can be had practically without cost, and in unlimited quantities, if it only be possible to find a cheap and realiable method of making NO.

The two constituents of this substance, nitrogen and oxygen, are both present in the gas engine cylinder as constituents of the air drawn in with the charge. When analyzing the exhaust gases of an ordinary gas engine it will be noted that if the engine is running very hot the exhaust shows a marked smell of nitric oxides, and it is obvious that under specially-prepared conditions this phenomenon may be made to appear regularly. At the highest temperatures, which are almost coincident with those of maximum pressure, part of the atmospheric nitrogen will combine with the surplus oxygen to form NO. To avoid decomposition of this combination the mixture must be guarded against gradually cooling down by adiabatic or other expansion—in other words, the gases must be quenched by the sudden injection of cold water. The quantity and distribution of this water injection will, therefore, determine the drop of temperature and pressure of the gases in the compressor cylinder, whence they are allowed to escape through a valve into an exhaust vessel, where they are mixed with water and air to produce first NO_2 and then HNO_3, according to the formula given above. The accompanying cut shows diagrammatically the apparatus employed, *K* being the cylinder of the gas engine, *W* the water inlet valve for quickly cooling the nitric oxide, while *A* is the exhaust valve leading into the chamber *O* where the nitric acid is formed.

The questions that naturally arise when studying this process are, first. the time or duration of high temperatures sufficient to produce NO in such quantities as will make the process an economical one; and second, whether the energy absorbed as negative work for carrying out the mechanical process of compression and the establishment of high pressures is low enough to be a negligible quantity in the commercial application of the invention. Herr Häusser, who described the process before a branch of the Society of German Engineers at Kaiserslautern, produced evidence tending to show that neither of these were of sufficient importance to make the process an unprofitable one. An attractive feature of the invention and one that is likely to hasten its industrial exploitation lies in the fact that the principle underlying it is extremely simple and can be carried out by almost any owner of a gas engine without increasing the initial cost, operating expenses, floor space, or complexity of the plant in any but a very small degree. The amount of power produced from a given engine with a given amount of fuel is of course reduced, but it is claimed that the value of the nitric acid generated exceeds the cost of the power lost to such an extent as to make it seem that the process stands on a sound commercial basis, as far as Continental conditions, at least, are concerned.

THE BEGINNING OF MECHANICAL VENTILATION AND HEATING.

Compiled in part from an article by R. T. Crane in the Valve World.

The history of heating and ventilating engineering in this country commences with Joseph Nason, who, upon his return from England in the latter part of 1842, began the introduction into this country of the Perkins system of hot-water heating, with which Mr. Nason was thoroughly familiar, having been for some years, while in England, in the employ of Mr. Perkins. In 1846 a radical departure in the method of heating—in this country at least—was made by the warming of the Boston custom house by means of mechanical propulsion of air. A large coil of ¾-inch pipe was massed in the basement, and from it to the several registers were run ducts of sufficient capacity to carry the warmed air. This plan of warming, while not new in France, was entirely novel in this country, and was the beginning of all subsequent systems in which fans were employed for distributing air. The fact that this plan of warming had already been employed in France does not detract from the credit due to Mr. Nason, as there is no evidence that while abroad he went to France, and it is highly probable that he was not familiar with the progress that had been made in that country. In 1855, in which year extensive alterations of and additions to the United States Capitol at Washington were in progress, Mr. Nason, at the request of General Meigs, then in charge there, went to Washington and planned a system of ventilating and heating for the Capitol. This was the first really scientific and complete job of the kind done in this country. Mr. Nason, as this job at the Capitol shows, had a thorough knowledge of the business, as it was then well known, and was at the time unquestionably the best informed and most experienced person on heating and ventilating in the United States.

The apparatus installed under Mr. Nason's direction consisted primarily of a heating surface of wrought-iron pipe, over which air was forced by means of two specially designed centrifugal fans, and conducted through ducts to the rooms to be heated and ventilated. This plan of having a large amount of heating surface located in one place and the air blown through it, the heated air being then conducted to such

places as it was needed, was for some years the favorite mode of heating. Some years after, a job of this kind was put in the new post office at Washington. It was also placed in several insane asylums.

In the late fifties B. F. Sturtevant began his work in Boston, which eventually led to his building up the largest blower business in the world. In the course of ten years he developed the blower and its uses to such an extent that it became a recognized factor in satisfactory ventilation. He replaced the United States Capitol fans with others of more modern design, and about 1870 entered the market with a unit combination of fan and steam heater. From the somewhat crude design of that day has been evolved the present type of fan blower heating apparatus to be found in every important public building and in thousands of industrial plants throughout the world.

BRIQUETTING TESTS OF THE FUEL-TESTING PLANT OF THE UNITED STATES GEOLOGICAL SURVEY.

The United States Geological Survey has conducted a number of tests on the briquetting of fuel at its fuel-testing plant, St. Louis. The results of these tests are summarized in a preliminary report recently issued. In the making of coal briquettes, the binding work is best performed when the particles of coal are coated and the void spaces are filled with binding material. This is best accomplished when the temperature of the mixture before compression is raised sufficiently to liquefy or vaporize the binder. The relation between the coal and the binder seems to be physical rather than chemical. The more important requisites of a suitable binding material for briquettes are as follows:

1. It must be inexpensive because of the small difference in the United States between the prices of slack or fine coal and those of lump coal. 2. It should be capable of abundant production in different parts of the country to avoid the necessity of long transportation. 3. It should be of such character as to make it easily handled and applicable at working temperatures. If used in solid condition, as in the case of pitch, the melting point should not be lower than the temperature of hot summer days nor ordinarily above that of live steam. 4. It should hold the briquette together strongly, not only during ordinary handling and transportation, but also during protracted exposure to weather and while burning. 5. The binder should not add appreciably to the ash of the coal, nor increase the clinker formation in the ash. It should not give off fumes, nor seriously increase the smoke in burning the briquettes. 6. The binding material should increase, or certainly should not decrease, the heating quality of the coal which is used in the manufacture of briquettes.

The condition which more than any other has prevented the development of the briquetting industry in this country is the low price of bituminous coal and especially the small difference between the price of the lump coal and that of the slack, or fine coal.

The high cost of the pitch which is generally used as a binding material is also one of the barriers existing in the way of the development of this industry. One of the purposes of the present investigation is to discover, if possible, some cheaper binding material, and the outlook in that direction is encouraging. The cost of manufacturing briquettes in France, Germany, Belgium, and England, including all necessary items except that of the coal and binding material, is estimated to range from 25 to 50 cents per ton, varying with the local conditions. Where pitch is used as a binder, as is almost universally the case in each of these countries, its cost for a ton of briquettes may be said to range from 50 to 80 cents. How far this cost may be reduced by the use on a commercial scale of cheaper binders remains to be seen. The most favorable outlook for the development of this industry in the United States is in connection with the use of briquettes in locomotives and in domestic furnaces and stoves. It can hardly be expected that, at anything approximating existing prices, briquettes can be manufactured for successful use in the ordinary power-plant furnaces of the country.

The briquettes experimented with weigh about 3½ pounds, and were made of such a size as would most nearly fulfill the requirements of stationary and locomotive boiler practice.

In the laboratory investigations, various substances were tested as binding materials in the manufacture of briquettes, both as to the possibility of their being used with the different varieties of bituminous coal and as to the percentage of each binder yielding the best results with each coal. These investigations related not only to the nature and the amount of the binder necessary for making satisfactory briquettes with each of the several coals tested, but also to the extent to which the binding quality of certain of these materials might be improved by the admixture of another binding material or another variety of coal.

The binders may be divided into two general classes—inorganic and organic. The former comprised clay, lime, magnesia, magnesia cement (magnesium oxide and magnesium chloride), plaster of Paris, Portland cement, natural cement, slag cement, and water glass. The organic binders consisted of wood products, sugar factory residues, starch, slaughter house refuse, tars and pitches from coal, natural asphalts and petroleum products.

The use of inorganic binding materials, such as those mentioned above, is not likely to prove practicable.

The use of clay, lime, and cements as binding materials was found entirely unsatisfactory, for the reason that they add largely to the ash constituent of the briquette. The briquettes made with these materials as bond went to pieces on exposure to water and weather, and their waterproofing, by soaking in oils, etc., was found difficult and expensive. In the tests with plaster of Paris, from 2 to 12 per cent of this material being used as a binder, the briquettes made were hard but brittle, and quickly disintegrated on exposure to moisture. None of the sugar-factory residues, namely, beet pulp, lime cake, beet-sugar molasses, and cane-sugar molasses, were considered satisfactory as binding materials for the reason that the briquettes made with them disintegrate on exposure to the weather, and no inexpensive waterproofing has as yet proved satisfactory on a commercial scale. Nor were any of the wood products, including rosin, pitch, pine-wood tar, hard-wood tar, Douglas fir tar, wood pulp, and sulphite liquor from paper mills when used alone regarded as satisfactory, though some of these materials used in combination with other binders gave results of some promise, and deserve further investigation.

The test made in which 0.5 to 3 per cent of starch was used as a binding material with different coals gave briquettes which were strong, burned smokelessly and held together in the fire until completely consumed. These briquettes, however, went to pieces when wet or exposed to the weather for a considerable time. Experiments as to the possibility of cheaply waterproofing these briquettes were sufficiently successful to warrant investigation in this direction.

Slaughter house refuse proved unsatisfactory for a number of reasons.

The tests with coal tars and the different grades of pitch made from these tars indicate that probably in the pitches the most satisfactory binders for the manufacture of briquettes will be found; and that these can be made at such a price as will bring the cost of the binding material used to not more than 50 to 75 cents per ton of briquettes. In the investigation of the asphalts as binding materials, impsonite from Indian Territory was found to be rather unsatisfactory, though in a number of tests with non-coking coals the result was improved by the addition to such coal of from 5 to 10 per cent of impsonite in addition to from 3 to 5 per cent of ordinary pitch or some other binding material. From 4 to 8 per cent of gilsonite and other asphalts from Utah gave fairly satisfactory results as a binder. This material is said to exist in Utah and elsewhere in large quantities, and while the price is at present too high to permit its extensive use as a binder, doubtless should the demand for it in this connection increase the deposits would be opened up to such an extent that it might be sold at lower prices. Experiments were made with several other asphaltic materials, and though the results were such as to warrant further investigation they were not altogether satisfactory. Asphaltic tar yielded fairly good results as a waterproofing material in briquettes made with starch. Asphaltic materials yielded the best results in waterproofing.

Crude petroleums have been tested as binding materials, with satisfactory results. The asphaltic petroleums were used successfully in waterproofing briquettes made with a starch binder, though it is doubtful whether this practice would prove entirely satisfactory in operations on a commercial scale.

Water-gas tar, which is obtained from illuminating gas plants, was not tested sufficiently to give satisfactory results, but it is believed that this material could be used as a binder if properly mixed with other somewhat similar materials. It is necessary, after this material is mixed with the coal, that the mixture should be raised to a sufficiently high temperature to liquefy and perhaps even to vaporize the tar. The cost of this binder would be from 45 to 65 cents per ton of briquettes.

TEST OF THE LEA-DEGEN TWO-STAGE CENTRIFUGAL PUMP.

Report by Prof. James E. Denton, of Stevens Institute of Technology.

For about two years Messrs. Julius Degen and E. S. Lea, Trenton, N. J., have been conducting experiments and taking out patents on centrifugal pumps, with the view of increasing their efficiency and at the same time reducing the cost of manufacture. Under the present condition of manufacturing ordinary centrifugal pumps a set of patterns is required for each size of pump, which, of course, means a great number of patterns to cover the requirements of pump users. The Lea-Degen design simplifies the problem by dividing the pump casing horizontally (for the purpose of assembling and examination) and vertically in the plane of each runner for the purpose of making a pump consist of as many runner units as are required for the character of service. They have succeeded in so designing their patterns that approximately 150 sizes and capacities of pumps are produced with ten sets of patterns. An interesting feature of this pump, referred to in our July, 1905, issue, is the method employed for balancing. This will be described later on in the account of the test. The following is an account of a test made by Prof. James E. Denton, of Stevens Institute of Technology, dated July 24, 1905.

General Description of the Pump.

The general design of the pump tested is exposed by Figs. 1 and 2, which show it to consist essentially of two shrouded runners, or pump wheels, mounted on the same shaft in a double case. The case is so partitioned that the water is drawn from the source of supply and put under pressure by the first wheel, and then delivered to the suction chamber of the second wheel. The second wheel then imparts to the water the same amount of energy it receives from the first wheel, thereby increasing the pressure, and then delivers the water into a spiral discharge conduit terminating in a diverging nozzle connecting with the main pipe. The outline dimensions of the pump follow:

Diameter of suction pipe	10 inches
Diameter of discharge pipe	10 inches
Outline diameter of each wheel	24 inches
Number of blades	8

Novel Features of the Pump.

The special features of the pump which represent patented advantages are as follows:

1. The case is divided through its horizontal diameter by bolted flanges so that its top half can be quickly freed, and lifted off, without disturbing either suction or discharge connections, thereby affording easy access to the internal parts of all the stages at once.

2. By means of bolted circumferential divisions of the case, provision is made for either using the suction and discharge end of a case together as a single-stage pump, or for adding as many intermediate sections as may be necessary to afford any desired pressure at any fixed speed. Additional stages can therefore be installed after a pump has been in operation without wasting any parts of the existing case.

3. A special arrangement of double cup-leather packing is used for both the suction and discharge ends and for the intermediate sections. The cup leathers are held against a flat collar, on extended pump-wheel sleeves, in such a manner that the leathers can follow up as they or the collars are worn, or the shaft may be shifted at will in either direction, with the leathers following, without changing the location of the leather with relation to the shaft collar, thus making a practically water-tight joint at all times. A spiral spring is used, between each pair of cup leathers, to insure their seating against the collars before pressure is put on the pump. Provision is made for setting out the leather packing on the suction end of the shaft by the water pressure of the high side of the pump.

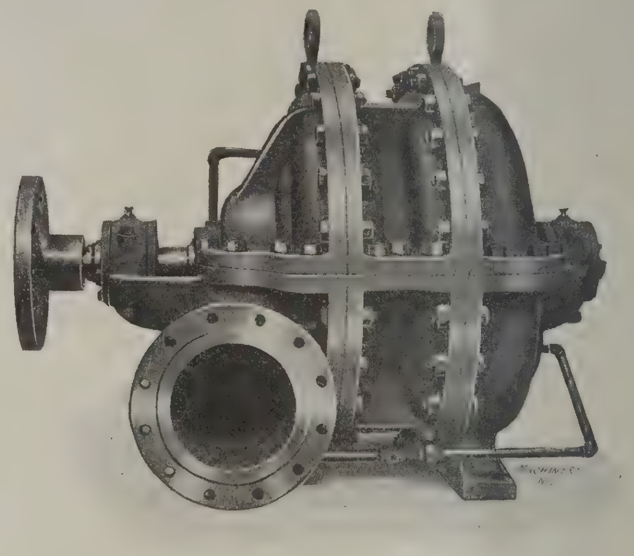


Fig. 1. Lea-Degen Centrifugal Pump. Note "Unit" Design of Shell Parts.

4. On the outside of main bearings, at each end, is placed a ball thrust-bearing, with adjusting collars, for shifting the shaft endways to balance the end-thrust of the pump runners. The balancing is accomplished by means of variation in the width of water space, on both sides of the wheels between the rim of wheel and the case. Experiment showed that as the wheel was moved laterally in the case, the pressure between the wheel and case increased on the side where the clearance was greatest, and was reduced on the opposite side.

General Description of Tests.

The pump was driven by a General Electric direct-current multipolar dynamo of 385 amperes and 220 volts' capacity used as a motor, and directly connected to the pump shaft.

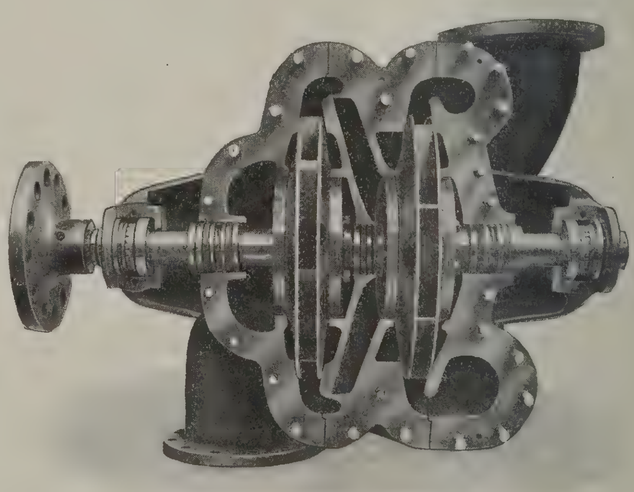

Fig. 2. Lea-Degen Centrifugal Pump, showing Runners.

It was arranged (Fig. 3) to lift water by suction, about seven feet, from a well fed from the Raritan Canal, and to deliver it through a 10-inch throttle valve, *C*, to a 6½-inch bell-shaped nozzle, *H*, to a weir tank, *M*, which was about 25 feet long by 10 feet wide and 10 feet deep, whence the water flowed through a rectangular notch 3.02 feet wide in a ¼-inch beveled iron plate, *L*, set in the middle of the end of the tank about 7 feet above the bottom.

A pitot tube, *I*, was applied under the nozzle, and its indica-

tions used as a means of quickly adjusting the discharge of pump to the several amounts of flow necessary for the tests.

The amount of water flowing was calculated from the weir height by the Francis formula:

$$Q = 3.33\ (l - 0.2\ h)\ h^{\frac{3}{2}}$$

The weir heights were taken with a hook-gage, *O*, in a barrel, *N*, communicating with the tank by a 2-inch pipe, *P*, having an open end square with the flow of water at a point 13 feet back of the notch. The surface of the water approaching the weir was made perfectly smooth by means of a grill lattice 6 feet from the discharge nozzle, and dam-boards set by trial.

The zero of the hook-gage was determined daily with a straightedge and checked by a surveyor's level. Readings of the gage could easily be made to 1-64 inch. The leakage of the weir was frequently determined. It remained practically constant at 18 gallons per minute, which was added to the quantity calculated by the weir formula.

At each speed the steps in the determination of the maximum efficiency were as follows:

The pump was primed† with the throttle valve *C* (Fig. 3) closed.

The throttle valve was then set wide open, and connection made with the mercury columns, which had been previously filled with water between the mercury and the cock connecting them to the main pipe. The speed was then adjusted by a rheostat, and the required data were observed at five-minute intervals until the average of the readings was practically constant. The throttle valve was then reset to secure a series of reduced rates of flow, which, by preliminary tests, were known to be sufficient to establish the "gallons-lift" curve (Figs. 4, 5 and 6). No data were recorded at a speed varying more than two revolutions from the assigned speed, a skilled assistant devoting his attention to this point. After the "gallons-lift" curves were secured, the pump was disconnected from the motor, and the power of the latter absorbed by a prony brake over the same range of watts applied to drive the motor during the pump tests. Thereby the "brake horsepower-watts" curves‡ (Fig. 7) were established.

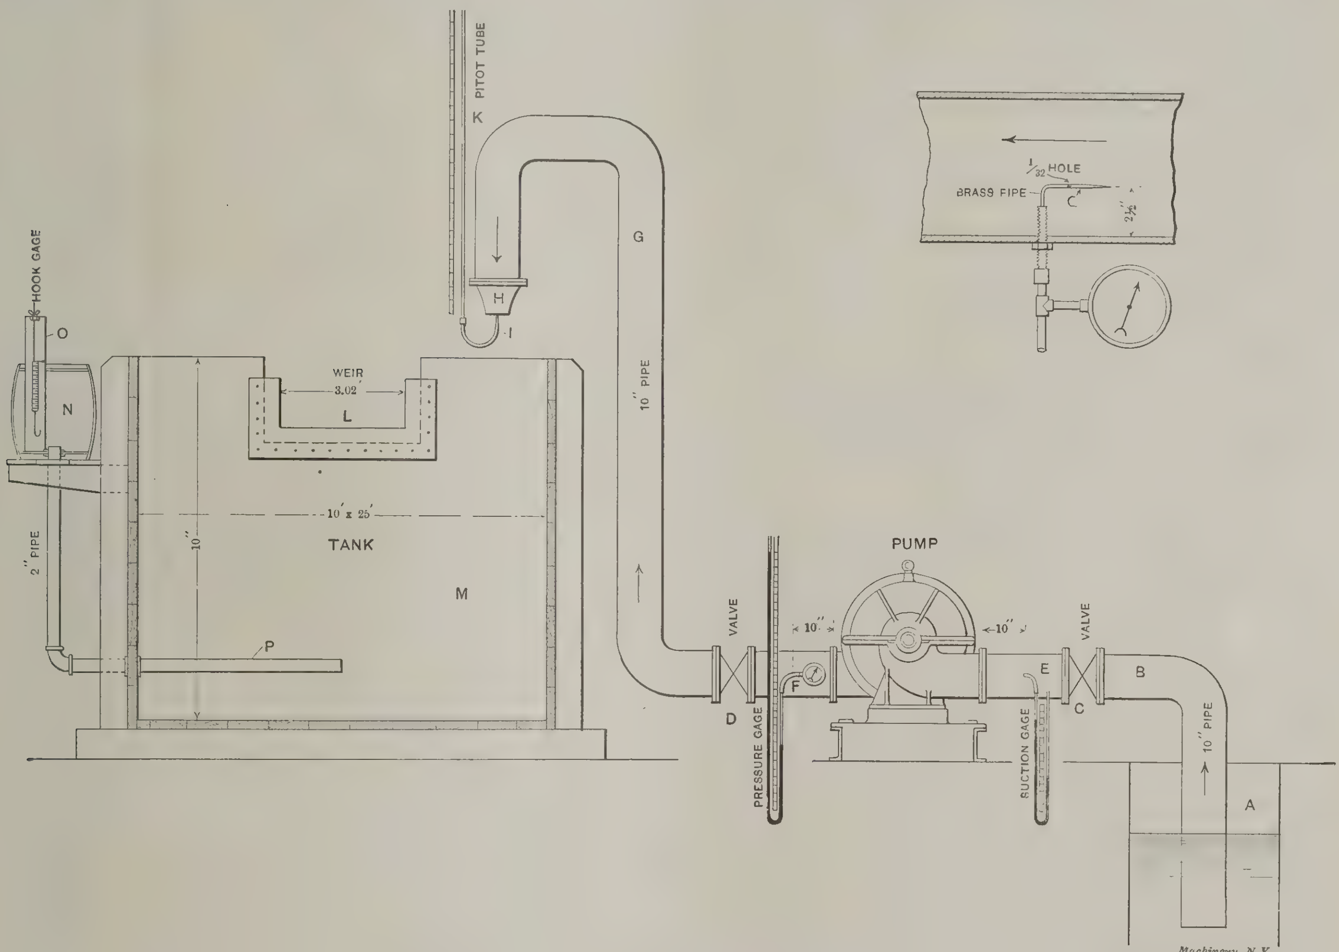

Fig. 3. Diagram of Apparatus for Testing Lea-Degen Centrifugal Pump.

The total lift of the pump was determined by adding the vacuum shown by a mercury gage, *E*, to the pressure above the atmosphere shown at *F*, the pipe diameter being the same at both points.

At *F* both a pressure gage and a mercury tube were used during most of the tests, the gage being calibrated by a Crosby testing apparatus. To secure a smooth surface in the main pipe for measuring the pressure at *E* and *F* the latter was taken through a 1-32-inch hole, *Q* (see sectional view), in the top of a ⅛-inch polished brass tube,* with a pointed closed end lying against the current.

Method of Procedure.

The pump was designed by Mr. Degen for practically equal efficiency for the range of speed between 400 and 600 revolutions per minute. Therefore, an efficiency test was made at 400, 500, and 600 revolutions, respectively.

From these curves the horsepower corresponding to the watts applied to drive the motor during the pump tests, was determined, and taken as the horsepower to drive the pump (column 6, tables 1-3).

The useful work of the pump is (column 5),

$$\text{Water horsepower} = \frac{\text{Pounds water delivered per minute} \times \text{total lift in feet}}{33{,}000} =$$

$$0.000252 \times \text{gallons per minute} \times \text{total lift in feet.}$$

The total lift is the sum of the suction vacuum (column 4), and the pressure (column 3), in front of the throttle valve, expressed in feet of water.

* The tube was located 2½ inches from the side of the pipe. Experiment showed that at the highest rate of flow there was an increase of ½ pound pressure when the 1/32-inch hole was moved from a point 3⅞ inches inside the pipe to a point ½-inch within it. The position of the tube in the pipe is not a factor in the test since it was the same at *E*, and *F*, and the velocity was equal at these points.

† The priming was done by water from the city mains acting through a 1¼ Penberthy ejector, no foot-valve being used on the suction pipe.

‡ For 400 and 500 revolutions these curves are straight lines, but at 600 revolutions, the straight line does not maintain, probably because the speed had to be regulated by changing the position of tne brushes.

0	122.08	49.80	7.04	0	22.90	0.0	....	26,880	600	0

The efficiency is then (column 11):

$$E = \frac{\text{Water horsepower}}{\text{Horsepower to drive pump}}$$

The prony brake was of the two semi-circular, solid-block type applied to a 28-inch pulley, with a 6-foot lever-arm acting on a knife-edge on a tested platform scale. It was carefully balanced, with its pulley, by mounting the whole com-

bination, with a mandrel through the pulley, on straightedges. A copious stream of water applied to a nipple in the top block, through a long vertical flexible hose, and a hand-tightening wheel, with a leverage of 1,000 to 1, enabled the highest loads to be maintained indefinitely with a very steady equipoise of the scale-beam. The electrical readings were made from a Weston instrument from the laboratory of the Stevens Institute.

The ratio of the quantity of water given by the weir to that given by the pitot tube is shown in column 8. This ratio is the value of the coefficient C in the formula for cubic feet per second.

$$Q = C \times \text{area of nozzle} \times \sqrt{2\,g \times \text{pitot head.}}$$

Conclusions.

The tests show that the pump afforded the following results under conditions of maximum efficiency:

At 400 revolutions, 77.7 per cent efficiency, with a capacity of 2,296 gallons under 43.6 feet lift.

At 500 revolutions, 77.6 per cent efficiency, with a capacity of 2,794 gallons under 67.4 feet lift.

At 600 revolutions, 77.97 per cent efficiency, with a capacity of 3,235 gallons under 100.7 feet lift.

In round numbers, therefore, the capacity at maximum efficiency is directly proportional to the revolutions, and the lift, or head, is proportional to the square of the revolutions. At each speed the efficiency averaged more than 76 per cent over a range of 600 gallons of capacity for the lower two speeds, and 900 gallons at the higher speed, the head remaining nearly constant.

Test of Effect of Altering Clearance upon the End Thrust.

Pipes tapped into the case on either side of the high wheel were connected to the two ends of a U mercury tube. With the shaft in the position in which it had been adjusted for the test, there was no difference of pressure shown by the mercury, and there was no evidence of labor in the thrust bearings for this position during the several days of operation of the pump for the tests of efficiency. When the shaft was moved 7-32 inch laterally from this position, the mercury showed an excess of pressure of ⅞ inch on the side of the wheel upon which the clearance had been increased.

[The balancing chambers on either side of the wheel are in communication with the annular discharge space surrounding the circumference of the wheel, communicating therewith by the clearance spaces referred to. If these clearance spaces are considered to be of considerable width it is clear that a pressure equal to that in the annular discharge space will exist in the balancing chambers, but if the clearance on one side of the wheel becomes smaller, owing to lateral movement of the runners, there will be a reduction of pressure on that side due to the sucking action of the jet of water emanating from the mouth of the wheel. This sucking action, therefore, will, reduce the static pressure of water in the balancing chamber on the side having the clearance reduced, or, putting it as above, the pressure will be greater on the side which has the greater clearance. The arrangement for balancing the end thrust is, therefore, not an automatic one, in the sense that the runners seek a balanced position; the shaft and runners are adjusted by hand until the end thrust is zero, and is then kept in this neutral position.—Editor.]

MACHINERY COMPETITION OF UNITED STATES AND GREAT BRITAIN.

Consular Report No. 2665.

The two great machinery-producing countries of the world are the United States and the United Kingdom. The American leadership has been in new and skillful mechanisms to save labor costs, the British in bulk of production and export. Both countries are rapidly increasing their foreign sales, as the following tables of comparison indicate, the American statistics being for the fiscal year ending June 30, 1906, which show 18 1/3 per cent increase over 1904, while the British figures of export for the first six months of 1906, show 24 1/3 per cent increase over the same months of 1904.

Great Britain does not compete with America in the trade for cash registers and typewriting machines, laundry, shoe,

AMERICAN EXPORTS, FISCAL YEAR ENDING JUNE 30.

and pumping machinery. In other lines competition between the two countries is keen. The United States exports of locomotives increased by 20 per cent from 1904 to 1906, while British exports increased 35 per cent. The most notable American increase was in the Central American States, where $37,150 worth of locomotives were sent in 1904, $60,810 in 1905, and $1,131,930 in 1906, while sales to Japan increased from $624,873 in 1904, $1,276,045 in 1905, and $1,996,398 in 1906.

* * *

TURBINE TROUBLES NOT SERIOUS.

In your issue of June, 1906, you devote some space to turbine troubles. I trust I may be pardoned for calling your attention to the prominence which you have given to certain of them. Quoting:

"The most serious trouble experienced with the Parsons turbine has been the tearing out of more or less of the blading upon occasions when the rotor and stator came into contact through some accident or otherwise."

Appearing at the beginning of this article this would lead one to the belief that the trouble was really very serious indeed, and was to be expected at any moment, a state of affairs which would not be altogether conducive to the peace of mind of a power plant manager who had to depend absolutely upon his turbines.

Now, no one will deny that blading troubles have occurred in the past and will occur now and then in the future from various causes, just as the flywheels break, connecting-rods give out, bearings get hot, cylinder heads crack, etc., in a steam engine that does not get proper attention. But it is important to bear in mind that blading troubles, while sometimes serious in themselves, are quite insignificant in proportion to the total experience that has been achieved in the turbine art.

As an example of the relative unimportance of blading trouble as compared with the breaking of similar parts in a steam engine (even so small a break as a piston ring), several cases may be cited in which a number of rows of blades have been lost while the machine was in service without being observed by the attendants and with no noticeable effect on the running of the machine. In one case blades were out for a period of several weeks without the turbine having been opened up for inspection or otherwise given more than ordinary attention. Furthermore, the effect on the capacity of the turbine is usually not felt except, of course, when the machine is operating near the limit of its capacity, which is rarely the case. As the Parsons type of turbine is a balanced machine, the rotor is always in equilibrium, the internal pressures adjusting themselves automatically, which makes

it possible to run with some blades out. The usual practice in cases of blading trouble is to temporarily remove the injured material, replace the cover and put the machine back into service until such time as repairs can conveniently be made, which is usually at night. If the work cannot be completed at one time, the machine is again assembled and continued in service until a further opportunity is available to work on it. These conditions are evidently not so "disastrous" as inexperienced opinion might lead one to think.

There is at the present time a prevalent and most unfortunate tendency to make much capital out of small troubles, and the length to which enemies of the steam turbine have gone to expose some little failing, easily corrected, is truly remarkable and often ludicrous. In instances of this kind the broadest possible view must be taken to avoid attaching undue importance to unimportant things; and the technical press can in no more effective manner demonstrate its beneficial powers than by rigorously sifting all reports savoring of undue pessimism.

Reverting again to your article, you mention the effect of vacuum in inducing heavy stresses upon the turbine casing. Now it is evident that the stresses upon a turbine casing from atmospheric pressure are quite balanced in all directions with the exception of the net area of the exhaust passages to the condenser. But the resultant downward pull is taken up directly by the turbine pedestal in either of several ways; in one, the rear footing of the turbine casing is made integral with the exhaust passage so that the excess pull exerted upon the casing is transmitted to the foundation through the rigid metallic structure at the exhaust end; in another construction the rear turbine footing is carried up as far as the main horizontal flange on the turbine casing and quite independent of the exhaust nozzle. This results in the excess pull due to vacuum being transmitted still more directly to the foundation.

As to the effect of the condenser weight, it is a more important matter to provide for variable expansion of the exhaust nozzle and connecting piping when operating on different vacua and for the possible settling of the condenser foundation. In numerous instances this has occurred, resulting in undue stress upon the turbine casing. The obvious remedy is a corrugated copper expansion joint, and on all but very large sizes of steam turbines, it is the customary practice to supply these expansion joints. It is well to remember that an installation when it is first erected may be most accurately attuned in all its parts, but how few installations of this character are gone over semi-annually, or even annually, for the purpose of checking adjustment and alignments to determine whether foundations have settled equally. Heavy stresses, often of dangerous proportions, may have developed in the interim, without giving the least external evidence.

East Pittsburg, Pa. J. R. BIBBINS.

THE A. L. A. M. STANDARD SCREWS AND NUTS.

The Association of Licensed Automobile Manufacturers some little time ago appointed a committee to investigate the subject of standard screws and nuts. These manufacturers have found, as have some other makers of high-grade machinery, that the United States or Sellers standard threads give pitches somewhat coarser than are desirable. Finer pitches have therefore been employed, each concern fixing a standard of its own. The resulting confusion has been a great annoyance to dealers, repair men, and the makers themselves, and it was to remedy this condition that the committee was appointed. Their report (of which the essential features are given in the supplement accompanying this issue of MACHINERY) has just been made public.

The shape of the thread is still that of the United States standard with straight V sides at an angle of 60 degrees, the top being flatted to one-eighth of the pitch and the bottom filled in by a like amount. The number of threads per inch has been made approximately half as many again, and the dimensions of the "hex-headed" nut, and head of bolt or "screw," as the report prefers to call it, have been made considerably smaller. The thickness of the head has also been decreased in both the case of the nut and the screw head. It has been definitely determined by experiment, however, that this thickness is amply large enough to compel the bolt or screw to fail by rupture in tension through the root of the thread just under the nut, the samples tried in no case failing by shearing of the threads, a condition which is, of course, as it should be.

A better material than that ordinarily used for screws is deemed necessary. The selection of a better material depends to a considerable extent upon the possibility of commercially machining it in screw machines, and such material has been found in several qualities of steel, having a tensile strength of not less than 100,000 pounds per square inch, and an elastic limit of 60,000 pounds per square inch, as compared with 50,000 or 60,000 pounds per square inch tensile strength and 35,000 pounds per square inch elastic limit now in common use. This material is also very much tougher, being lower in impurities and showing a very fine fracture, characteristic of a tough steel. As regards the destructive tests of tensile and shearing strength above mentioned, they were made both with ordinary material and with the material it is proposed to use for automobile work. The results were the same in both cases; that is, the screw broke at the base of the thread inside the nut.

The Association of Licensed Automobile Manufacturers, in the circular letter sent out with the report, say: "It is nothing revolutionary in any sense of the word, but, on the contrary, it conforms to the general practice of many machine tool and automobile builders. Like any new standard, it cannot be hoped that it will be adopted immediately or universally, but it is believed that it will gradually creep into use. As time goes on, it is probable that these screws will be found in stock just as the ordinary United States standard is now found. This cannot be done immediately; it must be accomplished by merit; that is, merit in this standard."

* * *

GOVERNMENT SUPERVISION OF SMALL DISTILLERIES IN GERMANY.

A consular report from Germany describes the method used by the German government in supervising the manufacture of denatured alcohol. There are some 70,000 farm distilleries in Germany and the problem of the government in supervising this immense number of small establishments would be a serious one if the same methods were followed that are used in the larger establishments. This is not done, however. The stills have to be made in a certain way, which includes a tank that can be locked with a government lock and sealed with a government seal. The small farm distilleries operate in the winter when the farmer has leisure to do something else than straight farm work. The farmer has to give the government thirty days' notice as to the time he wants to begin to operate his still. Some time during the thirty days an inspector comes along and looks the still over to see that it is clean, etc., and then he locks and seals the tank, after which the still is ready for the farmer. He may go ahead and distill until the tank is full. Then he informs the person who is to buy the alcohol from him, after which he notifies the government, and an inspector comes and removes the seal, measures the contents of the tank, and collects the revenue. If the farmer wants to denature the alcohol on the spot he can do so in the presence of an inspector, when the amount of the tax will be returned to him. But generally the farmers sell through the great central selling agencies, which denature at a central point and in large quantities, and collect the rebate from the government in considerable sums.

* * *

The year ending August 31, 1906, has been one of remarkable growth in the railroad department of the Young Men's Christian Association. Sixteen new railroad association buildings have been opened and ten other new associations have been organized, two of them among street railway men, making a total of 225. The membership is over 81,000 and there are now 149 buildings owned and occupied having a total valuation of $2,601,350. In addition sixteen other buildings are now being constructed at a cost of $538,000, and these when completed will make 165 buildings with a total valuation of $3,139,350.

MACHINERY, N.Y.

THE A. L. A. M. STANDARD SCREWS AND NUTS.—IV.

NOTES ON MATERIAL, FINISH, AND DIMENSIONS

1- Material

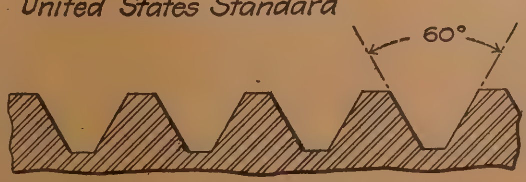
For all screws and nuts - steel,
Tensile strength, not less than 100,000 lbs. per square inch;
Elastic limit, not less than 60,000 lbs. per square inch.

2- Dimensions

All dimensions in inches.
Length of threaded portion: 1½ times body diameter.

3- Form of Thread

United States Standard



Flat top and bottom, one eighth of the pitch.

4- Finish

Screw heads shall be flat chamfered.
Plain nuts shall be flat chamfered.
Castle nuts shall be chamfered.
What is understood by screw makers as "semi-finish" shall be the finish for all heads and nuts.
Screws are to be left soft. Screw heads are to be left soft The plain nuts are to be left soft. The castle nuts are to be case-hardened

5-Tolerance

The body diameter of the screw shall be one-thousandth (.001") inch less than the nominal diameter, with a plus tolerance of zero and a minus tolerance of two-thousandths (.002") inch.

The nuts shall be a good fit, without perceptible shake

The clearance between tops of threads and bottom of threads in nuts shall be that existing in the present practice of machine screw makers; that is, the tap shall be between two-thousandths (.002") inch and three-thousandths (.003") inch large.

MACHINERY, N.Y.

NEW PLANT OF THE BOSTON GEAR WORKS.

The Boston Gear Works have erected a new shop for the production of gears at Norfolk Downs, Mass., a suburb of Quincy, six miles out from Boston on the Plymouth division of the New York, New Haven & Hartford R. R. The company, of which Mr. Frank Burgess is the animating spirit, has been located for the past seven years at 152 Purchase St., Boston, Mass., and they will still maintain the Boston office at 102 High St.

The main building, Fig. 8, is approximately square, being about 100 feet wide by 125 feet long, one story high with saw-tooth roof. There is a second story over the middle portion of the shop which is given up to the drafting room and offices for the clerical force. The building is exceptionally well lighted by large windows in the sides and the windows in the saw teeth of the roof, which face the north. The sides of the shop are covered with galvanized-iron clapboards.

The management of the shop consists of a central expert authority which controls the different departments through experienced men known as "jobbers." These men issue the orders for work to the shop directly, each handling those orders for which he is best fitted by experience and training. The machines are in charge of foremen who bear the same relation to the superintendent that the jobbers do to the central head before mentioned, and these follow personally the different jobs entrusted to them.

The worm gear department is equipped for the production of all classes of this style of gearing, many of the machines being of special design built by the firm for their own use. Hobs used for cutting teeth of worm gears are made in the toolmaking department and general use is made of high-speed steel for this work. This department is illustrated in Fig. 1.

The spiral gear and worm department, illustrated in Fig. 2, is equipped with a full line of machinery, and a specialty is

Fig. 1. Worm and Worm Gear Department.

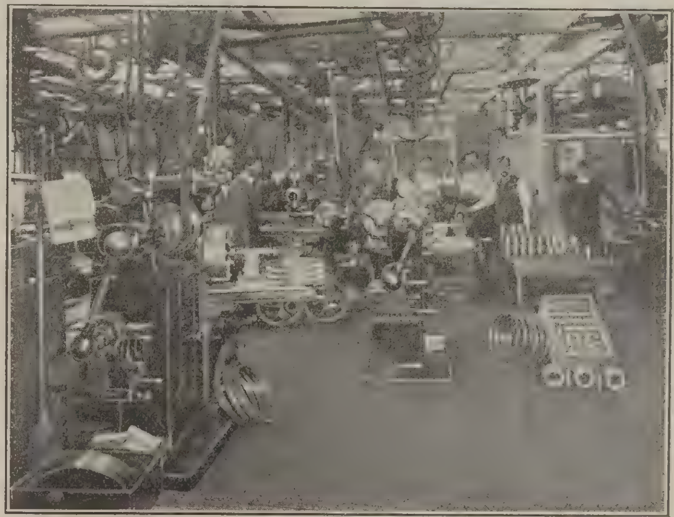


Fig. 2. Special Machinery for Cutting Helical Gears.

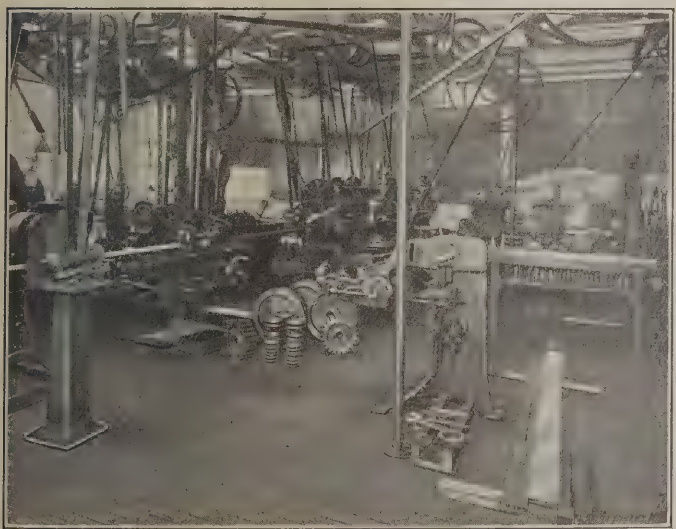

Fig. 3. Gear and Rack Department for Planing and Generating Spur Gear Teeth.

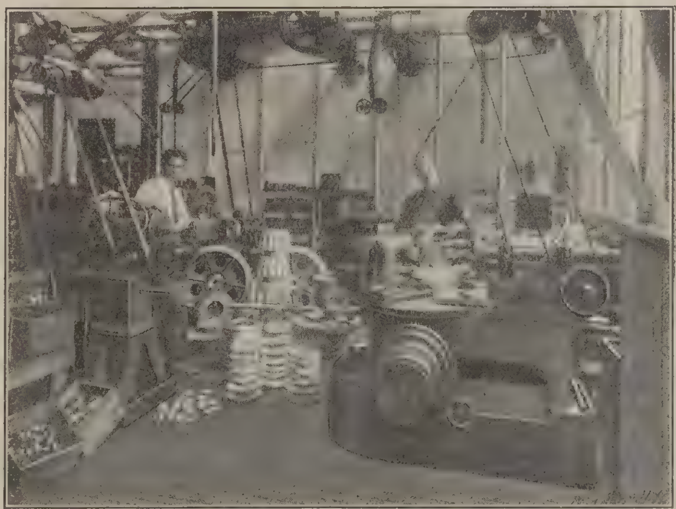

Fig. 4. Automatic Bevel Gear Planing Section.

made of all forms of spiral and helical spur gears and worms. This style of gearing is made to run at any required angle of shafts or with parallel shafts and at any speed ratio.

The spur gear and rack department shown in Fig. 3 also embraces the cutting of intermittent, elliptic, skew bevel and internal gears, ratchets, clutches, crown wheels, etc. At the extreme right in Fig. 3 is shown a spur gear machine with micrometer adjustment which gives the required center distance within 0.0005 inch of accuracy. This department is, of course, the largest cutting department in the factory. It is equipped with modern automatic machinery for generating the teeth of racks and spur and internal gears theoretically correct, these machines being of the Fellows type.

The bevel gear department shown in Fig. 4 is equipped

The motive power of the shop consists of two Hornsby-Ackroyd oil engines of 25 H.P. each. These are ordinarily run together, but may be run separately when occasion requires. A pump circulates hot water through the shop for toilet and cleaning purposes. Cold water at 80 pounds pressure is supplied by the Quincy Water Works.

The shop is classified into departments as follows: Worm gear department; spiral gear and worm department; spur gear and rack department; bevel gear department; toolmaking department; screw machine and automatic machine department; lathe department; brass model gear department; automobile department; polishing department; stock department; case-hardening department; testing department, and pattern department.

with Gleason gear planers and other machines for the accurate production of bevel and miter gears. A specialty is made in this department of automobile driving and differential gears and large contracts are made with various automobile manufacturers for gearing which they are not equipped for producing in their own shops.

The making of cutters, hobs, tools, and cutting of cams and repairing and building of machinery is done in the toolmaking department. All special tools, jigs, gages, etc., are also kept in this department.

Fig. 5 illustrates the screw machine department, which is equipped in the regular manner with turret lathes and automatic screw machines, and besides with a number of special attachments built by the firm for work of special character.

The brass model gear department is devoting itself to the manufacture of small work, such as pinion wire, clockwheels,

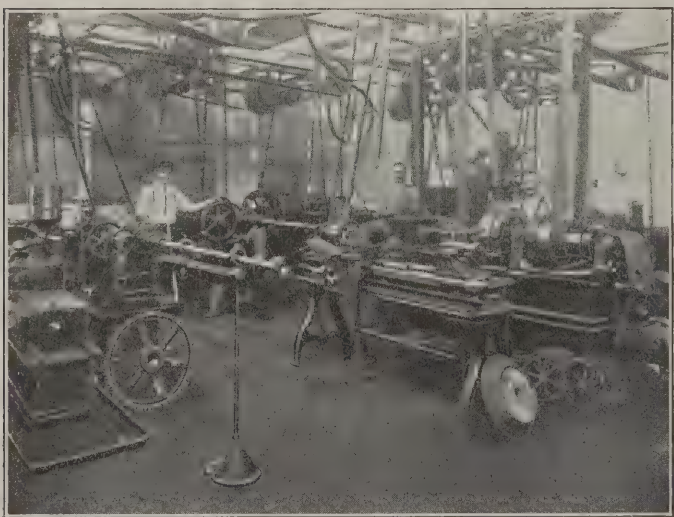

Fig. 5. Turret and Automatic Screw Machine Department

ratchet wheels, etc., and in fact contains machinery of all descriptions to be found in the other departments, except that these machines are designed for very small work. Orders in this section frequently run up to 25,000 pieces.

The automobile department, illustrated in Fig. 6, has derived its name from the fact that the "safety steering device," manufactured by the firm, is made principally in this department. This department also comprises the general machine department, where tools of a general character, such as engine lathes, etc., are placed.

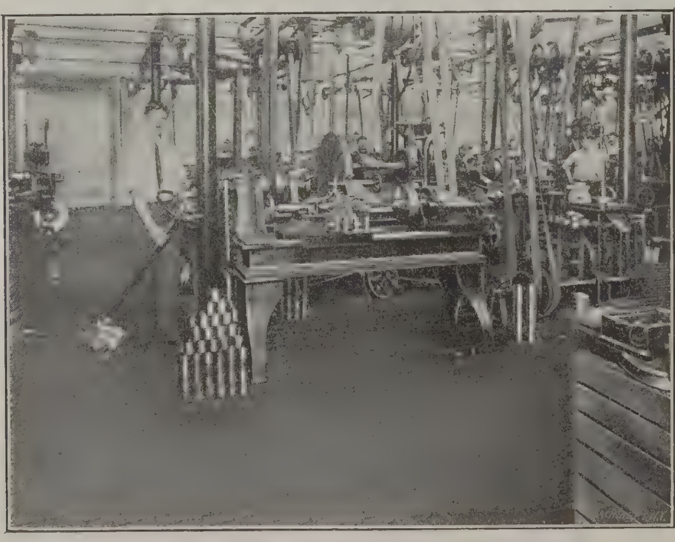

Fig. 6. General Machine and "Automobile" Department.

Fig. 7 shows the testing department, located in the center of the shop. This department stands under the direct supervision of the superintendent, and is conducted by the foremen of the various departments. It is well equipped for testing the products of the firm to very close limits, a number of devices having been designed particularly for this purpose.

The cost system of the shop is organized with a view of giving at once and in detail the cost of any job passing through the works. Accurate records of the time used on each job are turned in every day by the respective foremen.

The comfort and requirements of the employes has been taken in due consideration. The factory is provided with a

Fig. 7. View showing Testing Department and Tool Stock Room; Dey Time Clock at the Right.

lecture room, and with a large wash room with hot and cold water and individual lockers, each having its own key. The factory is, in fact, perfectly modern in its equipment in all respects, and very few things indeed seem to have been overlooked in its planning and construction.

ELECTRICAL STEEL MELTING FURNACE.

The primary difficulty with electrical steel melting has been that the use of electrodes has changed the composition of the metal. This difficulty seems to have been overcome in the new electrical furnace installed by Henry Disston & Sons at their Tacony works near Philadelphia, Pa. Briefly, the furnace is an electric transformer in which the metal to be

Fig. 8. General View of Boston Gear Works.

melted is arranged in a closed ring form, the crucible being in the shape of an annular ring. The crucible encircles the central portion of a laminated iron core which extends across the top, two sides and bottom of the crucible, constituting a closed magnetic circuit. An alternating current of low amperage is passed through a conductor surrounding the central portion of the iron core. With each alternation of current in this primary conductor a current of electricity is induced in the metal placed in the annular cavity of the crucible, by means of which the melting of the metal is effected. There is no contact between the primary and secondary circuits and there are no electrodes, consequently no alteration occurs in the metal operated upon. The steel is melted by the heat developed within its own mass by the passage of the induced current. The tests thus far made prove conclusively that the electrically melted steel fully meets the requirements of the highest standard of quality. It has been subjected to the usual chemical and physical tests and has been used in the manufacture of several of the products of the company. As far as the quality of the product is concerned it may also be noted that since the metal is melted in the absence of fuel gas it yields a very dense and fine-grained casting and its final composition is dependent solely upon the predetermined composition of the material.

MILLING OPERATIONS.

JOHN EDGAR.

In the editorial "The Value of the Camera as an Instructor" in the September issue, the editor in commenting on the article by Mr. Fairfield on "Planing a Small Machine Part," holds out the view that the milling machine could not perform the work in a very successful manner as compared with the planer. This of course leaves room for an argument, and being of a "butt in" nature, I feel that it is up to me to keep my record and try to show that the milling machine can handle the particular piece of work successfully in comparison with the planer, both in regard to finish and accuracy. It is mainly on just such work as this that the milling machine has proven its great advantage in the economical production of machine work. Why the editor singled out this particular job is beyond my comprehension.

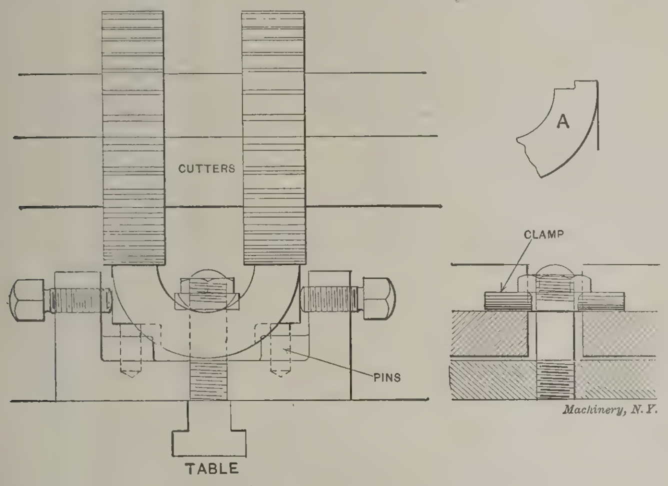

Fig. 1. Milling the Cap.

Taking the cap first we may hold it in a manner similar to that shown by Mr. Fairfield in his photographs and the operation may be performed on almost any style of milling machine. Take the plain miller, use two narrow plain cutters and hold the work in the vise; one or two cuts would be taken over the surface to be machined, using fast feeds with considerable depth of cut for the first cut, and a finer feed and higher speed for the final or finishing cut. A better surface cannot be obtained expending the same amount of time on a planer. The cutters must be in excellent condition in order to obtain good results, but the same applies to the planer tools as well. If we are manufacturing a large number of these pieces it will pay to make special fixtures for holding them, arranging them so that the extreme length of the table feed or travel may be used. We may arrange to take one or more rows of the castings side by side, depending on the size of the miller. This cap is a piece exceedingly easy to hold in a fixture such as shown in Fig. 1. The cap will be seen to be resting on pins where the bosses for the cap bolts come, this making a convenient and reliable foundation. The cap is held sideways by the setscrews on either side and is held down on the pins by the clamp shown in the sectional view. The drawing explains itself, so that but few words are necessary in connection therewith.

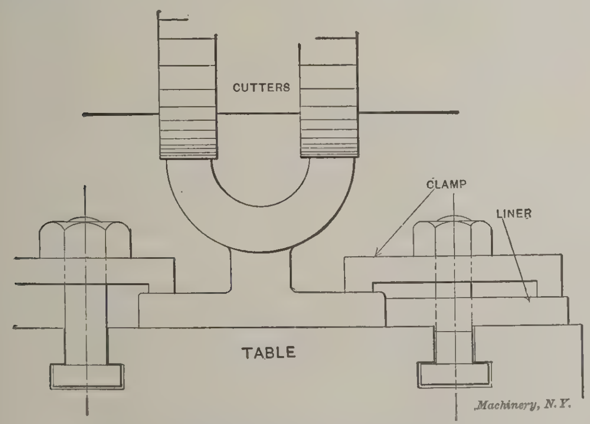

Fig. 2. Milling the Seat for the Cap on the Base.

In the holding of work on the milling machine table or in supplementary fixtures it seems to have become the idea that it is necessary to bolt it down with all the force that it is possible to use without stripping the thread on the bolts. So much strain is not necessary, serving as it does only to distort the table, making it run hard and eventually producing a permanent set which gives the working surface an untrue face. This straining of the binder bolts also wedges the T-slots out of shape, peening the metal above the T so as to project above the rest of the surface. An examination of the machine in operation will show that in 90 per cent of the work done the force or pressure of the cut is symmetrical and has but little effect on the work, all the holding required being merely that necessary to keep it from sliding either along in front of the cutter or sideways. This is accomplished by bunters and toe clamps. Of course it is necessary that the work be held down on the platen, but very little power is necessary in doing so. Had the cap been made with the matched fit shown at A instead of the straight fit, the advantage of milling over planing would have been much more apparent, as gang cutters would have finished the work at one setting, while the planer would have required at least two. But the real gain would be in obtaining interchangeable work which can be obtained on the planer only at the expense of considerable time and trouble, but which is a matter of course on the miller.

In performing the corresponding operation on the base casting we have the advantage of the broad base and the projecting surfaces for clamping which make it an easy matter to set and hold the work. The same that has been said regarding the operations on the cap may be applied to the base. Fig. 2 shows how this piece would be held. The clamps hold down the piece, while the piece is blocked up against a liner to insure a setting parallel with the travel of the table. The row is kept from shifting endwise by using the bunters mentioned above. In machining the foot of the base piece we are confronted by a job that presents a kind of milling operation which has many little points of interest. The problem of milling comparatively broad surfaces is presented. It is an acknowledged fact that the milling of such surfaces must be accomplished by cutters that are so constructed that the chip is broken up into short cuts, giving the operation the advantage of the single pointed tool in the question of power required, and truth of surface obtained. This is accomplished by notching the teeth of the cutter so that they may be presented to the work successively, both notches and teeth being cut spiral at right angles with each other. A surface produced by such a cutter will bear the strictest examinations as to truth without being found wanting.

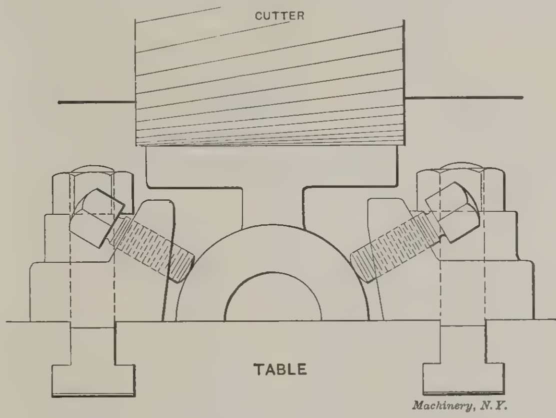

Fig. 3. Slab Milling the Lower Surface of the Base.

Fig. 3 shows one method of machining the bottom surface. In this method we use a plain milling cutter as shown, taking one or two cuts as the case may require. If very little stock has to be removed but one cut ought to be sufficient as the resulting surface will be good enough for the intended purpose. As will be seen the piece is held down and prevented from moving sideways by the screws which are tapped

through the strips bolted to the table. This makes a convenient method and one that will be found to answer the purpose very well. Another method of performing the operation is by the use of an end mill as shown in Fig. 4. This means of removing the metal is very efficient as a very true surface can be obtained with a much faster feed and deeper cut than can be done by slab-milling. The power necessary to revolve the cutter and force the feed is very much less than that used for slab-milling. While the surface may be badly marked it will yet be almost absolutely true. When the work is set up on edge as shown no trouble is encountered with the chips as is otherwise the case. We are fortunate in finding this piece to be a very easy one to provide jigs for, as it permits itself to be set in almost any position. The method used in Fig. 4 is a good one, and will be found very convenient. The top clamp is removed when the work has to be removed or placed in position. This clamp serves the double purpose of holding the work and of setting it in line, the screw being used to make any allowance for variations in the castings. When this method is chosen the machining of the bottom should be done before the cap bearing is milled as this gives a good solid setting for the latter operation. A great many operations may be accomplished by this latter method which are now milled with plain cutters. The action of the cutter in this operation closely resembles that of the

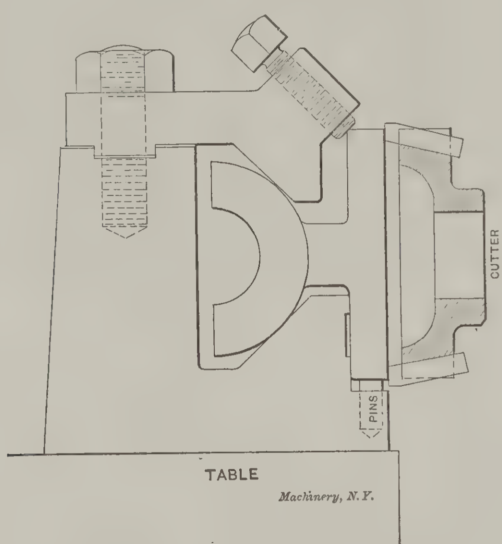

Fig. 4. Another Method of Milling the Lower Surface of the Base.

single pointed tool and has all the advantages that are claimed for this tool, but very few of the disadvantages, and it is a multiple cutter which means greater output.

The milling machine has made great strides in the last twenty years, but we may safely look ahead in the future for the real growth of this method of finishing machine details.

The cuts shown leave considerable to the imagination, as they show but an end view of the work. This is done because the same method may be used to advantage in holding one or a dozen pieces. Elaboration on the above does not seem necessary, since the principle is shown; and since it represents no particular case no figures are given.

The real purpose of the above is to let off a little pressure caused by the editor's comments, and as we milling machine men are very jealous of the machine's record we must always be at hand to contradict any remarks that may serve to cast reflections on its ability to "eat iron" *economically*.

* * *

An illustration of the cost of unwinding red-tape in the conduct of municipal affairs is that of New York City recently in making a small payment. An order directing the payment of five cents to a dealer for making a small blueprint from a tracing passed through the hands of eighteen city officers and cost the city $5, it was estimated, for the transaction. When municipal affairs are conducted on common-sense business principles there will be some hope of cities conducting their public utilities profitably—profitably in the sense of giving better service for less money than is now the rule.

SPRING SCREW THREADING DIES—A CRITICISM OF A CRITICISM.

A. L. VALENTINE.

In the October issue of MACHINERY appeared an article about spring screw threading dies, or rather a criticism upon an article about spring screw threading dies written by a contributor to MACHINERY in the August issue. This criticism led the writer to study more closely the points brought forth in the article written by Mr. Oberg in the August issue, than was done in the first place, and after having made a careful comparison between the different views brought forth in the articles of the two contributors, the writer could not refrain from "butting in," as it occurred to him that the criticism

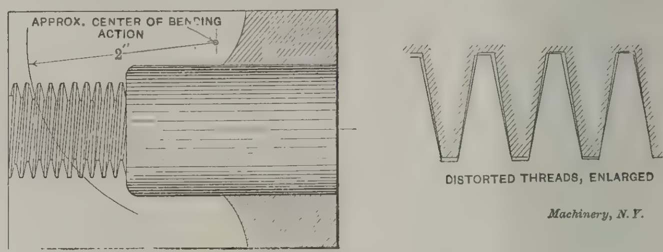

Fig. 1. Spring Screw Die with Special Threads, and Threads Distorted by Common Adjusting Method.

written by Mr. Johnson has several points in itself that should not pass by uncriticised. The need of this will be very apparent to any of the readers if they care to study the subject in question a little deeper, and not consider it from so purely a theoretical or so purely a practical side as was done by the two contributors above mentioned. The subject is one of wide importance and, as Mr. Oberg correctly mentions, there is so little said about these tools in the mechanical periodicals that it would be a pity to lay the subject on the "shelf" so soon. As the writer has had a good deal of experience especially in the making and testing of these tools, a few remarks from him might be of interest as well as of benefit to some of the readers of MACHINERY.

What most prominently attracted the attention of the writer in Mr. Johnson's criticism on Mr. Oberg's article, was the failure of the former to recognize any of the very valuable theoretical facts, set forth in Mr. Oberg's article, as being of any value, when it came to considering the subject from a practical standpoint; furthermore that it would be next to impossible to manufacture these tools as outlined in Mr. Oberg's article, as well on account of the difficulties encountered when making them as the impossibility to make the manufacture of them a financial success. Now, before going any deeper into the subject let me assure the readers of MACHINERY that *nothing was ever practically correct if it was theoretically wrong*, nor has it, in hardly any case, been impossible to devise ways and means of accomplishing anything, if this anything was actually desirable. It may, of course, not be possible without devising something new or something entirely different from old established ways, but is it not rather worth while going to this trouble and be nearly or perfectly correct than to be sure to be wrong, as Mr. Johnson frankly admits in his article that he is, as regards the size and the form of the thread in the spring screw threading dies he is making or in dies made as outlined by him in his article? He is indeed lucky not to have had to make these dies with much sharper angle of thread than 60 degrees, which can be clearly seen from his article and the way he is making his dies, that he has not. For if he had, he would certainly have found Mr. Oberg's way of making them not only practical but he would find it absolutely impossible to produce even a "nearly correct" threaded piece with a spring screw threading die made as outlined by him in his criticism. Let us as-

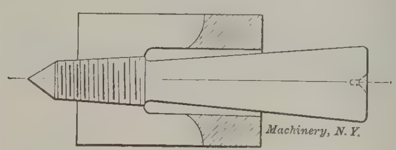

Fig. 2. Spring Screw Die Mounted on Threaded Arbor for Grinding.

sume, for example, that the writer would have made a number of special spring screw threading dies, which the firm he is working for had an order for a short while ago, as outlined by Mr. Johnson. The dies were 2-inch outside diameter and 3½ inches long; the diameter of the piece to be threaded was one inch, the inclusive angle of the thread was 20 degrees; 8 threads per inch, and the depth of thread was 3/16 (see Fig. 1, where the die is shown and where the thread is shown in enlarged scale with the correct angle and with the angle it would have had, had the die been closed to size after having been made as outlined in Mr. Johnson's article). Dies of above description ought to have been hobbed out about 0.015 inch over size, as they were to be used on brass, and in a die with a form of thread with the angle mentioned above it would not be sufficient to close it down to cut to size, it would have to be closed down to cut a certain amount undersize (thus still more increasing the error in the angle of the thread) to allow the piece threaded with the die to go into the hole tapped out with a tap having the correct angle in the thread, and finally after having adjusted the die down to cut small enough, imagine what a fine fit this threaded piece would have had in the tapped hole. It is admitted that these dies were out of the ordinary, and some one might even say that the rule should be dealt with and not the exception, but the example was given to show that theory will always work and produce correct results where practice fails to do so.

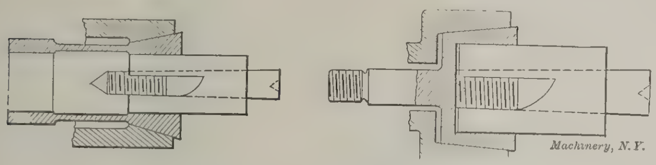

Fig. 3. Grinding the Outside of Spring Screw Dies.

Now let us look into the difficulties encountered when making a spring screw threading die as outlined by Mr. Oberg, and see if these difficulties are unconquerable and if they are real. The worst difficulty seems to be the grinding of the outside of the die true with the thread after hardening. Now if it should be utterly impossible to grind the outside of the die true with the thread after hardening in some cases why should we omit grinding the outside of all dies for this reason? No one can fail to see the advantage, I am sure, of having the part of the die by which it is held (the outside) ground true with the part doing the cutting (the thread). It may be difficult to grind some sizes of dies, but certainly not impossible even under manufacturing conditions as Mr. Johnson thinks it is. The advantages gained would, I think, be fully worth the cost of conquering the difficulties encountered, even in grinding one of these "impossible" dies. When grinding the outside of a die true with the thread after hardening, the writer would suggest holding the die, as outlined in Mr. Oberg's article, on a threaded arbor (Fig. 2), but not grinding the whole length of the die at once, as this would be impossible probably in some cases as Mr. Johnson says, but it should be ground for a length corresponding to the length of the thread in the die. The operator will find no difficulty in grinding up on the die for that length as the arbor and the die for that distance are practically one solid piece and are well supported by the centers of the arbor, which of course should not project outside of the die more than necessary. When this is done the die should be taken—with the arbor still in place in the die—and put into a machine equipped with a drawback mechanism and a spring collet or step chuck (Fig. 3). The die is then, of course, held by the outside by the already ground portion of same, and the back can if necessary be supported by the center of the arbor. Anyone making a business of manufacturing spring screw threading dies would find this operation very inexpensive. There are few up-to-date grinding rooms which have not some grinder rigged up with a drawback mechanism and collets used for other purposes; however we will come to the cost later.

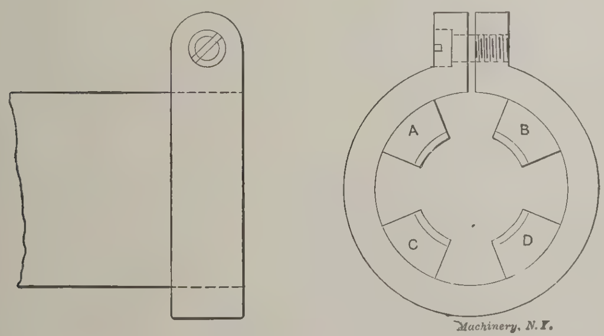

Fig. 4. Common Type of Clamp Collar.

The second difficulty encountered by Mr. Johnson in his criticism would be the closing in of the dies in hardening, if made as outlined by Mr. Oberg, viz., to be of the correct size at the point before hardening. Now Mr. Johnson himself in his article tells us of a way to harden these dies and that if the dies are hardened as outlined by him he claims they come out practically straight. His way of hardening is undoubtedly correct, and there is no danger of the prongs of the dies springing or going out of straight if hardened as outlined by him. Why can we not then harden the dies made as outlined by Mr. Oberg in this manner, and save the trouble of having them annealed and rehobbed an unlimited number of times on account of the prongs of the dies being closed in because of *improper* hardening?

Another difficulty was the problem of being able to make the "taper ring" clamp collar remain on the die in an automatic screw machine. Now, in the writer's opinion, there is no clamp collar made as yet that will excel this one, neither the commonly used one (Fig. 4) nor any of the two shown in Mr. Johnson's article. If the difficulty of keeping this "taper ring" clamp collar on the die in an automatic screw machine has been solved in some establishment visited by Mr. Johnson by means of holding it back on the die with a string that is no reason why this clamp collar is of no use; that merely shows that the establishment in question was lacking in mechanical supervision. While the writer can plainly see the points of superiority of the clamp collar shown to the left in Fig. 5 over the one shown in Fig. 4, he fails to see any superiority of the one shown to the right in Fig. 5. It is claimed in Mr. Johnson's article that both collars shown in Fig. 5 are superior to the one most commonly used (Fig. 4).

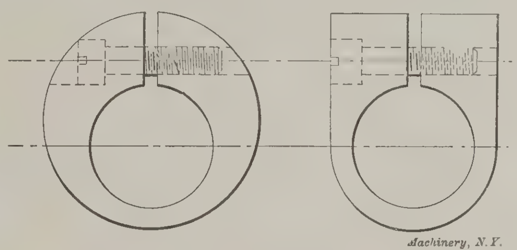

Fig. 5. Special Types of Clamp Collars.

Now as to the difficulties encountered in making the business of manufacturing spring screw threading dies financially successful, there is no doubt that the increase in the number of dies sold (on account of the reputation of furnishing the customers with perfect dies) at a smaller profit, will fully outweigh the smaller number of dies sold before at a larger profit. Furthermore, if we look into this extra expense a little more closely, we will find that it is a comparatively small item. A die not ground on the outside after hardening is made from either drawn wire of the correct required size or made from rough stock, which before being made into die blanks had to be turned and ground. A die ground on the outside after hardening is made from rough stock, rough turned and ready for grinding after hardening. Right here we have a saving of either the difference in price of drawn wire and rough stock or the saving of the cost of grinding the soft blanks. If we add to this saving the time saved in not having to be so extremely particular in making the tapped hole run perfectly true with the outside of the die, which we have to be if the die is not to be ground on the outside after hardening, we have quite an item to deduct from our grinding expenses after the dies are hardened. As regards the difference in the expense in making the die taps and hobs the writer can see none. The only increase the writer can see is the expense of making the arbor

used when grinding the outside of the die, but when considering that this arbor is made exactly the same and at the same time as the hob the expense is reduced to a minimum.

It is to be hoped that the contributor of the article about spring screw threading dies in the August issue of MACHINERY will not think that the writer takes up the defense of some of the theoretical points set forth in his article, on account of thinking him unable or incapable of defending them. It is just because the writer has had the opportunity of using spring screw dies in practice and attained results which were correct in every respect. The means employed were practically the same as outlined in Mr. Oberg's article, and they were not nearly as unfeasible to use, as the latter contributor seemed to think. Just because a new or untried idea may prove itself connected with difficulties, that should be no reason for its immediate repudiation. A thorough investigation should be allowed as to whether the difficulties are real, or if the advantages gained are worth the removal of the obstacles.

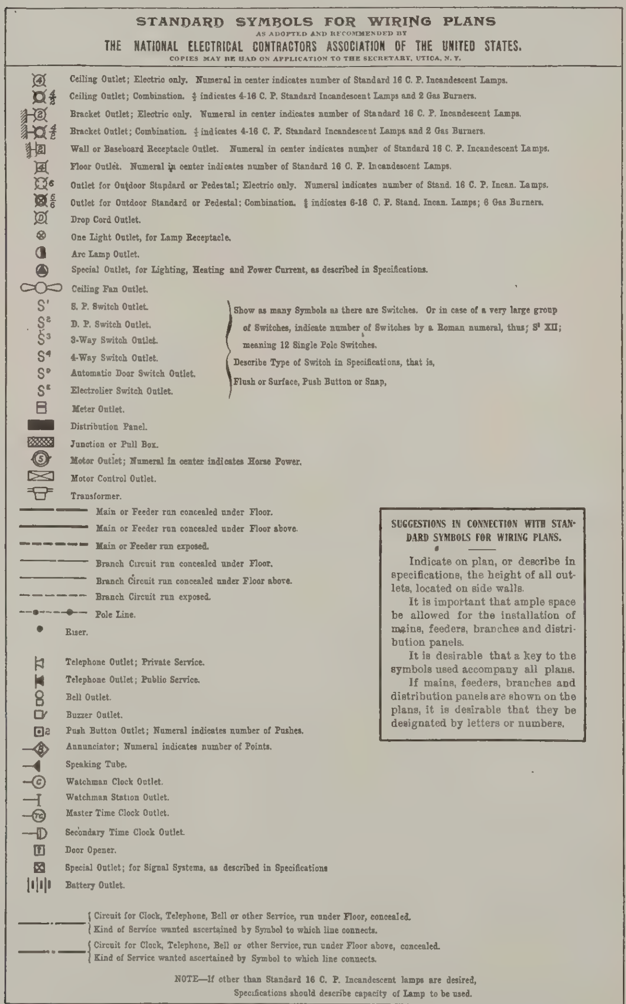
STANDARD SYMBOLS FOR WIRING PLANS.

The accompanying photographic reproduction shows the standard symbols for delineation in wiring plans which were adopted by the National Electrical Contractors' Association at their Cleveland Convention, July, 1906. These symbols were adopted after a year's careful consideration and conference with leading engineers, architects, professors, government



Copyright 1906 by the National Electrical Contractors' Association of the United States.

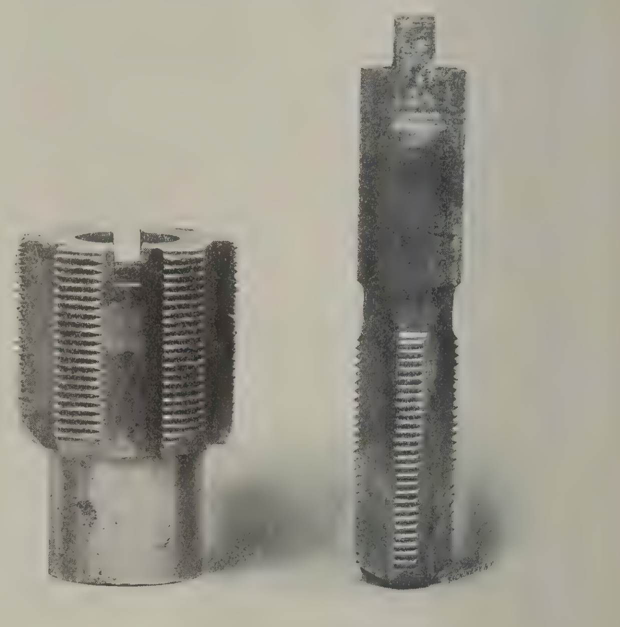
employes, editors of technical publications, etc. It is believed by the committee that they represent in convenient and readily recognized form the parts designated. The symbols and explanation shown in the reproduction are printed on cardboard, 10½ x 16 inches, and copies may be obtained upon request from the secretary, Mr. W. H. Morton, 94 Genesee St., Utica, N. Y.

* * *

Don't take a finishing cut on a broad surface of cast iron without first filing the scale on the front end all away as far down as the tool goes.

TWO TAPS WITH A GOOD ENDURANCE RECORD.

The accompanying halftone shows two taps used in the works of the Reo Motor Car Co., Lansing, Mich., which have a good record for endurance, each having tapped 10,000 holes ¾-inch deep. The larger tap is 2¼ inches diameter and the other 1 inch, and both are of the same pitch, 12 threads per inch. The length of holes tapped equals 7,500 lineal inches, or 625 feet of cast iron, and the taps are still in fairly good shape. The long endurance of these taps is attributed to the method of tempering developed by Mr. J. F. Sallows, foreman



Taps with Good Endurance Record.

blacksmith of the Reo Motor Car Co. The taps are soft enough to be machined anywhere except the teeth, and the same method is employed by him on all similar tools, only the cutting parts being made hard. Mr. Sallows' method is to temper at a low heat in cold salt water and sperm oil. We understand that his method of tempering will be fully explained in detail in a new book to be published soon by the Technical Press, of Brattleboro, Vt.

* * *

OCCASIONAL ANNEALING OF MACHINE PARTS TO PREVENT BREAKAGE.

On many machines the writer has noticed during his experience, there are frequent breakages of particular parts. It is almost periodically expected that certain parts will last just so long before they crack. In some cases this, of course, is unavoidable and occurs through excessive work on a particular part, which wears it rapidly, but where a piece breaks often with no great amount of wear on it we must look for another cause, and this will almost invariably be due to crystallization of the granular structure of the material. This crystallization of steel or iron will occur through frequent shocks, and any piece which is subjected to vibration will quickly become crystallized, and then the strain required to break the part is little greater than that required to break a section of glass of about the same dimensions.

To prevent the breakages of such parts, an excellent plan which has been found to give unfailing results is to remove from the machine such part and heat same to about 900 degrees to 1,200 degrees F. and allow same to cool in lime or in the furnace where it is heated. This is simply an annealing treatment and allows the structure of the material to assume its original condition as before being subjected to the disturbing influence.

This method has saved a considerable amount of repairing and replacement on such machines as engines, planers, trip hammers, and other machine tools where there is any shock or vibration. VIBRATION.

LETTERS UPON PRACTICAL SUBJECTS.

SIMPLE METHOD OF PROVING MULTIPLICATION.

In the August issue of MACHINERY there appeared an article which interested me on proving multiplication and addition by casting out the nines. For simple multiplication the operation may be simplified somewhat. Example as follows:

```
     31416
      7854
  --------
    125664
   157080
  251328
 219912
 ---------
 246741264
```

Add the digits in the multiplicand, $3+1+4+1+6=15$, and $5+1=6$. Add the digits in the multiplier, $7+8+5+4=24$, and $2+4=6$. 6 times $6=36$ and $6+3=9$. Add the digits in the product, $2+4+6+7+4+1+2+6+4=36$, and $6+3=9$. That is, add the digits in the multiplicand and multiplier until we obtain a result of one figure, multiply these together and add again until the result is expressed in one figure. The sum of the digits in the product, proceeding in the same way, should be the same.

This method is a very rapid one, as even a long multiplication may be quickly checked by a mental calculation. However, it should be noted that neither this, nor casting out the nines, is an absolute proof. A failure of either of these tests shows the example to be wrong, but if the digits anywhere are simply interchanged the answer may be incorrect and yet according to the above test be right. This, however, would seldom happen.

Wellsville, N. Y.

A GRINDING FIXTURE AND ITS WORK.

The line cuts and halftone illustrate a very fast and successful little fixture for grinding a radius on a segment gear blank. The work is previously finished to the dimensions given in Fig. 1, the dotted lines showing the stock left for

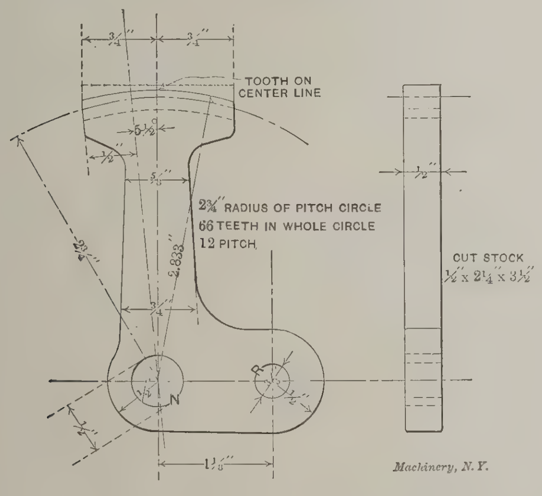

Fig. 1. Gear Segment to be Ground.

grinding the radius of the outside diameter of the segment blank. The grinding was done on a No. 3 Universal Landis grinding machine, the machine, fixture and a pile of rough and finished work being illustrated in Fig. 2. An assembled view of the fixture is illustrated in the drawing Fig. 3.

The fixture comprises a base suitably arranged for clamping to the swivel table of the grinding machine; this base carries at the height of the center of the grinding wheel a pin or fulcrum on which is pivoted a work-carrying arm which may be seen in Fig. 3. This arm is provided with a slot of a suitable width to receive the work, which is first slipped on to a projection of the fulcrum and then swung down into the slot where it is clamped by means of a thumbscrew, a locat-

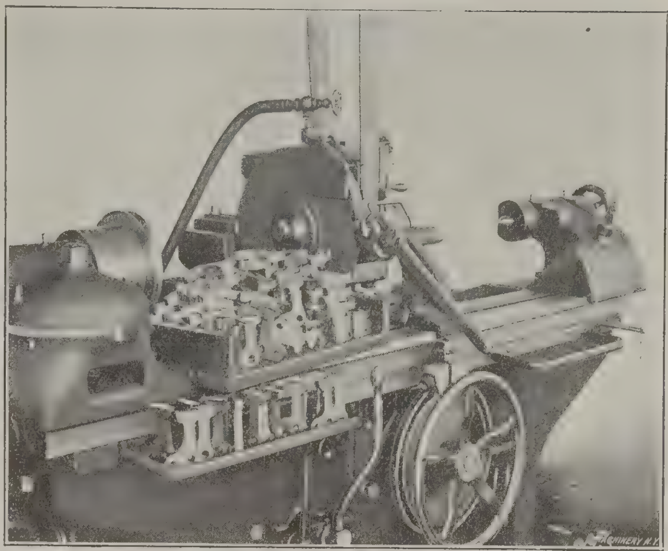

Fig. 2. The Fixture, Work and Grinding Machine.

ing pin being rightly situated to properly locate the work. Upon the fulcrum is also pivoted a gage, which is set so that its point will indicate when the work is ground to the right radius.

The work is ground, without traverse of the grinder, by swinging it slowly up past the face of the wheel, which is of such a width as to fully cover the work. Three cuts are necessary to bring it down to size, the last being a light or

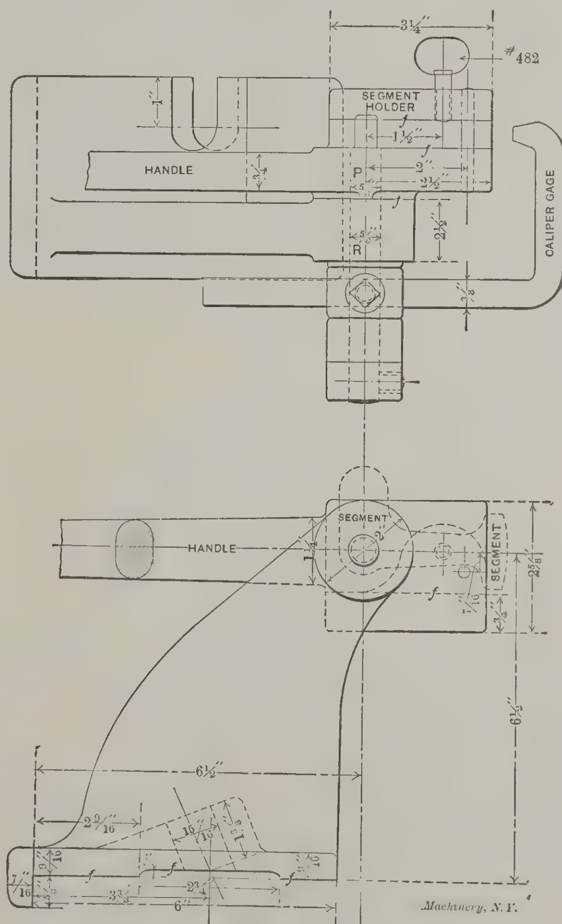

Fig. 3. Side Elevation and Plan of Fixture.

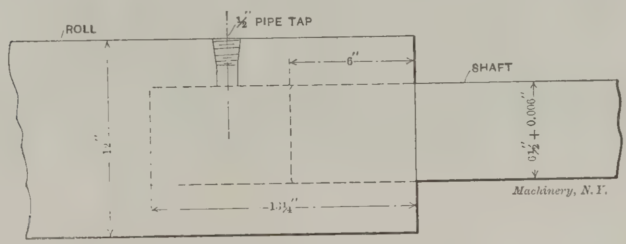
finishing cut. The material of these pieces was soft steel, and they were finished in this way at the rate of 40 per hour, the wheel showing average reduction for wear of about 0.001 inch for five pieces. Some of these were finished as fast as one in 38 seconds.

H. F. NOYES.

Waynesboro, Pa.

THE USEFULNESS OF HYDRAULIC PRESSURE.

The following occasion sets forth one of the many uses to which hydraulic pressure may be put. The top roll of our 10-foot plate bending rolls snapped off at the point where the driving shaft joins on during the process of rolling ¾-inch plate. The roll was then bored out to 6½ inches diameter for a distance of 13¼ inches. The corresponding end of the shaft was turned to a diameter of 6½ + 0.006 inch, as a shrinking fit had to be resorted to, there being no access to a suitable hydraulic press. The end of the roll was subjected to the proper degree of heat, and the shaft started to be put in place. Unfortunately, the rope loop supporting the shaft happened to exert a twisting strain on the shaft, causing it to twist the distance of half the width of the keyway. The few moments occupied in endeavoring to readjust allowed the roll to cool sufficiently to make it impossible to force in the shaft any further. The problem was then how to remove the



The Usefulness of Hydraulic Pressure.

shaft, as it had been inserted but six inches. Hydraulic pressure suggested itself, so the keyway was packed with lead very tightly; ½-inch pipe tap was tapped into the roll as shown in the cut; the hydraulic pump set to work, and with a pressure of 3,000 pounds per square inch the shaft was forced out. This instance suggests a novel use for such pressure, and one, which in our case, saved much valuable time and expense.

Springfield, O. CALVIN B. ROSS.

TO FIND THE RADIUS OF AN ARC WHEN THE LENGTH OF THE CHORD AND THE HEIGHT OF THE ARC ARE GIVEN.

I show herewith a method of obtaining the radius of a circle when the height of an arc and the length of its chord are given, thinking that there may be some of your readers who would like to put the formula in their note books. As shown in the sketch

A = apothegm of chord,
H = height of chord,
L = length of chord,
R = radius of arc.

$$\text{Then } R = \frac{\dfrac{\left(\dfrac{L}{2}\right)^2}{H} + H}{2}$$

This formula is derived as follows:

$$R^2 = \left(\frac{L}{2}\right)^2 + A^2 \qquad (1)$$

since R, A, and $\frac{L}{2}$ form three sides of a right angle triangle.

It is also plain that

$$R = A + H. \qquad (2)$$

Squaring this we have:

$$R^2 = A^2 + 2\,AH + H^2 \qquad (3)$$

Combining 1 and 3 we have:

$$\left(\frac{L}{2}\right)^2 + A^2 = A^2 + 2\,A\,H + H^2$$

Simplifying and transposing

$$2\,A\,H = \left(\frac{L}{2}\right)^2 - H^2$$

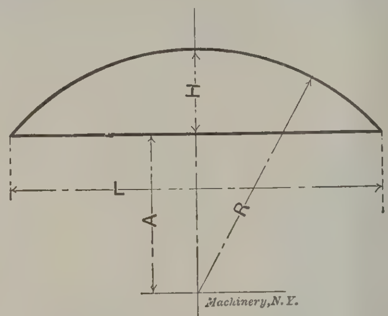
$$A = \frac{\left(\dfrac{L}{2}\right)^2 - H^2}{2\,H}$$

Substituting this value for A in equation 2 we have:

$$R = \frac{\left(\dfrac{L}{2}\right)^2 - H^2}{2\,H} + H$$

which simplified gives the formula proposed above.

When the height and radius are given this formula may be



To Find the Radius of an Arc.

rearranged to be used in finding the length of the chord, thus:

$$L = 2\sqrt{H\,(2R - H)}.$$

Find, for example, the radius when the height of the chord is ⅜ inch and the length of the chord is 1½ inch. Substituting these quantities in the formula given, and solving, we have:

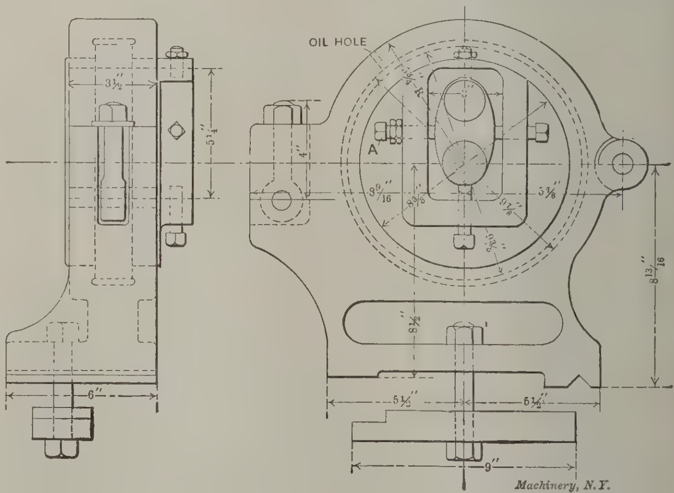
$$R = \frac{\dfrac{\left(\dfrac{L}{2}\right)^2}{H} + H}{2} = \frac{\dfrac{0.75^2}{0.375} + 0.375}{2} = \frac{\dfrac{0.5625}{0.375} + 0.375}{2} = \frac{1.5 + 0.375}{2} = 0.9375 = R$$

The radius is therefore 0.9375 inch, or 15/16 inch.

Torrington, Conn. E. C. FALK.

A CRANKPIN TURNING DEVICE.

The device shown in the accompanying cut was designed to turn the crankpins of small crankshafts so that they would be in line. The crankshaft for which this device was designed was of the drop-forged type, 2½ inches throw, with webs of the shape shown in the cut. The distance between the bearings was from 3 to 4 feet, so that in turning the



Device for Turning Crankpins.

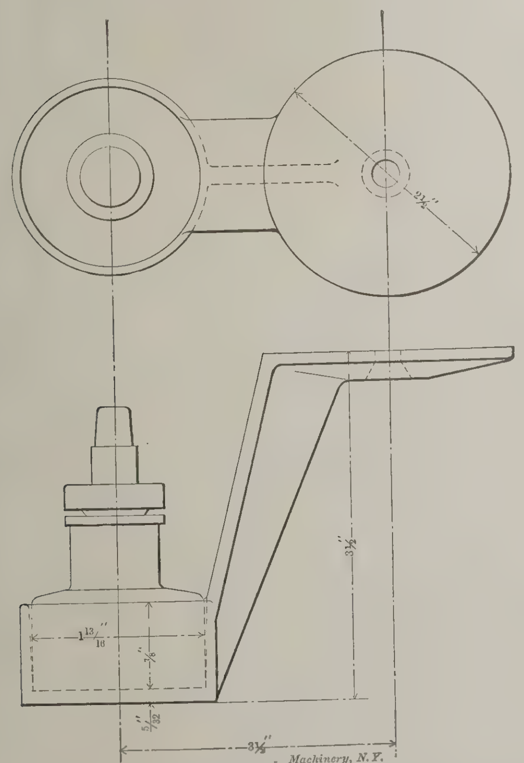
pins, the shaft would spring, consequently the pins would be out of line. After many complaints from the erecting floor, the drawing room "got busy," with this device as the result. I saw it working, and in my judgment it did "the trick." The idea is an old one, as I have seen it before in a more complicated form, but owing to its simplicity of construction and manipulation I offer it to the readers of MACHINERY, some of whom may have the same difficulties to overcome.

The device consists of two parts, a steady-rest, and a piece which I will call a chuck. The steady-rest is fitted to a lathe and bored out in place. The chuck is turned to a running fit in the rest. Before the shaft is put in the lathe, it is lined up on the planer and a light cut taken off the four sides of the web, just enough to make a flat surface for the setscrews to bear against. Another reason, in fact the most important one, will be explained farther on. The shaft is now placed in the lathe on centers which give it the desired throw. The pin is set central by means of the setscrews shown. When this has been done, the setscrew at the top is locked by means of the check-nut. The two check-nuts on the setscrew *A* are screwed against the side of the chuck. As it is necessary to move this screw when moving the crankshaft, two check-nuts are required; the first to indicate the position of the screw and the second to lock the first. The pin is now ready to be turned. After one pin has been turned, the setscrews on the bottom and sides are loosened and the device moved to the next pin. The top setscrew not having been moved, we have that point. Setscrew *A* is now screwed into its original position, made possible by means of the check-nuts. The other two setscrews force the web against these two fixed points and the job is ready for turning the other pin.

As all the flat bearing surfaces are in line and the setscrews occupy the same position after each setting, it will be seen that there is small possibility for the pins not coming in line. In taking the shaft out of the lathe, nothing has to be changed, as the hole in the chuck is large enough to allow the webs to pass through. H. M. C.

CONVENIENT INK BOTTLE HOLDER.

I noticed in the June issue of MACHINERY a neat arrangement for holding the ink bottle securely and "right side up." This matter has been a great source of trouble with most draftsmen and many schemes have been used. I always kept the bottle I was using in a drawer attached to the table, and found that a very effective method of overcoming the difficulty. We now have in our drawing room a bracket holder,



Ink Bottle Holder.

as shown in the cut. This holder is attached to the under side of the table by a single screw so that it may be swung around out of the way. This arrangement obviates the necessity of hauling everything around to find the missing bottle as it is always in the right place; it also eliminates the liability of blotting the work when filling the pen. The danger of spilling the ink is also reduced to a minimum. It seems that all the bad points of all other methods are overcome in the holder shown herewith.

Mr. Moody's arrangement is good, but the idea of using an ink bottle as a paper weight does not appeal to me as being satisfactory or advisable. My idea is that the drawing board is made to hold drawings, and drawings only, the fewer the better. JOHN EDGAR.

Hyde Park, Mass.

SINGLE-STROKE AND CONTINUOUS-RINGING BELL.

Referring to question 22 in "How and Why," September issue of MACHINERY, I give herewith a sketch of a single-stroke bell, Fig. 1; also a continuous-ringing bell, Fig. 2.

When the button in Fig. 1 is pressed, the plunger *P* will run up into the solenoid and strike the bell one stroke. In

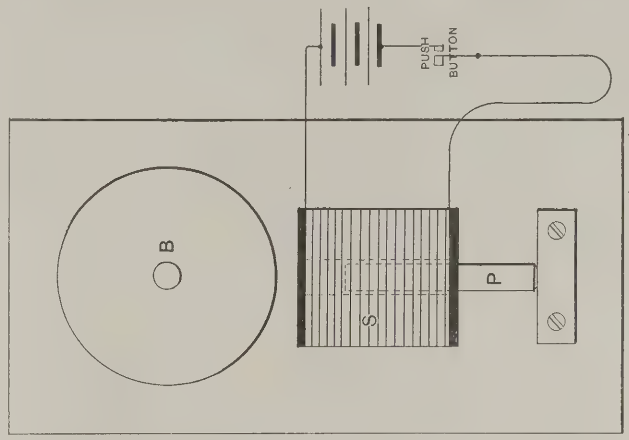


Fig. 1. Single-stroke Bell. Read Cut with Plunger Vertical.

the off position the plunger rests on a small wooden block. This device was installed at the Union Station, Minneapolis, by myself and works satisfactorily.

The continuous-ringing bell is constructed so that wire *a* from the right-hand solenoid crosses to the left-hand contact piece *b*, and the wire *c* from the left-hand solenoid crosses to the right-hand contact piece *d*. The switch is pivoted at *P* and when the plunger is in the position shown it is attracted toward the right-hand end. When it moves to the right-hand it touches the contact *d* and closes the circuit for the left solenoid and opens the circuit for the right solenoid. Then the left solenoid drives the plunger through to the left and

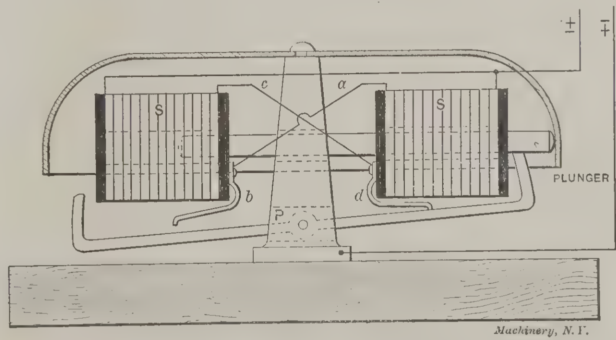

Fig. 2. Continuous-ringing Bell.

strikes the bell. The plunger is then an electromagnet because of the action of the coil and draws the left end of the switch toward it, the switch being made of iron. The switch then touches the left contact piece and closes the circuit for the right-hand coil and opens the circuit for the left-hand coil. The plunger then flies to the right and strikes the bell. The switch is hung so as to be slightly unbalanced, thereby securing contact to one of the coils and enabling the plunger to start. JOSEPH CHAMBERS.

Tacoma, Wash.

THE APPRENTICESHIP QUESTION.

The article on "The Apprenticeship Question" in the August issue was a very timely one, it seems to me, and came from a man who well understands the question, judging from

what I have read of his writings, but it seems to me there are some points that have been overlooked in his articles which would be helpful to all concerned. While my judgment may not be very accurate, it seems to me that many apprentices are not receiving the attention they are entitled to. Most boys, when they start to learn the machinist's trade, are ambitious to learn. Why is it, then, that after ten or twelve months' service in a shop this spirit is lacking? The boy is listless and has not the enthusiasm that he had at the start. What is the cause?

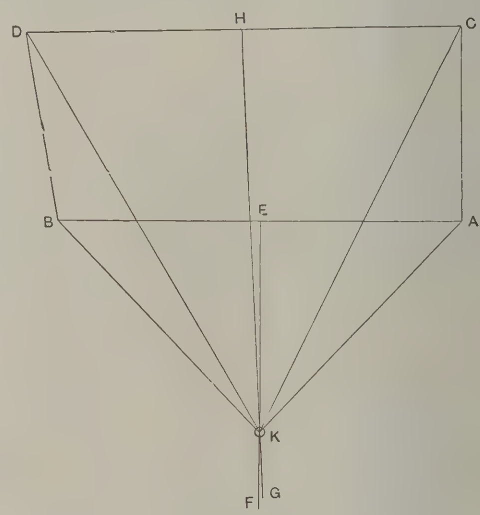
Just as long as apprentices are employed in shops there will be some who come in who are not adapted to the trade. The management is not always to blame for this, because there is no way of determining beforehand if the boy is mechanically inclined. But after ten or twelve months' service it should be possible to judge very accurately as to fitness for the work and during the probationary service the management should not be idle in their attention to the boy. If one wants results from a boy (or from a man, for that matter) he must be kept interested in his work. When put to a machine he must be shown explicitly how to operate it and the best way of performing the work. He must be given an opportunity to form an idea of what is required and it must be impressed upon his mind that it is important that he is doing all his work right. He must not be permitted to develop a slovenly manner of work. If his interest is kept up he will turn out far more work and it will be of a higher class comparatively. He must be given as wide a range of work as the shop permits, and the expectancy of better work will prove a strong incentive to good results.

A great many boys commence to complain of their pay after six or eight months' service unless there is a hard and fast schedule. As a preventative of this, it is advisable that time is taken to show the apprentice the cost of some of his work, and in many cases this is sufficient to cure the greatest "kicker," because it is well known that the ones who usually do the most "kicking" are the ones who perform the least work. If the apprentice had an idea of what he is worth and knew what the machine he is working with is worth per hour, including his services, he would be able to figure his output. This would give him the means to realize whether he is paid too low compared with his more skilled companions in the shop. The ability of estimating the cost of machine work is one that is very rarely ever taught an apprentice, but it is of the greatest value. It is gratifying to find that many of our large concerns are awakening to this fact and are establishing schools of instruction. Of course it takes time and trouble to show the apprentice the how and why, but it is better to spend the time thus than to spend it trying to catch him "playing possum." When I hear of an official complaining of his apprentices as being "no good," it lessens my respect for him as a shop manager. He is the man who is at least partly responsible for their failure as mechanics because of his lack of attention and interest in their development. It would be much better for him to have them brought up to be first-class mechanics and to give some of his time in accomplishing this than it is for him to hire any man that comes along to do his best work and afterward find that many a man whom he has hired is no better than those he has. The former he will pay high wages because he does not know them, but his own boys cannot get the same pay because, as he thinks, he knows them. This inconsistency is hard to understand. If the men in charge would spend more time and more interest in developing their own apprentices, teach them how to estimate, give them opportunities to gather information in mathematics and mechanical drawing, it would be found that it would be for the mutual benefit of all concerned. A few hours a week spent this way would cost the management very much less than an hour or two a day spent by every apprentice worrying over a blueprint, only to still get mixed up in the end and spoil the job. The foreman cannot be everywhere at once, although I have seen a few that were marvels in the latter particular, if you were not looking for them. A good idea would be for a manager to take a few trade papers and when through with them give them to the apprentices instead of throwing them in the waste basket. An apprentice should be accustomed to read things pertaining to his trade. If the boy will read trade papers at noon instead of dime novels, the man will be able to take a responsible place in time of need. It may be that some firms have the best way of doing things, as far as they can see, but it may be that upon considering the matter more closely things may look different. When the apprentice is doing well he should be encouraged as readily as he is blamed when he is doing wrong. If some one would try some of the suggestions put forth, it would be for the benefit of us all, if he would let us know of his experience. E. T. STRONG.

Urbana, Ill.

OLD EUCLID DISPROVED AT LAST.

If the editor would have permitted me I should have entitled this "Startling Revelation in the Science of Mathematics," and should have had the heading printed with 3-inch-high letters, because, in fact, my discovery is of so unique a character as to put me in a class with Newton and Pascal. For more than 3,000 years we have considered the statements of Euclid as unquestionable, but at last it has been possible by a simple method to disprove the truth of the very foundation of geometry! Draw a straight line, AB, as shown in the cut. From A draw a line AC at right angles to AB. From B draw a line BD at an angle larger than 90 degrees to AB. Make BD equal to AC. Draw CD. Divide AB in two equal



Old Euclid Disproved.

parts at E. Draw EF at right angles to AB. Divide CD in two equal parts at H and draw HG at right angles to CD. EF and HG intersect one another at K. Draw AK, BK, CK, and DK. We are now ready for the startling revelation. AEK and BEK are right-angle triangles. BE equals AE, EK is mutual for both triangles, consequently the triangles are equal and the angle EAK equals EBK, and the line AK is equal to BK. The triangles CKH and DKH are also equal, being right-angle triangles, with the side DH equal to CH and the side HK mutual to both. The side CK is then equal to DK. If we now consider the triangles ACK and BDK we know that AK equals BK, CK equals DK, and BD was originally made equal to AC. Consequently these triangles are equal, and the angle CAK equals the angle DBK. If from these angles we subtract the angles EAK and EBK respectively, which we have found to be alike, the remaining angle CAB is equal to DBA. The angle CAB is a right angle according to our construction. The angle DBA is larger than a right angle. We have proven them to be alike by means of the fundamental propositions of geometry. Hence Euclid must be wrong in the very first principles upon which he founds his geometrical propositions.

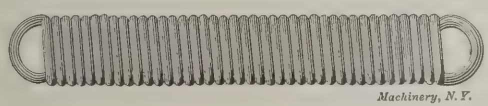
It may be that the editor will not consider my discovery epochal, and that it is the reason for his declining the 3-inch high letters for a heading, but even if his check should fail, I am convinced that my discovery is the very greatest in the field of science during the present year, and I expect to receive the Nobel prize for scientific research, which would

amply compensate me for my disappointment in regard to the 3-inch high letters for the heading, upon which my heart was particularly set.

R. S.

COMMENTS ON "TO INCREASE THE WORKING LENGTH OF COIL SPRINGS."

Referring to the article entitled "To Increase the Working Length of Coil Springs" in the August issue of MACHINERY, the writer wishes to call attention to some points not mentioned which will materially alter the case. In the two cuts shown in the article the working length of the open-wound spring appears greater than that of the close-wound spring. However, the distance a spring will safely extend is determined by the number of acting coils it contains, and not by the number of inches of working length. Each of the springs shown has about nine acting coils and therefore both the springs will be about equivalent in their action. Now, if the close-wound spring were made with one-half of each end coil bent up for hooks instead of using the tapered ends and forged hooks, several more acting coils would be added to each end of the spring without increasing the length over all, and consequently the close-wound spring could be made shorter for a given working length than could the open-wound spring with links. The cut shows a spring made in this manner. This is the style of hooks generally used on extension springs, being easier and cheaper to make and in 99 cases out of 100 gives fully as good service.



Increasing the Working Length of Springs.

There are, however, two important advantages in the open-wound spring with links, which are not referred to in the article mentioned; first, the impossibility of injuring such a spring by any reasonable overload. The spring simply compresses under overload until the coils touch and then acts as a solid connecting link; second, the fact that in the case of the coil part breaking the links act as a safety device maintaining the connection between the parts to which the spring is attached. For instance, when used as a trace spring to relieve the horse of the jars caused by the unevenness of the road, if the coil should break, the trace is still attached to the whiffletree and no runaway or accident follows.

F. E. W.

METHOD OF DIVIDING FRACTIONS BY TWO.

Under the heading, "Method of Dividing Fractions by Two," an article was published in the August issue, evidently with the intention of placing on exhibition the longest known method for cutting a fraction "through the middle." Mr. Lang attacks a fraction in about the same way as a farmer would cut off a piece of cold-rolled shafting, commencing with a file, then using a cold chisel for a while, after which he might take turns with the pipe cutter and milling machine, and if he did not happen to think of the emery grinder he would undoubtedly finish with the hacksaw, the tool which should have been used at the start. It may be that the other tools might do the job, but nobody is likely to care to wait for the result obtained in that way.

A man who cannot set his dividers to one-half the given fraction of the dimension for the diameter without looking up his table of decimal equivalents first should not expect pay for overtime. Although there are quite a few mechanics (?) who have passed through their apprenticeship and are still deficient in fractions, I do not believe that the given method will be of any assistance to any of them.

The quickest way is always the best. Try this: taking for example, $11/64 \div 2 = 11/64 \times \frac{1}{2} = 11/128$; cutting this short for convenience, we say $64 \times 2 = 128$, and using the same numerator we have 11/128. This principle is equally applicable to the division of fractions by any number. For instance, $7/9 \div 2 = 7/9 \times 2 = 7/18$, and by Mr. Lang's method we experience some difficulty in finding the decimal equivalents of 7/9 or 35/9, and even if such tables were available, the simple rule that you learned when you were nine years old would give the correct result quicker than you can find it in the table. Just add enough ciphers to give the proper number of places to the numerator and divide by the denominator; thus, $7/9 = 7.0000 \div 9 = 0.7777$, which is sufficiently accurate for a measurement with micrometers; by the same formula 55/64 becomes $55.000000 \div 64 = 0.859375$. I do not want to belittle the value of tables and note books; some of the data sheets are worth many times the price of the paper, but I am surprised to see a good mechanic waste his time in the way mentioned.

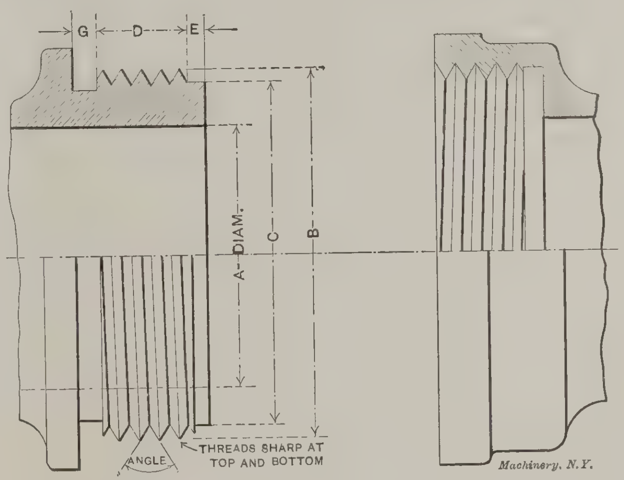
EUGENE PIERCE.

Ilion, N. Y.

[We are not at all sure that Mr. Pierce can carry out his lengthy divisions, particularly when halving 64ths any quicker than Mr. Lang carries out his simple multiplication and looks in his table, but the criticism is so unique in its certainty and in its comparisons that we felt under obligation to publish the matter and permit our readers to judge for themselves. To find the decimal equivalent at once, and divide it by two, seems the simplest way in regards to 64ths. In regards to 32ds, 16ths, etc., there seems to be no need of either multiplications, nor lengthy divisions, and Mr. Pierce is, of course, applying the correct principle for such cases, if he simply multiplies his denominator by two.—Editor.]

STANDARD HOSE COUPLING FOR NAVAL CONSTRUCTION.

There was published, in the July issue, Standard Hose Couplings, as agreed upon by the National Fire Protection Association. This standard differs somewhat from the one used in naval practice. The following table of dimensions



STANDARD HOSE FOR NAVAL CONSTRUCTION.

A	*B*	*C*	*D*	*E*	*G*	Angle.	No. of Threads per inch.
1/2	1 1/16	Bottom of Thread.	5/16	1/16	1/8	60° 0″	14
25/32	1 9/32	Bottom of Thread.	1/2	1/16	1/8	60° 0″	11 1/2
1	1 5/16	Bottom of Thread.	1/2	1/16	1/8	60° 0″	11 1/2
1 17/32	2 3/32	1 31/32	1/2	1/16	1/8	77° 20″	10
2	2 13/32	2 9/32	3/4	1/8	1/8	66° 18″	7
2 17/32	3 11/32	3 1/8	3/4	1/8	1/8	66° 18″	7

3 1/2	4 5/16	4 3/32	3/4	1/8	1/8	66° 18″	7
4	4 7/8	4 21/32	1	1/8	1/8	66° 18″	7
4 1/2	5 3/8	5 5/32	1	1/8	1/8	66° 18″	7
5	5 7/8	5 21/32	1 1/4	1/8	1/8	66° 18″	7
5 1/2	6 3/8	6 5/32	1 1/4	1/8	1/8	66° 18′	7
6	6 1/8	6 21/32	1 1/2	1/8	1/8	66° 18″	7
6 1/2	7 3/8	7 5/32	1 1/2	1/8	1/8	66° 18″	7
7	7 1/8	7 21/32	1 1/2	1/8	1/8	66° 18″	7
7 1/2	8 3/8	8 5/32	1 1/2	1/8	1/8	66° 18″	7

complies with the naval specifications for hose threads and may be of some value to the subscribers employed in marine works which are at times engaged in naval construction.

Brooklyn, N. Y.

A. H. NOURSE.

SHOP KINKS.

A DEPARTMENT OF PRACTICAL IDEAS FOR THE SHOP.

Contributions of kinks, devices and methods of doing work are solicited for this column. Write on one side of the paper only and send sketches when necessary.

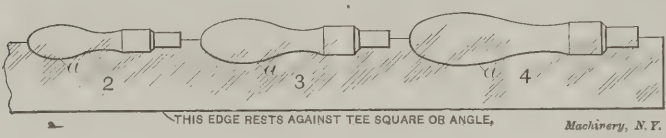
A HANDY SCREWDRIVER.

The machinist many times wants a small screwdriver, and the kind used by watchmakers do not have the "grip" needed. I made one like the cut from 3-32-inch steel wire, about 4 inches long, and it has seen many years' service and is

good yet. The part *A* is made of brass ½ inch in diameter, 3-16 inch thick, and knurled on the edge. The cup piece *B* is also of brass, dished as shown. F. H. J.

TEMPLATE FOR DRAWING MACHINE HANDLES.

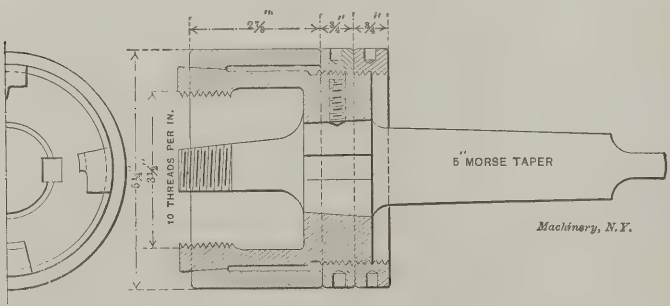
The drawing of machine handles may be facilitated very much by the aid of a celluloid template. Two templates are made, one containing profiles of the four smaller sizes, and the other containing the three larger sizes. If there is a forming tool for each size it is an easy matter to make the



templates and thereby have the drawings the same outline as the formers. They not only facilitate drawing, but also allow of a proper section for each requirement. The outline, *a*, of the lower half of the handles is scratched on the templates and is filled in with black wax. WINAMAC.

LARGE SPRING SCREW THREADING DIES.

Thinking that some of the readers of MACHINERY may be interested in a large spring screw die of which type I have designed several, the one in the accompanying cut being the largest, I hereby submit it for their approval. This die was made to use in a limited space, the collar and the check



nuts running within 1-16 inch of a projecting flange, it being impossible to use any other type of die. These dies work in a very satisfactory manner and are used on brass. They do not need a lengthy description, as the cut will explain their operation and construction satisfactorily.

Boston, Mass. LOUIS F. LANG.

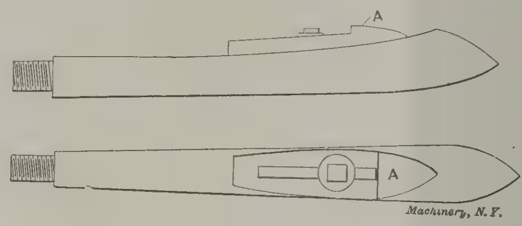
HOW TO PREVENT A UNIVERSAL CHUCK BECOMING CLOGGED WITH CHIPS.

Here is a way which I have used to prevent a universal chuck becoming clogged up with chips. Take apart the chuck and in the outer shell lay out three holes ⅝ inch diameter for a 6-inch chuck, midway between jaw race and pinion wrench holes, where it will weaken the shell the least, and a distance in from outer face of chuck so that the point of the drill will break through about 1-16 inch from the inner face. The holes should be drilled ½ inch further after the point breaks through, cutting a groove in the inner face with the lip of the drill. A ⅝-inch hole is about the right size for a 6-inch chuck; smaller or larger chucks would, of course, need smaller or larger holes in proportion. Use dry graphite instead of oil in the chuck. A chuck with holes drilled as above is specially good for turning composition metal at high speed, and will clear chips almost as fast as they get in.

South Boston, Mass. F. B. POOLE.

A PIPE PULLER.

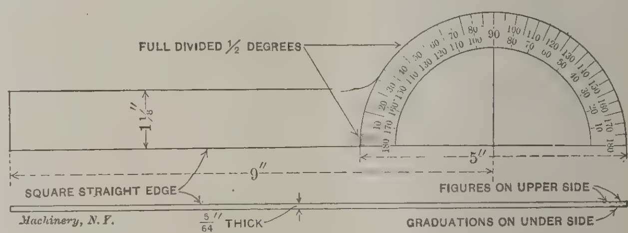
Did you ever have a pipe to pull out of the ground, that you could not get hold of? If so, the device shown in the cut will be of value in many cases. Of course it has to be made to suit the size of pipe inside. No explanation is necessary, as the cut shows the device very plainly. The tool is secured



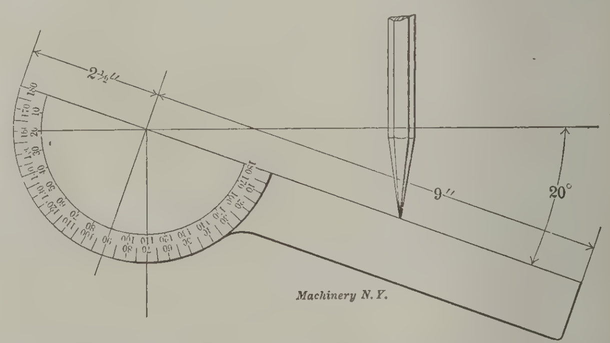
into a piece of pipe of proper length, and pushed down in the hole until the end enters the hole in the pipe to be pulled out. When the pull is made, the part *A* slips down, wedging in the pipe, and pulls the pipe out. F. H. J.

DRAFTSMAN'S IMPROVED PROTRACTOR.

I enclose a sketch of a protractor which was designed to meet the demands for one that would be better suited for dividing a circle than can be done with those now on the market. It is not intended to do the work that the B. & S. protractor can do, but principally to facilitate the plotting of angles for cams and cam charts. In laying out angles of this



kind or in general work with the ordinary protractor it is necessary first to point off the angle, then to remove the protractor and draw the line through the point. This protractor, having an extended arm, enables the operation to be done with the one setting. A number of draftsmen have shown their desire to obtain one, so an order has been placed with a



prominent manufacturer to make them, which is to be done at a reasonable price. They are made of transparent celluloid with the graduation on the under side. A few extra ones are now on hand as it was necessary to order more than were wanted. C. E. JOSSELYN.

Bridgeport, Conn.

* * *

Don't take a heavy stock cut off with a planer and then a finishing cut without letting up on the work and allowing all of the strain to come out.

* * *

Don't forget that after the stock cut is made on cast iron, every finger mark, or drop of water, or drop of oil, will show up when the finishing cut is made.

SHOP RECEIPTS AND FORMULAS.

A DEPARTMENT FOR USEFUL MIXTURES.

This page will be used for the publication of shop receipts which the contributors know from experience to be practicable. Nearly all readers of MACHINERY can add something, and it is desired that they use this page as a medium for exchanging useful formulas. It makes no difference if they are old and supposedly well-known, provided they have not already appeared in this department.

253. CEMENT FOR FASTENING TOOLS IN THEIR HANDLES.

Mix one part beeswax, one part fine brick dust and four parts black rosin. E. H. McClintock.
West Somerville, Mass.

254. TAPPING HOLES IN CAST IRON.

Kerosene oil used as a lubricant for tapping holes in cast iron is the best lubricant known to the writer.
Philadelphia, Pa. Wm. Davis.

255. ACID-PROOF CEMENT.

Mix a concentrated solution of soda with pulverized glass to form a paste. W. R. Bowers.
Birmingham, England.

256. FLUX FOR BRASS.

One ounce common soap, ½ ounce quicklime, ¼ ounce saltpeter. Mix into a ball and place in a crucible when lifted out of the furnace. This is sufficient for about 50 pounds of metal. W. R. Bowers.
Birmingham, England.

257. DUSTING FOR MOLDS FOR BRASS WORK.

To produce light castings of brass and gun-metal with a clean face and fine skin, first dust the mold with pea meal and on top of same add a slight dust of plumbago; for heavy castings dust only with plumbago. W. R. Bowers.
Birmingham, England.

258. A LUBRICANT FOR CUTTING THREADS.

After trying various kinds of lubricants in cutting threads on tool steel, machine steel, etc., I found that common lard (not lard oil) mixed with about one-third turpentine gave the best results. The mixture may be applied with a small brush.
Paterson, N. J. Stephen Courter.

259. ANTI-SLIP BELT MIXTURE.

To make a cheap anti-slip belt mixture and one that is very effective, use 95 per cent rosin and 5 per cent machine oil. Melt the two together slowly, taking care not to burn the rosin. When melted stir together thoroughly and apply warm, using a little at a time while the belt is running.
Pittsburg, Pa. Samuel Strober.

260. BLACK BRONZE FOR BRASS.

Dip the article, cleaned bright, in aquafortis (nitric acid); rinse the acid off with clean water, and place it in the following mixture until it turns black: Hydrochloric acid, 12 pounds; sulphate of iron, 1 pound, and pure white arsenic, 1 pound. It is then taken out, rinsed in clean water, dried in sawdust, polished with black lead and lacquered with green lacquer. Jos. M. Stabel.
Rochester, N. Y.

261. SELF-LUBRICATING BEARINGS.

In hard gun metal bushes, bored a good fit to shaft and split, drill four holes per square inch of surface, each ¼ inch diameter by ¼ inch deep. The holes are to be flat at the bottom and to be spaced zigzag, so that one row of holes is between the holes in the opposite side thus: . ˙ . ˙ . Fill the holes with a compound prepared as follows: Melt 1 pound solid paraffine and add 2 ounces of litharge, dissolved isinglass and sulphur; add further 2 pounds of fine plumbago and mix thoroughly. J. H. Holdsworth.
Toronto, Canada.

262. VARNISH FOR DRAWINGS.

Dissolve by gentle heat 8 ounces of sandarac in 32 ounces of alcohol. Another receipt is: Dissolve 2 pounds of mastic and 2 pounds of a lammar in 1 gallon turpentine without heat. The drawings must first be sized with a strong solution of isinglass and hot water. W. R. Bowers.
Birmingham, England.

263. TO WATERPROOF CLOTH TOOL BAGS OR CASES.

To waterproof tool bags or cases made of duck or other cloth, either of the following formulas may be used.

Use ½ pound of alum and 2 ounces of saltpeter dissolved in 1 quart of water. Immerse the article to be waterproofed in this mixture for 40 minutes, and boil hard; then rinse in cold hard water, hang up and let dry thoroughly before using.

Melt ½ pound of paraffine wax and mix in 1 quart of gasoline. Immerse the article in this and wring out and spread out to dry. In a short time it is ready to use.
E. W. Norton.

264. CEMENT FOR LEATHER BELTS.

To prepare a good cement for leather belts, soften equal parts of good hide-glue and American isinglass in warm water for about 10 hours. Mix the two ingredients together thoroughly and then pour on a quantity of pure tannin and boil until the mass is sticky. Just enough tannin should be added so that the mass will have a good consistency when boiling hot. To apply the cement, roughen the surfaces to be cemented and apply the cement while it is very hot. Press the parts together firmly and hold in that position until dry.
Olney, Ill. T. E. O'Donnell.

265. SOLDER PREPARATION FOR ALUMINUM.

The most successful solder preparation for soldering aluminum yet secured is made up in the following manner. Melt together 64 parts, by weight, of tin, 30 parts of zinc, 1 part of lead, and a small amount of rosin. All parts, of course, must be mixed together very thoroughly while in molten condition. When thoroughly mixed the alloy should be run out in bars of desired sizes. Clean the surfaces thoroughly and apply the solder. No chemical is required, the rosin used being sufficient to cause adhesion, although it is advisable to heat the parts to be soldered gently to assist in making a good adhesion. T. E. O'Donnell.
Olney, Ill.

266. TO BLUE STEEL WITHOUT HEATING.

When it is not desirable to blue steel by the heat process the following solution may be used with excellent results: Water, 1 quart; hyposulphite of soda, ½ ounce; acetate of lead, ½ ounce. Dissolve the acetate of lead and hyposulphite of soda in the water and then heat to the boiling point. The article to be blued should be thoroughly cleaned and dipped into the hot bath until the color changes to the required tint. It should then be removed, rinsed and dried. A more brilliant result is obtained by coppering steel articles with blue vitriol solution and then dipping. The same process may be used on both brass and copper with success. M. E. Canek.

267. SOLDERING WITHOUT HEAT.

Take 1 ounce of ammoniac and 1 ounce of common salt, an equal quantity of calcined tartar, and 3 ounces of antimony. Pound this well together and sift. Put this in a piece of linen, and enclose it well around with fullers' earth about an inch thick; let it dry, then put it in one crucible, covered by another crucible over a slow fire to get hot by slow degrees. Keep up the fire until the content of the crucible gets red hot and melts. Then let it cool gradually and when cold pound the mixture. When you wish to solder anything put the two pieces you want to join together on a table close to one another. Make a crust of fullers' earth, so that, passing under the joint and holding to each piece it shall be open at the top. Then throw some of the powder between and over the joint. Dissolve some borax in some hot wine, and with a feather dip in the solution and rub the powder at the place of the joint. It will immediately boil up. As soon as the boiling stops the consolidation is made. The calcined tartar is made by placing crude tartar in a covered crucible and raising it to a low red heat. Allow it to cool gradually.
Rochester, N. Y. Joseph M. Stabel.

HOW AND WHY.

A DEPARTMENT INTENDED TO CONTAIN CORRECT ANSWERS TO PRACTICAL QUESTIONS OF GENERAL INTEREST.

Give all details and name and address. The latter are for our own convenience and will not be published.

27. H. T. M.—What are the precise advantages of the bull-wheel used in planer construction. Do these advantages exist when the bull-wheel and the rack are cut with ordinary gear cutters?

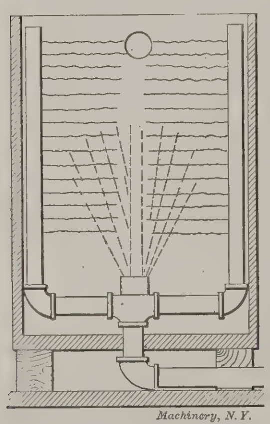
A.—The use of the bull-wheel in planer work is largely because of constructive reasons. If the rack be meshed directly with the driving pinion, one of the reduction gears must necessarily extend above the level of the platen unless the rack be carried low. The introduction of the bull-wheel allows the reduction gearing to be all below the platen, and also gives the advantage, if it be one, of a large pitch circle to work with the rack; consequently the lifting action of the bull-wheel on the table is not as great (with the cycloidal tooth system) as it would be if a pinion were employed. With the involute tooth system, however, the angle of pressure remains unchanged for large or small gears so that this feature is really of not much importance. One successful American planer (Whitcomb-Blaisdell) is made without the bull-wheel.

---

28. F. S.—1. How should a square wire spiral spring 5¼ inches long, 24 coils, 0.525 inch outside diameter, wound on a mandrel 0.35 inch diameter, wire 0.080 inch square, be hardened? This spring must be compressed into a square of 2 inches and must extend to its full length. The steel is 0.65 carbon. 2. How should tool steel rolls for rolling wire to a thickness of 0.023 inch thick by 0.237 inch wide be hardened? The rolls are 8 inches diameter by 4¾ inches face and have a hole through the center for a shaft 3½ inches diameter. They must be so hard that a file cannot touch the face and must be free from checks or cracks. The steel is 1.10 carbon.

Answered by E. R. Markham, Cambridge, Mass.

A.—1. In treating springs the desired final condition is elasticity and not hardness. Many times the hardener makes the mistake of getting springs too hard—and too brittle. Then in reducing brittleness the temper is drawn too low in order to let the spring stand up to its work; if the temper is not drawn low the spring breaks. When possible springs should be hardened in oil. If oil does not produce the desired result water must be applied instead, but it should be kept as warm as possible and still produce the desired hardness. Oil will work in most cases where the wire is no heavier than that stated in the inquiry, and even where it is several times the size, if the carbon content is sufficiently high. When oil fails to give the desired results it is generally because of lack of circulation or what is known as a "still" bath. Various expedients are employed to keep the oil in motion, but the best results follow when it is forcibly brought in contact with all parts of the steel alike, and this is accomplished in the case of a spring of the style under consideration by employing a bath of the form shown in the accompanying cut. There are six or more pipes extending up the side; these are perforated and the oil is forced through the opening toward the center. The pipes are so arranged that they may stand close to the sides of the receptacle or be swung toward the center for small work. The oil being projected against all parts of the spring alike insures uniform hardening and avoids the evils arising from the formation of gas next the work as occurs in a still bath. The stream of oil coming from the bottom also further agitates and forces the heated oil and gases to the top of the bath from which it is drawn off by a pump through cooling coils immersed in a tank of running water and then forced back through the hardening bath. Either lard or sperm oil works well, or in fact almost any fish oil answers nicely with such an arrangement. When drawing the temper best results follow if the springs are placed in a kettle of oil and the contents heated to the proper degree as denoted by an accurate thermometer. The exact temperature required cannot be stated as a great deal depends on the kind of steel used, the heat at which the spring was hardened and the use for which the spring is designed. However, if the spring be properly heated when hardened the temperature should not range far from 580 to 630 degrees F. For steel of the carbon content mentioned the first figure mentioned should be about the required temperature. 2. The hardening of rolls of the kind and purpose mentioned is not boy's play; it calls for experience and expert handling. A good grade of steel is required and one low in harmful impurities. The rolls must be carefully annealed before the machine work is completed. After boring the hole ⅛ or ¼ inch smaller than the finished size and turning off the outside surface or skin carefully, anneal the roll to remove all internal strain and then finish to size. When hardening the roll it must be carefully and uniformly heated; rapid heating is to be avoided as the outer surface at the ends will be heated much more rapidly than the balance of the piece. Rapid heating of such a piece means uneven heating and uneven cooling, consequently severe internal strains and bad results. If the carbon content is 1.25 or under, the roll should be packed in an iron hardening box with charred leather, and in charred hoofs, or charred hoofs and horns if it exceeds the percentage mentioned. The cover should be luted with fireclay and the box placed in a well-designed furnace where a uniform heat can be obtained. When uniformly heated it may be hardened in a bath of the description shown in the answer to question 1, using water or brine instead of oil. A jet of water from the faucet or hose should be allowed to play down upon the surface of the bath, as otherwise the end of the roll that is uppermost in the bath will not cool as rapidly as the remainder. Hence, uneven contraction will result. When dipping in the bath the rolls should be held by a rod passing through the shaft hole. It is possible to pack several rolls in one hardening box and to heat several boxes at a time in an ordinary furnace, thus making the cost of heating comparatively low. After hardening immediately remove the tendency to cracking from hardening strains by reheating over a fire, turning the roll while heating to insure uniform temperature throughout; heat until a drop of water will form steam when placed on the surface. Allow the roll to cool in a dry, warm place where no current of air can reach it. In conclusion would say that unless a shop is provided with suitable equipment for doing this work and great care is devoted to it the results will be unsatisfactory. Probably no one class of hardening has given more trouble in the past than this.



* * *

An example of the beneficent effect of any medium that reduces shock and vibration is found in the rubber-tired carriage. Rubber tires for carriages have come into extended use during the past few years. They have the advantage of not only being noiseless, but the wear and tear on the body and wheels are greatly reduced. The shock to steel tires on an ordinary country road eventually loosens the spokes and wears the felloes, but with rubber tires all small obstructions are met yieldingly by the tires and the impact absorbed without transmitting the vibration to the wheels or body. It is claimed that while rubber tires are more expensive in the outset and for maintenance, the reduction in running repairs to other parts of carriages makes their use a positive economy.

* * *

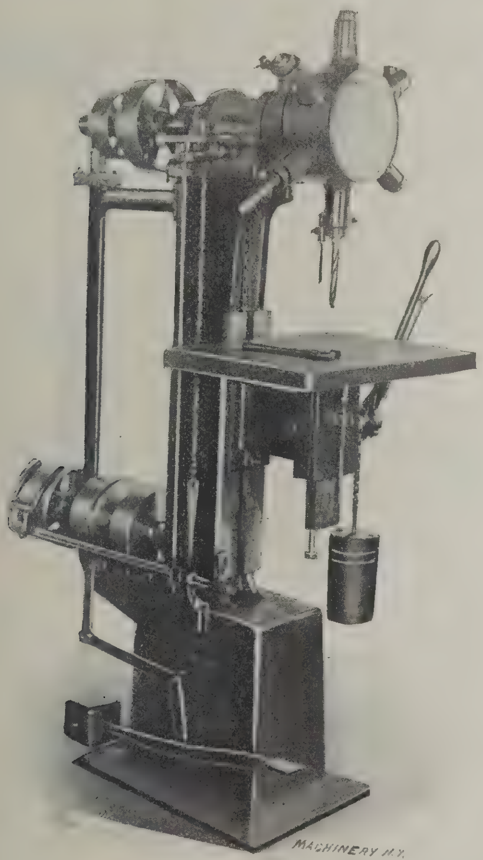
The enormous proportions of the Krupp Works at Essen, Magdeburg, Kiel, Annen and other places in Germany is more easily apprehended when it is considered that these works, and the coal mines operated in connection with them, had on the first of April, 1906, in their employ more than 62,500 persons, of whom more than 5,000 were officials and clerks. The company's principal plant in Essen consumes during one year as much water as does the entire city of Dresden, which has a population of over 400,000 inhabitants. It is also of interest to note for comparison with conditions in the United States that the average daily wage paid in 1905 to the workers in the cast steel plant was $1.22 per person.

MACHINERY AND TOOLS.

A MONTHLY RECORD OF NEW APPLIANCES FOR THE SHOP.

IMPROVED TURRET DRILL.

A. E. Quint, of Hartford, Conn., has redesigned his well-known turret drill, introducing, among other improvements, an improved feed arrangement to the work table, involving the use of a ratchet hand lever with an adjustable counter-balance which may be accurately adapted to work of any weight. The head follows the usual construction in this machine, and may be made for 6, 8, 10 or 12 spindles, of which only the one in actual use rotates. The machine is provided with back gears and reversing friction clutch for tapping, the clutch being operated by the pressure of the foot on the pedal for the reverse movement. The release of the foot allows the forward clutch to engage itself. The machine allows a maximum distance of 20 inches between the table and the end of the spindle. The distance from the center of the spindle



Quint Improved Turret Drill.

to the face of the column is 8¼ inches, the size of the table is 14 x 20 inches, and the weight of the machine ready for shipment is 840 pounds.

HEAVY AUTOMATIC PINION CUTTING MACHINE.

The machine of which a front view is shown in Fig. 1 and a rear view in Fig. 2, is built by the Eberhardt Bros. Machine Company, 66-68 Union Street, Newark, N. J. As indicated by the title, it is particularly designed to cut steel pinions of coarse pitches at a fast rate of feed, as fast, in fact, as the cutters will stand. It is therefore adapted to manufacturing purposes where quantities of similar gears are required to be cut, as in the case of car motor pinions, and for jobbing as well, since the machine is capable of cutting the coarse pitches in iron, bronze and steel up to its capacity, which is 30 inches in diameter. Ordinarily when buying a machine for cutting pinions exclusively, in order to obtain a strong enough spindle drive to cut 2 or 3 diametral pitch in steel with heavy feed, the purchaser has been forced to pay for a machine capable of taking a 60-inch gear at the least, even though his work may be entirely confined to small diameters. The machine shown herewith is in fact practically a 60-inch machine furnished with a short column and simplified in many details that would need to be elaborated somewhat if the full capacity were used. One of the simplifications to which attention might be called, for instance, is the arrangement of the ele-

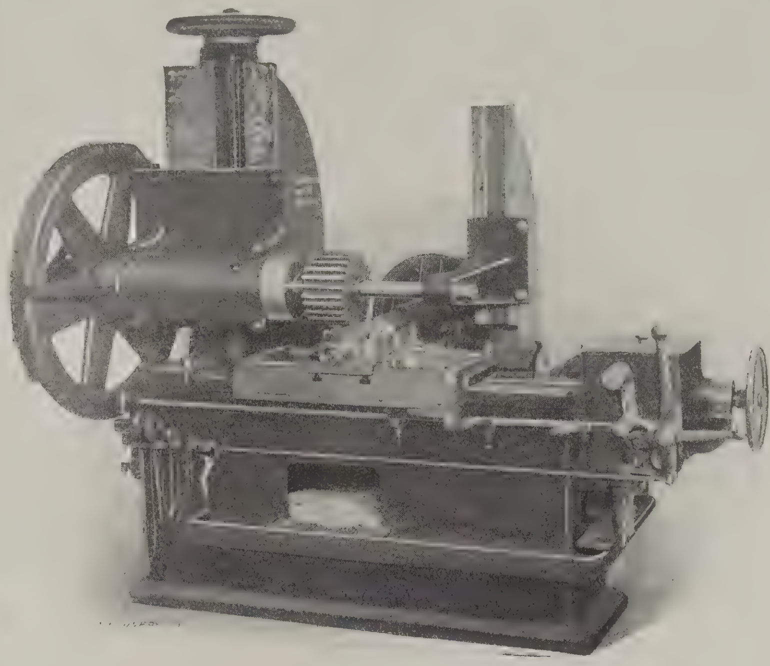


Fig. 1. Automatic Pinion Cutting Machine. Front View.

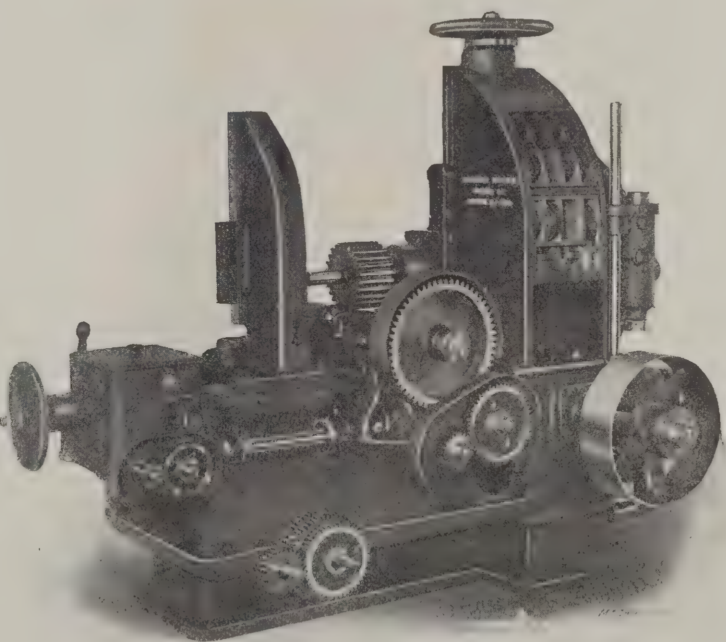

Fig. 2. Automatic Pinion Cutting Machine. Rear View.

vating screw and hand wheel for the work spindle saddle, this arrangement being possible on account of the shortness of the column.

Three of the prominent features of the design are the exceptionally long cutter slide with the spindle in the center, the placing of the thrust for the feed screw at the column end of the bed so that the slide is pulled instead of being pushed (a principle used throughout the design), and the unusually rugged drive for the cutter. In addition, the indexing and feed mechanisms are so constructed that the engagement of one precludes the simultaneous engagement of the other, thus

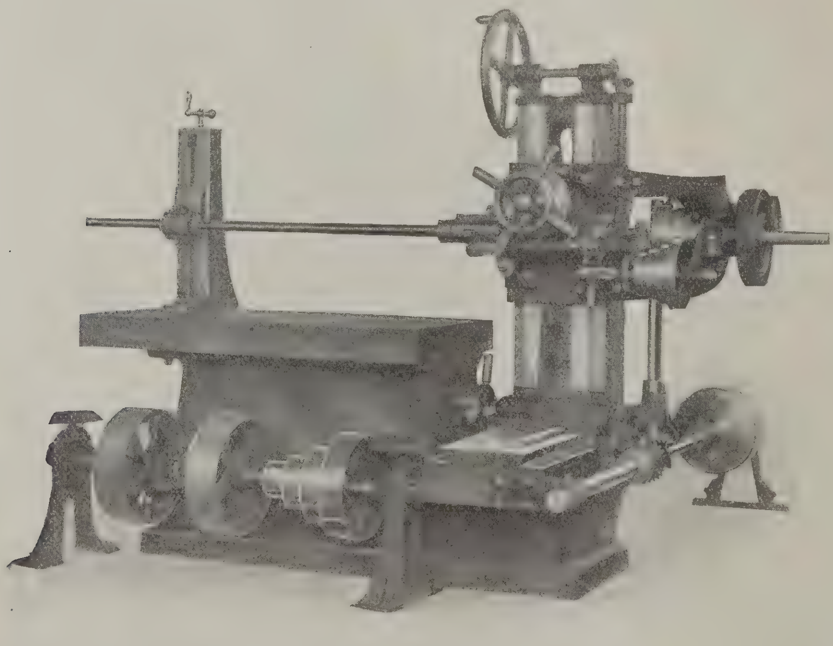
while the machine is indexing it is impossible for it to feed, and while the machine is feeding the indexing lever cannot be operated. These movements are automatically interlocked whether the machine is running or whether it is being adjusted by the workman.

The spindle driving arrangement is well shown in the rear view, Fig. 2. A large spur gear is mounted on the spindle, which is a tool steel forging of large diameter, and this gear in turn meshes with an elongated pinion below it, thus providing for lateral adjustment of the spindle and driving gear as a whole, and doing away with the necessity for a sliding key or keyway at this point. This lateral adjustment is so great, in fact, that it is possible to mount a roughing and a finishing cutter side by side on the arbor, as is done in the machine here illustrated. The changes in cutter speeds are obtained by change gears mounted as close to the spindle as possible. This permits the driving shafts to be kept at a constant high speed, subjecting them only to a comparatively light and unchanging torsional strain. The cutter speeds and feeds are, of course, independent, so that one may be changed without affecting the other. The spur gear for the spindle drive was adopted on account of its smooth running and high efficiency, as demonstrated by experiment.

The indexing wheel is of very large diameter, as can be seen, especially when compared with the range of work the machine is intended for. It is of the generated type and made very accurately. A graduated dial is provided reading to thousandths of an inch to facilitate the accurate setting of the depth to be cut. The work arbors are drawn in and forced out by means of the bolt at the rear of the work spindle. The frame of the machine is constructed to form an ample reservoir for the cutting lubricant. A special guard close up to the cutter compels the chips to fall directly into the base of the machine, from which they are removed either at the side or the front. Suitable strainers are provided for separating the chips from the lubricant.

NO. 2 BARNES HORIZONTAL DRILL.

The horizontal drill shown in the accompanying halftone is a recent product of the B. F. Barnes Co., Rockford, Ill. Its general arrangement is that of a horizontal boring machine. It has a stationary table 24 x 48 inches, to which the

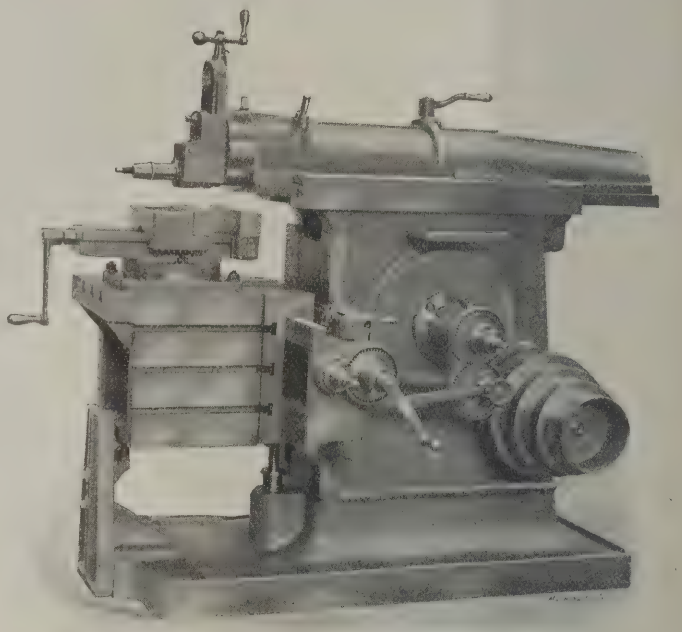


No. 2 Barnes Horizontal Drill.

work is clamped. The spindle is carried by a vertical adjustable saddle on a laterally adjustable column and has a longitudinal feed of 19 inches. The vertical adjustment of the spindle head is 18 inches. The feeding mechanism, located on the saddle, is power driven with an automatic stop, or may be operated by a hand wheel. All clamping levers and adjusting hand wheels are conveniently located and readily accessible to the operator from the front of the machine. A reversing friction countershaft is supplied with the machine. The spindle can be used at any point on a surface 36 inches long by 18 inches high. The spindle is 2 1-16 inches in diameter and is bored for a No. 5 taper. The cone pulley, for 3-inch belt, has the well-known internal back gear device used by this firm on its other drilling machines. The machine requires a floor space over all of 7 feet 6 inches by 8 feet 6 inches and weighs about 3,800 pounds net. The outboard boring bar support shown in the cut is furnished at extra cost.

TWENTY-ONE-INCH AVERBECK SHAPER.

The shaper shown in the accompanying halftone and built by the H. J. Averbeck Shaper Co., 52-56 E. Second Street, Covington, Ky., presents in its construction several unusual features. One of the most striking is the provision of an automatic stop for the table feed. A rod extends from end to end



Twenty-one-inch Averbeck Shaper.

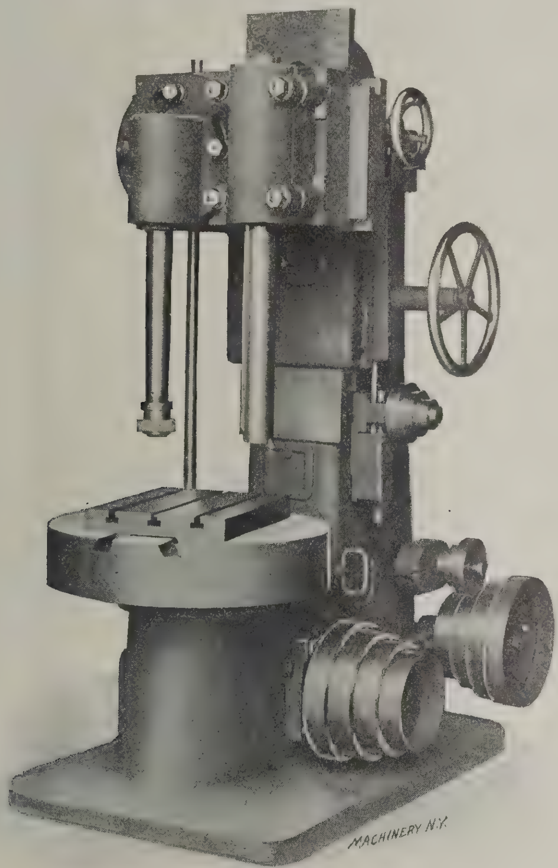
of the cross rail and on this are mounted adjustable dogs which come in contact with the table as it is fed in either direction, the resulting movement of the rod throwing the feed mechanism out of engagement. This enables the operator to adjust the machine for any length of cut he desires. Two stationary dogs are also provided which cut off the feed at the extreme travel of the table in either direction, so as to avoid all possibility of breakage of any part of the feed mechanism. The lever seen just above the gearing at the back of the rail is used to engage, disengage or reverse the feed. A "two to one" gear ratio is provided in the feed gearing which allows either a quick return or slow hand feed. Another novelty is in the design of the table support. This consists, as may be seen from the cut, of a vertical knee bolted to the base, carrying a roller in a vertically adjusted bracket on which the table is free to feed either to the right or to the left. This arrangement, while giving a firm outboard support, places the bearing surface in a position where it is not liable to be clogged with chips. The table is slotted on both top and sides, there being four of these slots on the top. The vise provided may be clamped on either side of the table or the table removed and the work clamped on the saddle.

The machine shown, which has a 21-inch stroke, may be shifted at will to work at a gear ratio of either 18 to 1, or 5 to 1. This, in connection with the 4-step cone, gives eight cutting speeds to the ram with a range of from 8 to 84 strokes per minute. The cross feed connecting rod is automatically

adjustable to any height of rail through the operation of the guide rod. The length of the stroke and position of the ram can be changed at any time from the working side of the machine. The extreme length of stroke is 21½ inches, the horizontal travel of the table is 26 inches, the vertical adjustment is 16 inches, while the feed of the tool block is 8 inches. The machine will take a 3⅛-inch shaft under the ram for key seating. The top surface of the table is 21¼ x 16 inches and the weight of the whole machine is about 3,200 pounds.

SAXON CYLINDER GRINDING MACHINE.

The Saxon Machine Co., 32 Main St., Room 10, Holyoke, Mass., have designed the machine illustrated for the special purpose of performing internal grinding operations on gas and gasoline engine cylinders, air compressor cylinders, and other similar surfaces which must be true, in good alignment, and accurately finished. It grinds to the center of a 24-inch circle and to a depth of 18 inches, regardless of the shape of the



Saxon Cylinder Grinding Machine.

work. The machine has, as will be seen, the general form of a vertical boring mill, including as it does an upright column provided with a slide for carrying the grinding spindle, with a rotating table at the base to which the work is attached. The main frame is a solid casting with a base for the faceplate and a column for the cross rail. The revolving faceplate has its bearings well protected from dust and is driven by the cone pulleys on the right side of the machine. It can be furnished with two sets of three T-slots each, crossing each other at right angles, or will be provided with a sliding table as shown. With this latter arrangement, duplex cylinders can be ground without altering the setting of the work. The cone pulleys provide eight speeds for the table. If desired, a geared speed box may be used in place of it.

The grinding spindle is of crucible steel, accurately turned and ground, and is carried by a sliding head attached to the cross rail. The bearings are of a special metal superior to phosphor bronze for this work. They are adjustable and protected from the dust. The feed of the head on the cross rail is accomplished by a screw with a dial graduated to thousandths of an inch. The traverse of the head is automatic, being controlled by a reversing rod actuated by dogs, which may be placed in any desired position, or it may be operated by hand with a lever provided for that purpose. Six rates of speed are provided for each speed of rotation of the work. These are obtained by the small cone pulleys shown or by a geared speed box, which will be furnished instead if so ordered. All the adjustments can be made from the operating

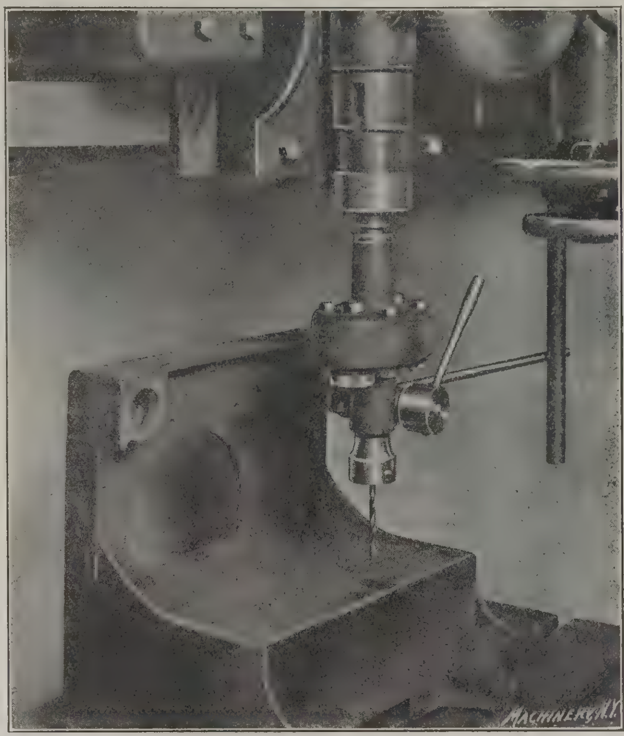


Fig. 1. Graham Drill Speeder in Operation.

side of the machine. The boring bar is an extra attachment which converts the machine into a boring mill for the roughing operations. The net weight of the machine is about 4,000 pounds.

THE GRAHAM DRILL SPEEDER.

Fig. 3 shows a halftone and Fig. 2 a line cut of the device shown in operation in Fig. 1. Its makers, The Graham Mfg. Co., Providence, R. I., call it a "drill speeder," and its purpose, as indicated by its name, is to allow the use of small drills at high speeds in machines which would ordinarily be too heavy and slow of movement for the work desired. A

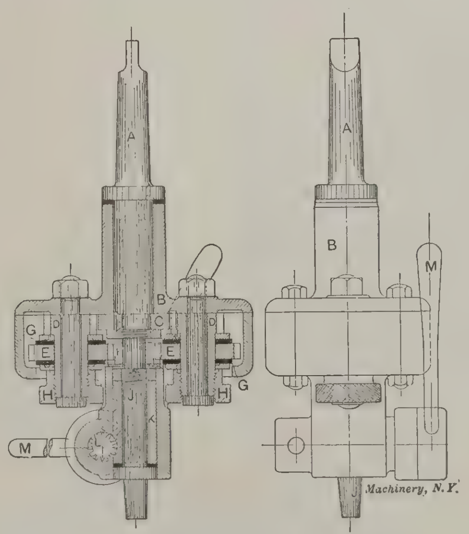

Fig. 2. Design of Graham Drill Speeder.

common condition met with by the machinists in the ordinary run of work is that of drilling oil holes 1-16 or ⅛-inch diameter in large castings which have considerable work to be done on them by the radial drill. Not only does the spindle of such a machine move too slowly for the work desired, but there would be difficulty in safely feeding so small a drill

with the large feed mechanism. This device gives, in such a case, the requisite speed and the required sensitiveness of feeding. The main body B is of cast iron. The upper part forms a bearing for the spindle A, which has a tapered shank and fits in the hole in the end of the machine spindle. The lower end of the casing forms a bearing for sleeve K, which carries the high-speed spindle. This sleeve is fed by the small pinion L with its attached handle M, in the same way that a sensitive drill press spindle is fed. A spring is provided which always returns handle M to its upper position. The high-speed spindle J is splined for a key in pinion F, but is free to move up and down, the upper end having a bearing within main spindle A as shown by the dotted lines. Gear C keyed to the lower end of spindle A through gears D and E, drives pinion F and through it spindle J at an increased rate of speed, in a way that will be readily understood from the cut. Gear E is not keyed to the hub on pinion D, but is prevented from turning on it by the pressure of friction washers G. This friction may be adjusted to any required degree by means of knurled nuts H, which project through the lower side of the gear casing.

Fig. 3 Graham Drill Speeder.

The device shown is the result of evolution, various designs having been tried out until a satisfactory arrangement was developed. The speeder is made in two sizes. No. 1 size has a speed ratio of 4 to 1 with a capacity for drills up to ¼ inch. The shank has a No. 3 Morse taper, with the speeder spindle fitted for a standard chuck. The length exclusive of the taper is 8½ inches and the weight 14 pounds. The No. 2 has a ratio of 3 to 1, with a capacity up to ½ inch. Its weight is about 18 pounds.

THE CATARACT BENCH MILLING MACHINE.

The bench milling machine shown in Fig. 1 is manufactured by Hardinge Bros., 1034 Lincoln Ave., Chicago, Ill., and is designed for general use by watch and clock manufacturers, instrument and toolmakers, and others having small accurate work to do. It is made, in part, of attachments provided for the new Cataract bench lathe, the headstock being the same as that used for the lathe; it has a half-inch hole through the spindle. The table of the machine can be lowered to 7 inches from the center of the main spindle; it is 12 inches long and is provided with three T-slots. All the screws have dials graduated to thousandths of an inch, making the machine valuable for use in laying out jigs and in die work.

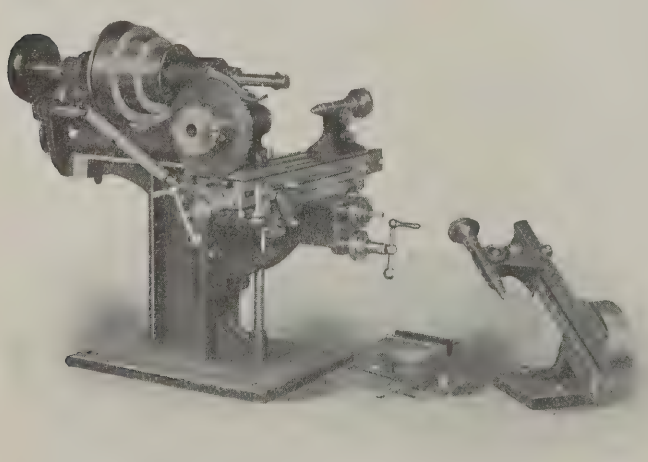

Fig. 1. Hardinge Bros. Bench Milling Machine.

The dividing head is 2½ inches from the center line to the table, and it carries a 4-inch index plate. The spindle is bored to receive a split chuck of the same design as that used in the lathe headstock and in the spindle on the same machine. This dividing head may be used in connection with the adapter shown at the right in the cut. This device allows the tailstock and index head to be set together at any angle up to 45 degrees, making it suitable for taper reamer and tap work. A small vise is provided for this machine, so that a great variety of operations may be easily performed.

The milling attachment to the regular Cataract bench lathe is built, as shown in Fig. 2, on the same general lines, being identical in every respect with the exception of the main frame. It will be noticed that to get the proper height for the frame above the bench the head stock is raised 3 inches above the top of the bed. Attention is also called to the countershaft arrangement here shown, which is provided with the lathe when desired. This countershaft has a cone at the right which is driven by a pair of gears and may be raised to the proper amount, so that the head can be taken from the bed and placed on the milling machine attachment without having to change the length of the belt. The same attachments as are used with the lathe are adapted for use with the milling machine.

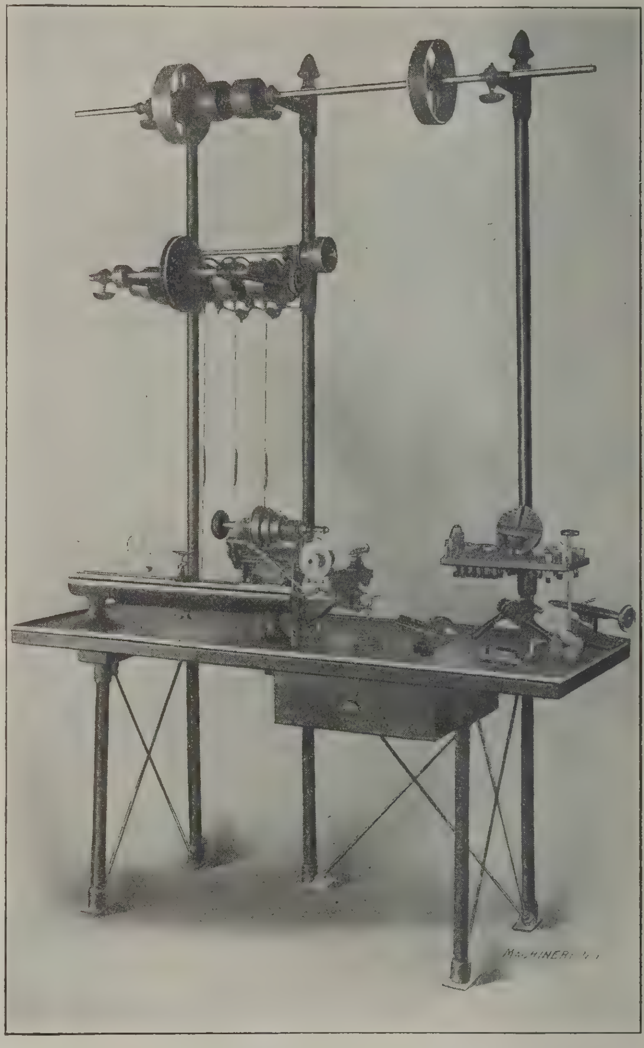

Fig. 2. Hardinge Bros. Bench Lathe Milling Attachment.

STANDARD 14-INCH CHAMPION ENGINE LATHE.

This lathe, of which a halftone view is shown in Fig. 1, is the product of the Champion Tool Works Co., 2420 Spring Grove Ave., Cincinnati, Ohio, and is designed to meet present-day conditions. The spindle, which has a 1 9-16 inch hole throughout its length, is of hammered crucible steel with round journals revolving in phosphor bronze boxes. Feeds can be reversed in either the apron or the head, and the apron mechanism is so arranged that the rod and screw feeds cannot be engaged at the same time. As shown in Fig. 2, lever B engages the slot in quill D, which is mounted on the splined feed rod. This quill carries the two bevel gears, E and E', either of which may thus be made to engage with large bevel

gear *F* of the feed gear train in the apron. Only when lever *B* is in the central position, and the bevel gears *E* and *E′* are out of mesh with gear *F*, can split nut *C C′* be closed upon the lead screw. The automatic stop is actuated by collars on the splined feed rod which may be clamped at any point on its length. This feed rod *W* has a limited end movement in either direction from the central position shown. Springs *X* and *X′*, bearing on collars *Y* and *Y′*, keep the rod in this central position normally. Gear *U* revolves loosely on *W* and is driven by gear *T* on the shaft above it. This gear *U* is provided with an internal chamber having clutch slots adapted to engage with a transverse driving pin in the feed rod. When the feed rod *W* is shifted to either side of the central position by the apron mechanism striking either of the adjustable collars, the driving pin is disengaged from the clutch slots in *U* and the motion of the rod is arrested. Either of gears *Q*, *R*, and *S* may be engaged with a mating gear on shaft *O*, thus giving three changes of feed.

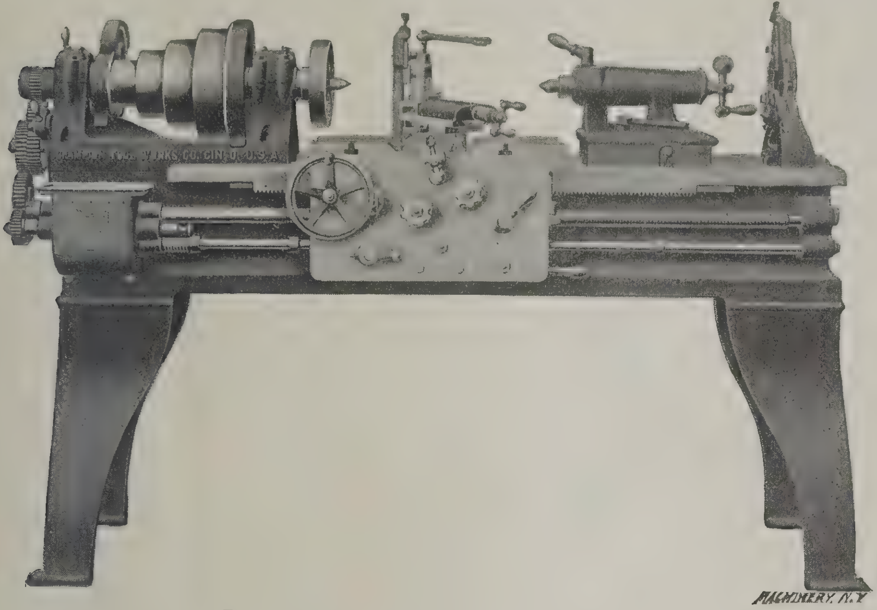

Fig. 1. Standard 14-inch Champion Engine Lathe.

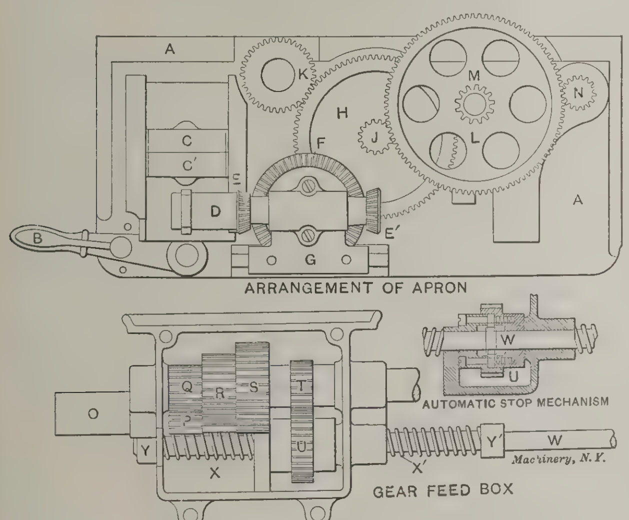

Fig. 2. Details of Champion Engine Lathe.

The machine, as shown in Fig. 1, has a 6-foot bed with a swing of 15 inches over the ways. The four-step cone is designed for a 2½-inch belt. The back gear ratio is 9 3-16 to 1. The net weight of the lathe with a 6-foot bed is 1,500 pounds.

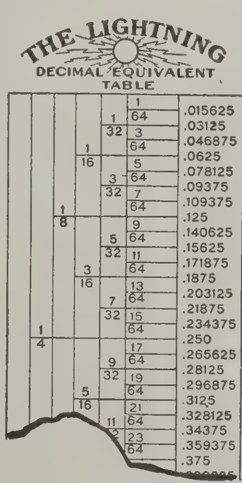
ADDITIONS TO THE LINE OF BICKFORD PLAIN RADIAL DRILLS.

In Machinery for January, 1906, was published a description of a line of plain radial drills developed by the Bickford Drill and Tool Co., Cincinnati, O. One of the prime features of the design was a speed change device in which the gearing was so proportioned that the revolutions per minute for any size drill is obtained with a great degree of exactness. The arrangement of the mechanism was also such that changes could be made instantly without shock, even while the machine was running at full speed. The 4-foot, 5-foot and 6-foot sizes of the Bickford plain drills have been redesigned along similar lines, the principle of the speed box being identical with that on the smaller machines. A somewhat different arrangement of the head is used on these larger sizes, however.

The feeding mechanism furnishes eight rates of feed ranging in geometrical progression from 0.007 to 0.064 inch per revolution of the spindle. Any one of these feeds is instantly available. The tapping mechanism is located in the head and permits the backing out of taps at any speed with which the machine is provided, regardless of the speed used in driving them in. It is operated by a friction clutch controlled by a lever within convenient reach of the operator. A depth gage is provided, which serves a double purpose. It is in the form of a graduated circular T-slot in a disk geared with the feed rack in such a way that its relative position with relation to the spindle is always constant. Besides enabling the operator to read all depths from zero without the usual delays necessary when scaling or calipering, it supplies a convenient means for setting the automatic trip. The graduations show exactly where each should be located to stop the feed at the desired points. This trip operates at as many different points as there are depths to be drilled at one setting of the work. In addition, it leaves the spindle free to be advanced or raised throughout its full length without disturbing the setting of the dogs. It also throws out the feed when the spindle has reached the limit of its movement.

HANDY TABLE OF DECIMAL EQUIVALENTS.

W. E. Gould, 142 Hazelwood Avenue, Detroit, Mich., has devised and copyrighted the "Lightning Table of Decimal Equivalents" of which a section is shown in the accompanying line cut. The original is about 4 inches long and has its edge graduated after the fashion of a 1-inch rule, although, of course, this makes the scale four times as great as the original. Each of the different fractions up to 1-64th, namely, the halves, quarters, eighths, sixteenths, thirty-seconds and sixty-fourths, has its own column in which the fractional quantity is placed. The decimal equivalents are in a vertical column at the extreme right. This arrangement is very convenient for quick reference, since it takes advantage of the user's already acquired quickness in reading a rule graduated in the ordinary manner, and has all fractions of the same denominator arranged in the same vertical column. It should prove useful to machinists, draftsmen, etc., and may be tacked up on the belt shifter, cemented to the T-square, or fastened in any other position for ready reference. Although printed on opaque celluloid, the marking is protected in such a way that it is permanent. The price is 15 cents.

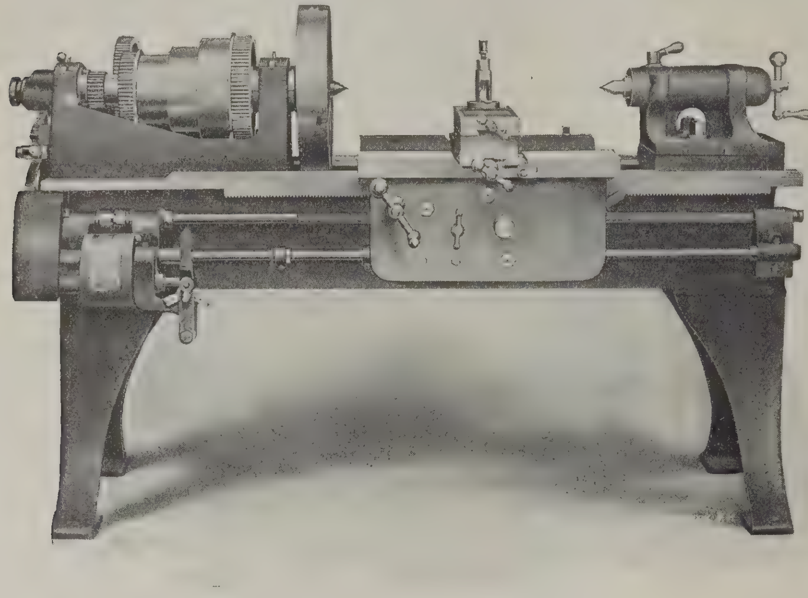


Handy Table of Decimal Equivalents.

THE WHITCOMB-BLAISDELL 16-INCH ENGINE LATHE.

This lathe is one of a new line which the Whitcomb-Blaisdell Machine Tool Co., Worcester, Mass., have recently brought out to supersede the various other designs which they have hitherto built. The distinguishing features of this line are the rigidity of the design, the increase in effective belt power,

and greater facility of operation. The beds are of the box pattern. The increased power of the lathe is obtained by the use of double back gears with a three-step driving cone carrying a wide belt. Nine changes of speed are thus obtainable and the effective belt power at the different speeds is much more nearly equal than is the case where a four- or five-step cone is used. The smallest cone diameter is sufficiently great



Whitcomb-Blaisdell 16-inch Engine Lathe.

to give ample belt contact at the high speeds, so that on the other steps an excess of power is provided.

The feed mechanism has been strengthened throughout to agree with the increase in spindle power. Five changes of speed are instantly obtainable through the lever under the headstock. The friction which controls the feeds is self-adjusting and in such a position as to be easily and safely operated. An automatic stop is provided. A friction countershaft, large and small faceplates, and the necessary wrenches are furnished with each lathe. The swing over the bed for this machine is 18¼ inches, although it is rated on the 16-inch basis. There is a 1¼-inch hole through the spindle. The machine with a 6-foot bed weighs 2,100 pounds.

EVERETT McADAM CONTINUOUS ELECTRIC BLUE-PRINTING MACHINE.

A new blueprinting machine of the continuous type having a number of novel and interesting features is shown in the accompanying cuts, Fig. 2 being an elevation and Fig. 1 a line cut which shows the principle of the device. The result sought in the design of the machine is the ability to use blueprint paper directly from the roll without cutting into sheets, and to feed this paper to a continuously acting machine, to which the tracings are supplied continuously and as rapidly as the printing can be done. As shown, the roll of paper is contained in a box at the top of the machine, feeding out through an opening at the bottom. The box is light-tight and protects the paper when it is not in use. In the center of the machine is a large rotating cylinder of glass within which are mounted two mercury vapor lamps whose light, intensified by a reflector at the front, is used by making the prints. Four drums are placed around this central rotating cylinder with their axes parallel with it and a series of narrow belts run over these drums and around the cylinder, in such a way as to furnish a means for tightly holding the paper

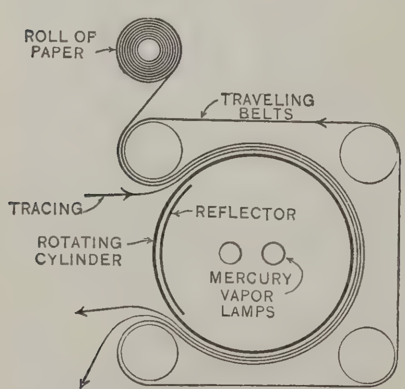


Fig. 1. Diagram of Electric Blueprinting Machine.

and the tracing beneath it to the revolving glass surface. As shown by the arrows in Fig. 1, the tracings are inserted between the paper and the belts at the upper part of the machine, and are delivered below, both feeding and delivery being at the front. Three-fourths of the surface of the glass cylinder is utilized for printing. The glass cylinder and the belts are kept in motion by a small electric motor having a variable speed controller which may be instantly changed to suit the depth of printing desired, the sensitiveness of the paper used, or the transparency of the tracing from which the print is made.

With this description of the machine in mind the advantages of the arrangement will be readily apparent. The blueprint paper itself, in continuous printing, is not touched by the hands; it feeds in of itself. There is no limit to the length of print which may be made. The machine being five feet long, a print may be made five feet wide and the length of a roll of blueprint paper. The mercury vapor lamp used requires no more attention than an incandescent lamp and has no carbon to renew. Inasmuch as the printing is done from the inside of the cylinder on the concave surface, all the rays strike the surface at practically right angles. All of the rays emitted by this form of lamp used are actinic, so that most effective transformation of electricity into chemical action is obtained. The machine is self-contained. To be put in operation it merely needs to be connected to the nearest electric light circuit, when both the motor and the lighting apparatus are ready for operation. Not only is this action continuous so far as the feeding of the paper is concerned, but its construction makes it unnecessary to use the "apron," found on some other machines, which has a limited

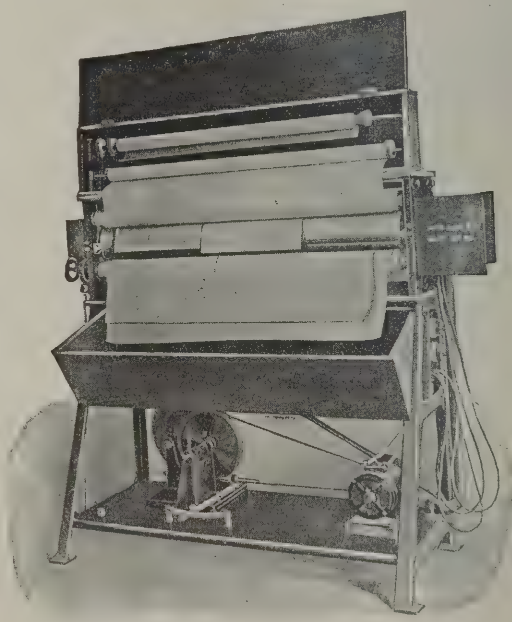

Fig 2. Everett-McAdam Electric Blueprinting Machine.

length and requires to be re-rolled after a certain period of operation, and to be renewed occasionally after a considerable period of service. It must not be thought that printing from the roll on sensitized paper is absolutely necessary; for any case where but one or two small prints are required, cut sheets may be fed to the machine in the same way as with other forms of automatic blueprinting machinery. A point which might be mentioned is that in printing from large tracings of which several reproductions are required, the leading edge may be fed back into the machine again as the trailing edge disappears, without wasting an inch of the sensitized paper, and still preserving the continuous printing feature.

The makers of this device, the Revolute Machine Co., 523 West 45th St., New York, state that, although the machine

has been on the market less than a year, there are already forty of them n daily use. The increased demand has made necessary the organization of this firm, which has equipped a shop exclusively for building them. The machine is very compact, requiring only a floor space of 2 feet by 5 feet.

DEDICATION OF THE NEW ENGINEERING BUILDING OF THE UNIVERSITY OF PENNSYLVANIA.

The University of Pennsylvania, on October 19, dedicated their new engineering building. The erection of this building was determined upon originally owing to the increasing needs of the engineering courses, and its early completion was made absolutely necessary by the burning of the former building devoted to the subject; it has been planned with the utmost care for the purposes to which it is devoted, by Prof. Spangler of the mechanical and electrical engineering courses, and Prof. Marburg, who fills the chair of civil engineering. The arrangement of this building and its laboratory equipment, in many respects unique, will be described with more or less detail in an early issue of MACHINERY.

The building, which had been decorated for the occasion, was opened for private view, throughout the day to the guests of the university. After a luncheon at 12:30 the dedicatory exercises were held in the large assembly room on the second floor. The invited guests, consisting of representatives of foreign countries and delegates from various schools and scientific societies, assembled there to witness the conferring of the degrees and listening to the addresses prepared for the occasion. The degree of Doctor of Science was conferred on Marie Michel Henri Vetillart, Alexander McKenzie, Charles Whiteside Rae, John Fritz, Mansfield Merriman, Samuel Matthews Vauclain, Frederick Winslow Taylor, Frederick Pike Stearns, Samuel Sheldon, Henry Wilson Spangler, Edgar Marburg, and Ramon Ivarrola. The addresses of the occasion were delivered by Frederick W. Taylor, who spoke on "A Comparison of University and Industrial Discipline and Methods," and by Alexander C. Humphreys, whose subject was "The Engineer as a Citizen."

* * *

FIFTH ANNUAL CONVENTION OF THE NATIONAL MACHINE TOOL BUILDERS' ASSOCIATION.

The National Machine Tool Builders' Association met in New York October 9 and 10 for their annual convention, the headquarters being at the Hotel Breslin. Papers were read and discussed on various subjects of interest to the trade. One on apprenticeship was read by Mr. E. P. Bullard, Jr., of the Bullard Machine Tool Co., being a continuation of the work started at Atlantic City last spring. The committee on apprenticeship was continued. Mr. J. N. Gunn, of Gunn, Richards & Co., New York, was introduced by Mr. Fred. A. Geier, of the Cincinnati Milling Machine Co., to speak on costs and cost-keeping. Mr. Geier added some remarks urging the desirability of a more uniform method of keeping costs in machine tool shops, and his remarks were supplemented by Mr. Rivett, of the Rivett Lathe Mfg. Co. The general report was that the machine tool business is thriving all over the country. The following officers were elected for the coming year: President, E. M. Woodward, Woodward & Powell Planer Co., Worcester, Mass.; secretary, P. E. Montanus, Springfield Machine Tool Co., Springfield, Ohio; first vice-president, Wm. Lodge, Lodge & Shipley Machine Tool Co., Cincinnati, Ohio; second vice-president, F. E. Reed, F. E. Reed Co., Worcester, Mass.; treasurer, W. P. Davis, W. P. Davis Machine Co., Rochester, N. Y. The usual entertainments of the delegates were tendered by the *American Machinist* and MACHINERY. The location or time for the next convention was not definitely decided upon.

* * *

MACHINERY'S ANNUAL OUTING.

Four hundred and thirty-odd machine tool builders, mechanical engineers and others identified with machine construction and distribution in some capacity or other, accepted MACHINERY's invitation for its annual outing on October 10, and most of them were on the steamer *Sagamore* when she left Twenty-first Street for West Point on the forenoon of that day, the afternoon and early evening being spent on the trip, covering a distance of one hundred and eight miles. About an hour and a half was spent at the nation's Military Academy, looking over the grounds and watching the training of Uncle Sam's future lieutenants, captains, majors and generals. All who could be gathered together were grouped on a steep and slippery hill behind a battery and shot at by a man with a 12 x 22 camera. Some escaped.

These outings were instituted by MACHINERY for the purpose of bringing together people who are particularly interested in machine tools and kindred lines, so as to promote good fellowship in the trade and enable those who attend to greet their old friends and make new ones. In this and other ways the outing appears to have been a success, and MACHINERY was proud of the fine body of representative men whom this occasion brought together.

* * *

PERSONAL.

Carl H. Au, instructor in mechanical engineering, Worcester Polytechnic Institute, has resigned to accept a position with the American Steel & Wire Co., of Worcester, Mass.

Louis H. Frick, Cheyenne, Wyo., has resigned as assistant superintendent of the American District Steam Co., to accept the position of manager of the Cheyenne Light, Fuel & Power Co.

Louis Block, for twenty-four years with the De La Vergne Machine Co., New York, and for more than twenty years at the head of its engineering department, has opened an office at No. 45 East 42d Street, New York, to serve clients in the capacity of consulting engineer.

FRESH FROM THE PRESS.

HENLEY'S ENCYCLOPEDIA OF PRACTICAL ENGINEERING AND ALLIED TRADES. Edited by Joseph G. Horner. Volume 1 (A-Boi) and 2 (Boi-Fil), each containing 240 pages 7½ x 9½ inches, profusely illustrated. Published by Norman W. Henley & Son, New York. Price per volume, \$6.00; \$25.00 for the set of five.

This work, which is to be completed in five volumes, necessarily is broad in scope, and simple and practical in its treatment of technical subjects, being intended for everyday use by craftsmen and others having to do with practical engineering. The subjects are arranged alphabetically in the usual encyclopedia style. The complete work will contain upwards of 10,000 topics, 2,500 pages, and nearly 3,000 engravings. Mr. Horner, the editor, is a well-known English writer and compiler of technical literature, and it may be said that he has devoted his energies conscientiously to this work in review. The work, although "shoppy," is distinctly English in its tone, but this is not particularly disadvantageous, for English engineering practice is well worthy of the study of American mechanics. Many of the illustrations are halftones printed on plate paper, a feature which adds distinctly to the value and worth of the work. The subjects treated mathematically, such as thermodynamics, beams, steam, etc., were written by men who combine experience of a practical character with scientific training. The method of treatment, which has been adopted, avoids the evils of very long articles on any one subject; instead of treating the subject of engines or lathes or machine tools, for example, in one comprehensive article, a general survey only is given under those heads, and then each type of engine or lathe or machine tool is treated separately under its proper heading, such as blast engine, axle lathe, planing machine, etc. This makes the finding of a specific subject simpler than when treated exhaustively under one head.

RAILWAY ORGANIZATION AND WORKING. Edited by Ernest R. Dewsnup. 498 pages, 5 x 8 inches. Published by the University of Chicago. Price \$2.00.

This book is a compilation of special lectures delivered before the classes of the University of Chicago on the subject of railway transportation during the period extending from November, 1904, to May, 1906. These were delivered by officials of various railway systems and have been brought together and edited by Mr. Dewsnup in the form of an attractive but not wholly balanced volume treating authoritatively, in a sense, upon various features of railway organization and working. The subjects by chapters are as follows: The Work of the Law Department of a Railroad Company; The Passenger Department; Railroad Advertising; Suburban Passenger Service; The Industrial Commissioner; The Problem of Handling Less-Than-Carload Freight Expeditiously and Economically at Terminal Stations; Office Work in Terminal Yards; Car Distribution and the Supervision of Fast Freight; The Problem of Car Service; Freight Claims; Some Notes on Freight Rates; Organization of the Operating Department of Railroads; The Purchasing Agent: Ballast; Railway Terminal Facilities; Railroad Signaling; Classification of Types of Locomotives; The Compound Locomotive; Car Construction; Duties of a Controller or Chief Accounting Officer; The Auditor of Expenditures; The Work of the Freight Auditor; Vitalized Statistics; Railway Development in Canada; Railway Education; Appendix.

MANUAL OF WIRELESS TELEGRAPHY, by A. Frederick Collins. 232 pages, 2¾ x 7¼ inches, 90 cuts. Published by John Wiley & Sons, New York. Price \$1.50, cloth; \$2.00, morocco.

The book has been written for the purpose of giving a clear idea of the principles and apparatus used in wireless telegraphy to general readers, but more especially to those who would become wireless telegraph operators or experimenters. The description of an experimental wireless telegraph which can be constructed at small expense will interest amateurs and experimenters. The elementary theory is discussed at some length, following which the book describes the various wireless telegraph systems, including the Marconi, DeForest, Telefunken, Clark, and Fessenden. A chapter is devoted to adjusting and operating the instruments which, of course, is a very important part of an operator's knowledge. Examples of the wireless telegraph alphabet, which differs somewhat from the regular Morse alphabet, are given. It includes a list of stations equipped with Marconi apparatus and a sample chart for April, 1906, showing the intersections of

points of earliest communication on the Atlantic with the various steamships equipped with a Marconi apparatus. The book concludes with a glossary of wireless telegraph words, terms and phrases. It is a readable and, we believe, reliable work on the subject and just what a practical man interested in the subject would like to get hold of.

NEW TRADE LITERATURE.

Chas. A. Strelinger & Co., Detroit, Mich. "Book of Tools," being a 550-page catalogue of tools, machinery and supplies.

Saxon Machine Co., 32 Main Street, Room 10, Holyoke, Mass. Pamphlet describing and illustrating Nos. 2 and 3 surface grinders. Dimensions for same are included.

The Tabor Mfg. Co., Eighteenth and Hamilton Streets, Philadelphia, Pa. Catalogue illustrating and describing the Tabor hinged machine, its operation, sizes and special features.

Warner Instrument Co., 56-59 Roosevelt Avenue, Beloit, Wis. *Auto-Speed*, a monthly magazine devoted to the interests of the autometer and containing items of interest to automobilists.

Newhall Chain Forge and Iron Co., 9 Murray Street, New York City. Catalogue No. 101, descriptive of hand forged crane, block and hoisting chain and method of manufacture.

Latshaw Pressed Steel and Pulley Co., Pittsburg, Pa., have issued a new folder giving price list of the Latshaw steel split pulley and illustrating the six-, twelve-, eight- and sixteen-arm pulley.

Fay & Scott, Dexter, Me. New catalogue No. 12, treating standard engine lathes. Special features of these lathes are outlined in the first part and specifications and illustrations of the different sizes follow.

Ingersoll-Rand Co., 11 Broadway, New York City. Catalogue No. 45 B—Rock Drills, describes these tools in full and illustrates them working in various excavations, as the Hudson River tunnel, construction of the Eastern Chinese Railway, etc.

Coates Clipper Mfg. Co., Worcester, Mass. Bulletin No. 20, describing worm feed drill press, flexible shaft buffing outfit, flexible speed multiplying grinder, and other apparatus for flexible transmission.

The Milwaukee School of Trades, Inc., 156 Clinton Street, Milwaukee, Wis., have issued a prospectus for the year 1906-1907. The book sets forth the purpose of the school, its organization, maintenance, etc., and outlines its system of instruction and the courses offered.

Crocker-Wheeler Co., Ampere, N. J. Bulletin No. 69 describing a specially arranged generator for direct connection to steam or gas engines. These generators are built in sizes to give outputs of 1½ K.W. to 19 K.W. and meet the demand for small direct connected units for isolated plants and residences.

The Cincinnati Planer Co., Cincinnati, Ohio, have issued a new catalogue descriptive of their line of planers. These planers have been redesigned with special reference to high speeds. Attention is also called to the variable speed planers, several types of which are illustrated.

The Joseph Dixon Crucible Co., Jersey City, N. J., publish an interesting pamphlet on the subject of steam traps. It is an illustrated description of the several varieties, with valuable suggestions by W. H. Wakeman, expert steam engineer and author of well known books on steam engineering.

The Gleason Works, Rochester, N. Y., have given us something out of the ordinary in their new catalogue on gear planers. This is most attractively gotten up in its artistic arrangement and in the high grade of cuts used. The descriptive material is confined to the front of the book, halftones of the various planers following, and line cuts showing mandrels used on the planers completing the material.

E. R. Markham, 66 Dana Street, Cambridge, Mass. Folder announcing that Mr. Markham will give advice in machine shop methods, designing special machinery and tools, hardening, tempering and annealing steel. Those who wish to consult him should advise him of the questions to be answered and he will notify them of the fee required.

Bulletin No. 139, which has just been issued by the B. F. Sturtevant Co., of Boston, Mass., in its engineering series, presents a full line of generating sets driven by direct-connected vertical enclosed engines with forced lubrication. The published list contains fourteen sizes ranging from 3 to 50 K. W. in output; the former driven by a 3½ x 3 engine and the latter by a 12 x 10. All of the engines were especially designed for generator driving.

Sprague Electric Co., 527 W. 34th Street, New York City. Pamphlet No. 314 on electric motors for driving ventilating fans and blowers, giving general descriptions of a few types of motors and including a list of installations of ventilating apparatus operated with the Sprague Electric Co.'s motors. Bulletin No. 219 takes up round type direct current motors. This includes description of the motors, specifications for different types and illustrations of the application of these motors to various machines.

Montgomery & Co., 105-107 Fulton Street, New York City, have issued a novel form of catalogue, No. 24, listing Grobet Swiss files, machinists' hand taps, music wire, emery wheels, twist drills, etc. This matter is arranged in tabulated form on two folders pasted within a strong manila cover. The pages of the folder, starting with the one pasted to the cover, are of decreasing width so that the titles of the pages form an index, showing at a glance where the particular table or list is to be found. The convenience of the arrangement can only be appreciated by an examination of one of the folders. They are sent to any address upon application.

The S. Obermayer Co., with factories in Cincinnati, Chicago and Pittsburg, have recently placed on the market a new factory riddle which is stronger and has greater wearing qualities than any riddle heretofore manufactured. The main feature of the new riddle is that the rim and liners lap; a strip of galvanized iron is bent squarely over them which prevents the joints catching and breaking when brought into contact with other objects. The name adopted for the new riddle is the "Rockwell." Descriptive circulars will be sent upon request.

The Yale & Towne Mfg. Co., 9 Murray Street, New York City, have conceived an original idea of assisting their dealers to market goods sold to them. They issue a booklet entitled "Suggestions for Selling Yale Padlocks," in which they tell their dealers the means that they have prepared to secure the buyers' attention. These include some printed matter; a book about padlocks, containing many suggestions for the uses of padlocks; a catalogue of the complete line of Yale & Towne padlocks; for those who do not care to read technical descriptions a story entitled "The Little Black Box" illustrating the merits of the Yale padlocks. Package labels, envelopes, etc., are also supplied. All of the above matter is given to the dealer free of charge and his name and address printed upon it.

The American Locomotive Co., 111 Broadway, New York City, have just published a pamphlet, "Consolidation Type Freight Locomotive," which describes and illustrates a large number of the consolidation locomotives built by the company for various railways. The description includes only consolidation locomotives weighing less than 175,000 pounds; it will be followed shortly by a pamphlet illustrating locomotives of this type weighing more than 175,000 pounds. The present pamphlet opens with a description of the 2-8-0 type, giving its distinguishing characteristics and special advantages for heavy freight service, or service on light rails where the wheel load is limited. The principal dimensions of thirty consolidation locomotives ranging in weights from 66,000 to 175,000 pounds are given; the tables being arranged in order of weights. Side elevation and end elevation drawings of the typical design are shown and the remainder of the pamphlet is taken up with halftones of the thirty locomotives mentioned in the tables. This pamphlet is the third of a series to be issued by the company and which will include all the standard types of locomotives and constitute a record of its production. Copies of the pamphlet already issued on the Atlantic, Pacific and Consolidation types may be had upon request.

MANUFACTURERS' NOTES.

The Whitman & Barnes Mfg. Co., Chicago, Ill., announce the removal of their New York office from 111 Chambers Street to 59 Center Street.

The Whitney Mfg. Co., Hartford, Conn., are making unusual preparations for 1907, having in process new methods, new machinery, and a new modern fire-proof factory building.

The Jeffrey Manufacturing Co., Columbus, Ohio, have established a new Canadian branch office in Montreal, Canada, at Lagauchetiere and Coté Streets.

The Von Wyck Machine Tool Co., Cincinnati, O., lathe manufacturers, are erecting a large addition to their plant which will enable them to more than double their present output.

The firm of Maris Bros., 56th Street and Gray's Avenue, Philadelphia, Pa., consisting of Frank Maris, Charles E. Maris, and M. B. M. Tatum, was dissolved October 1, 1906. The firm will be continued by Frank Maris and Charles R. Maris.

Latshaw Pressed Steel and Pulley Co., Pittsburg, Pa., announce that they have appointed Henry J. McCoy Co. distributors for New York City, Chas. E. Ring & Co. for Brooklyn, R. Gray, Jr., Inc., for Newark.

The F. H. Bultman Co. announce the purchase by them of the plant and business of Mr. F. H. Bultman. All correspondence, invoices, statements of accounts, etc., should be addressed to the company at 2108 Superior Avenue Viaduct, Cleveland, Ohio.

The Patterson Tool and Supply Co., Dayton, Ohio, on account of their growing trade in Indiana, have located their Mr. A. G. Schonacker at 508 E. Twenty-third Street, Indianapólis, and from this location are taking excellent care of their Indiana customers for machine tools and supplies.

L. H. Gilmer & Co., Philadelphia, Pa., dealers in endless belting, machinery and supplies, announce that they have opened an office at 302 Mooney Building, Buffalo, N. Y., in charge of G. W. Gilmer, Jr.; also an agency in Glasgow, Scotland, 209 St. Vincent Street, in charge of Mr. Wm. F. Reid.

The N. P. Bowsher Co., South Bend, Ind., recently had a city fire alarm box installed on the ground between their factory and lumber yards. This, in connection with the district patrol service and private hydrants, gives the Bowsher Co. protection not excelled by any other factory in the city.

The Gisholt Machine Co., 1316 Washington Avenue, Madison, Wis., which acquired the plant of the American Turret Lathe Co., Warren, Pa., about a year and a half ago, are operating the plant, building their 30- and 36-inch boring mills there at present. The plant has been in operation for something over a year and is now employing about 125 men.

The Fox Machine Co., Grand Rapids, Mich., report that their orders have for some time run far in excess of their capacity; this applies particularly to the Fox light milling machine. To keep up with their orders they have started a night crew, which together with the day work, means operating the shop twenty-two hours per day.

The Patterson Tool & Supply Co., Dayton, Ohio, have sold their lathe manufacturing business to Chamberlin & Evinger. The purchasers have formed a company composed of H. T. Chamberlin, E. R. Evinger and W. D. Foster. The firm will be known as the Miami Valley Machine Tool Co. Ground has been broken for a new factory building which the firm hopes to occupy by January 1st. Meanwhile they are building lathes in the old shop.

The Hide & Leather Association of New York City on Saturday, October 27, unveiled a historical tablet in the wall of the Schieren Building at Ferry & Cliff Streets, New York. A luncheon was served to invited guests at the conclusion of the ceremony. The district where this building is located was the birthplace of the leather and tanning industry of the city, and the leather business is still centered in this section.

The Star Corundum Wheel Co., Ltd., Detroit, Mich., have recently closed contracts for a new factory building which will be erected on Cavalry Avenue and Wabash R. R., Detroit, Mich. The building will be 70 x 175 feet and will be constructed of reinforced concrete and made fireproof throughout. Power will be furnished by a three-phase electric motor and the plant will be equipped with up-to-date machinery throughout for the manufacture of abrasive wheels. Their line includes principally solid corundum wheels, the vitrified, silicate and elastic processes being employed.

The Independent Pneumatic Tool Co., First National Bank Building, Chicago, Ill., held its annual stockholders meeting September 10, 1906. Besides a new board of directors the following officers were elected for the ensuing year: James B. Brady, President; W. O. Jacquette, First Vice-President; J. D. Hurley, Second Vice-President; C. E. Eri son, Treasurer; A. B. Holmes, Secretary. The business of this firm has shown a phenomenal increase during the past year. The manufacturing plant is several months behind in its orders and a large increase in floor space of the factory has become necessary. A gratifying growth in the foreign demand has been reported.

The Electric Controller & Supply Co., Cleveland, Ohio, announce the opening of a Chicago office in the Merchants' Loan and Trust Building, 135 Adams Street, Chicago, Ill., with Mr. W. M. Connelly in charge. Mr. Connelly was connected with the electrical department of the Homestead works of the Carnegie Steel Co. for five years and resigned his position there to become electrical engineer of the Ensley plant of the Tennessee Coal, Iron and Railroad Co. at Birmingham, Ala., which position he held for three years and resigned to enter Central Station Work at Birmingham, Ala., and at Houston, Tex., where he organized and had charge of the sales department. Mr. Connelly enters upon his new duties fully equipped to take care of the interests of the Electric Controller & Supply Co. in the Chicago district.

The Standard Roller Bearing Co., Philadelphia, Pa., have purchased the entire plant and real estate of the Pennsylvania Iron Works Co., which adjoins the present property of the Standard Roller Bearing Co. By this purchase the company have acquired five factory buildings with a total of 110,000 square feet floor space and a plot 120 x 1,600 feet, all located on the main line of the Pennsylvania Railroad. Two hundred and fifty thousand dollars was paid for the property. The Standard Roller Bearing Co. are at present erecting the largest reinforced concrete building in Philadelphia; it is five stories in height and 100 x 120 feet on the ground. This building will be devoted exclusively to the manufacture of annular ball bearings, automobile axles, etc. Over 1,200 people are now employed and this number will shortly be increased to 1,800. When the alterations are completed in the Pennsylvania Iron Works property it is expected that over 3,000 will be employed.

CONTENTS FOR NOVEMBER.

The contents of the November number of the *Century* are a delightful blend of facts, fiction and theory. A noteworthy feature is the first installment of Mrs. Frances Hodgson Burnett's new serial—"The Shuttle," a story the opening chapters of which give promise of Mrs. Burnett's best work. Mr. Mason's strong story, "Running Water," is continued, the plot growing more tangled and our interest even more firmly enlisted. There are numerous short stories; an article on Whistler, the artist; an interesting study of Julia Marlowe with portrait in tint. The first of a series of papers by Ellis Paxson Oberholtzer which will particularly interest American business men appears in this number; it is entitled "Jay Cooke and the Financiering of the Civil War" and is illustrated by reproductions from daguerreotypes, paintings, etc. "Mr. Bryan and Our Complex Social Order" is the title of a paper by Franklin H. Giddings discussing the same subjects taken up in Mr. Bryan's Essay on Socialism which appeared in the *Century* of last April.

MISCELLANEOUS.

RAILWAY MACHINERY.

A special edition of MACHINERY devoted to Locomotive and Car Equipment and Mechanics.

December, 1906.

ELECTRICAL EQUIPMENT OF THE ERIE RAILROAD SHOPS AT HORNELL, N. Y.

The operation of machine tools by electric motors has an exceedingly wide field, but no class of manufacturing establishments exemplifies the adaptability of electric drive more than railroad shops. The large work handled necessitates extensive buildings and the use of great lengths of shafting and belting if power is transmitted mechanically from a central source. Rush repair jobs are frequent and require a great deal of overtime and Sunday work, when power requirements are small, as but sufficient machinery is operated to complete the particular work in hand. Mechanical transmission of power under such conditions is wasteful in the extreme, owing to the surplus power required to overcome the friction of shafting and belting throughout the shops. Where electric drive is used—either individual or group—a flexibility is obtained that cannot be secured by any other means, as it permits the use of a few machines independently, obviating the objectionable features enumerated and permitting operation with a minimum power-house capacity, thereby effecting a considerable saving in fuel.

There are many other considerations in connection with power transmission, one of the most prominent being the layout of the plant, which is especially important in a railroad shop, as it is generally made up of a number of separate buildings aside from the main machine and erecting shop, such as boiler shop, carpenter shop, tank shop, blacksmith shop, pipe shop, etc.—which are necessarily scattered, widely distributing the power requirements and necessitating the use of a number of prime movers. Where engines are used, steam is supplied either from a central boiler plant or by individual boilers forming a combination unit with the engine. The former arrangement is exceedingly poor from an economical standpoint owing to the low efficiency resulting from the usual excessive condensation which takes place in long lengths of steam pipe. Either method involves the expenses of skilled attendants, which amounts to a considerable sum annually. These conditions are, however, rapidly changing; electric motors are superseding steam equipments and have many times proved that they fulfill all requirements—reducing operating expenses, requiring a very small amount of attention, providing power that is perfectly reliable, and reducing the time of starting and stopping and changing speed to a minimum.

Other applications may be found in cranes and in transfer and turn-tables where the electric motor is superior to every other motive power, owing to its ease of control, efficiency and reliability.

It was these considerations that led the Erie Railroad Com-

Fig. 1. Interior of Power House.

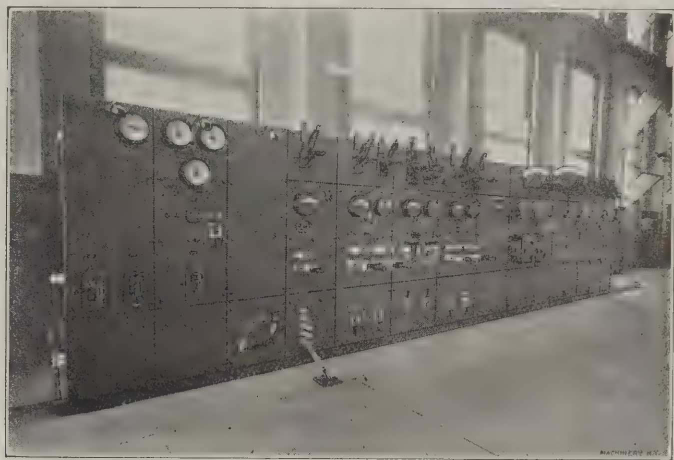

Fig. 2. Switchboard.

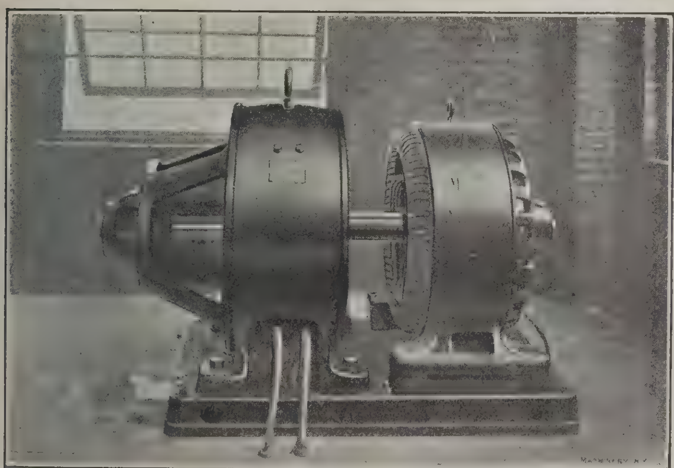

Fig. 3. Motor Generator set for Yard and Depot Lights.

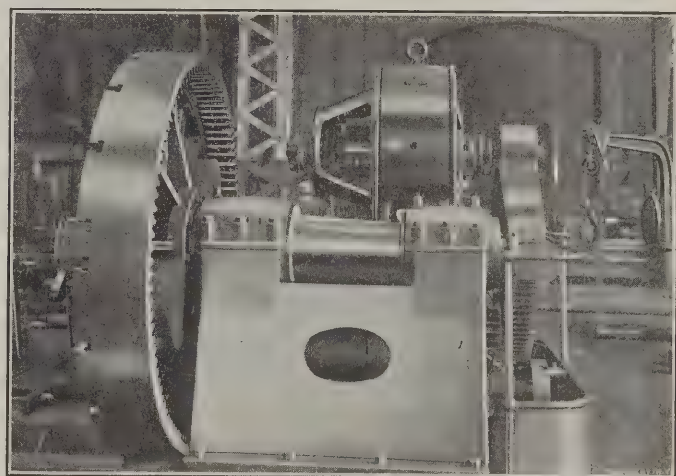

Fig. 4. Forty H. P. Motor Operating Niles Driving Wheel Lathe.

pany to abandon mechanical transmission of power and adopt the electrical drive at its Hornell shops, which now utilize electric power entirely and furnish an excellent example of the expediency and use of both individual and group drive.

When the present management took charge of the Erie Railroad it adopted broad and comprehensive plans for the development of the entire property, which are rapidly making it one of the most modern and efficient railway systems in the country. These plans embraced extensive alterations and additions to the many shops of the system in order to enable them to respond rapidly and efficiently to the increasing demands made upon them by the necessary additions to the rolling equipment.

New shop buildings and roundhouses have been constructed, old machines replaced by new, an efficient shop organization effected and the entire mechanical department brought up to a high standard of efficiency. This work under the direction of Mr. E. A. Williams, general mechanical superintendent, and Mr. G. W. Wildin, mechanical superintendent, has been carried on at many different points on the system, but the most extensive single installation of modern shop equipment is at the Hornell shops located at Hornell (Hornellsville), N. Y. At this point new buildings have been erected, additions made to old buildings, a new power house erected and a large number working shop in existence, therefore it was finally resolved to make the installation consist entirely of direct current apparatus with the exception of a small generator set which is used to supply the current necessary for the present yard and depot lights. This installation is an excellent illustration of the principle that each railroad shop must be considered as a separate and independent problem, and it is impossible to lay down any hard and fast rules which can be taken as guides, but that each particular case must be thoroughly investigated and a final decision reached in conformity with the conditions existing at that point.

As indicated above, the enlargement of the power house at some future time has not only been contemplated, but provided for. The type of apparatus to be placed in the engine room, however, will be determined upon at the time of making the addition, as the present system can readily be expanded in either of two ways. Additional power can be obtained by the installation of the necessary capacity, either in an alternating current generator which would supply the lines direct, the present motor generator set acting as a tie between the present units and the future one, or a direct current generator, with the necessary transforming apparatus for alternating current, can be installed if it is found that conditions demand that this be done.

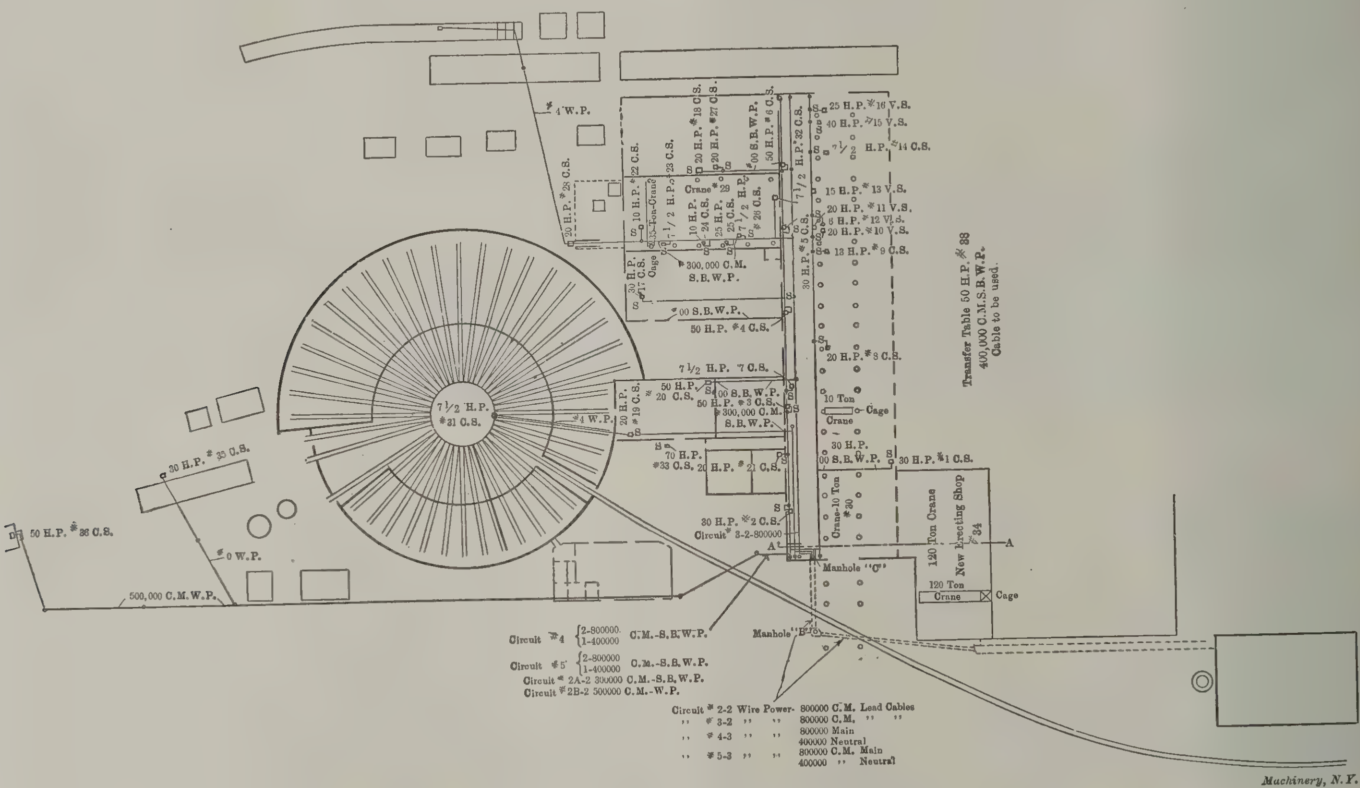

Fig. 5. Shop and Circuit Layout, Erie Railroad Shops, Hornell, N. Y.

of new machine tools, with a complete system of electric drive, installed. This installation is an interesting and instructive illustration of the latest engineering practice for a railway shop where the largest proportion of power is required at short distances from the power house and a large amount of variation in speed and crane loads occurs.

Before making a final decision as to the type of electrical apparatus to be installed, a careful comparison was made relative to the advantages and disadvantages of both the alternating current and direct current types of apparatus for the service contemplated. This analysis included not only the motors themselves, but also the various accessories, such as wiring, controllers, etc. Due consideration was also given to an installation involving the use of both alternating and direct current motors, but while it appeared probable that at some time in the future, an equipment of this nature would be necessary, it was decided that present conditions do not justify the installation of both types of motors. Under the conditions existing at Hornell, it is apparent that all of the motors are located well within the limits of 220 volts distribution, and in addition that there is at this time no wood-

The power house is a large brick structure of fireproof construction, with concrete roof and flooring, and has ample provision for light and ventilation. The building is large enough to provide for future extensions, foundations already being in place for doubling the boiler capacity so that it is only necessary to erect the additional units. The interior of the power house, showing the engines and generators, is shown in Fig. 1. The boiler plant consists of four Babcock & Wilcox units of 400 horse-power, operating at 150 pounds pressure and equipped with chain grates. All live steam mains are provided with the Holley drip system. The coal handling and stoking is especially interesting as, from the time the coal is dumped from the cars until it is fed into the furnace, it is conveyed automatically. The coal passes from the car into a chute which empties into a crusher, and is then conveyed by an endless belt to the top of the power house, where it passes through another chute to the second conveyor that distributes it in the bunkers over the boiler room. From there the coal passes through chutes to hoppers in front of the furnaces, where it is fed into the chain grates. The amount of coal admitted into the hoppers is controlled in the boiler room by

means of levers. The conveyors, which were manufactured by the Exeter Machine Company, have a capacity of 60 tons per hour and are operated by a 10 horse-power and a 13½ horse-power Westinghouse type S motor. The coal crusher is operated by a 20 horse-power type S motor.

The generating equipment consists of three Ball & Wood cross-compound, high-speed condensing engines, two of 500 horse-power each, direct connected to two Westinghouse 300 kilowatt, direct current, 250-volt, 3-wire generators running at 150 revolutions per minute, and one of 400 horse-power direct connected to a similar generator of 200 kilowatts capacity operating at 200 revolutions per minute. The engines run condensing except in cold weather, when the exhaust steam is utilized in heating the shops. Water for condensing purposes is stored in a large well which derives its supply from a small river near the power house.

F oil switches. Mounted upon the motor panel is a circuit breaker, an ammeter, a field rheostat and a motor-starting switch. The three generator panels are provided with the usual apparatus for a three-wire installation. The load panel is equipped with two switchboard type integrating wattmeters, two ammeters and two voltmeters.

The six feeder panels control six circuits as follows: Circuit No. 1—New erecting shop, 120-ton crane and transfer table. Circuit No. 2—Carpenter shop, blacksmith shop, new boiler shop and tank shop motors. Circuit No. 3—Roundhouse turntable, machine shop, coal pocket and ash-pit motors. Circuit No. 4—All lineshaft motors. Circuit No. 5—Individual drive motors. Circuit No. 6—Motors in power house for coal conveying apparatus. Each feeder panel is also provided with switches for controlling the various lighting circuits.

Current is transmitted by cables through a large tunnel to

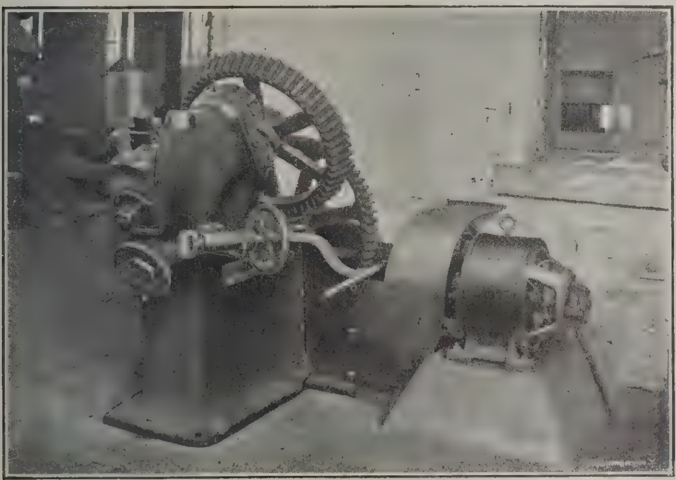

Fig. 6. Seven and a Half H.P. Motor Operating Lennox Bevel Shear.

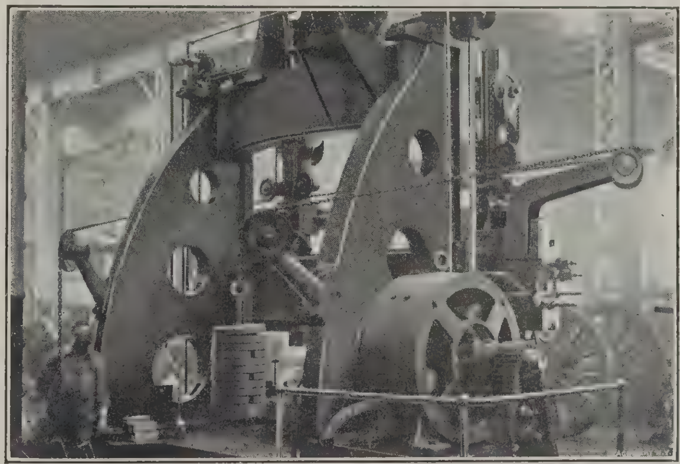

Fig. 7. Niles 90-inch Boring Mill Driven by 20 H. P. Motor.

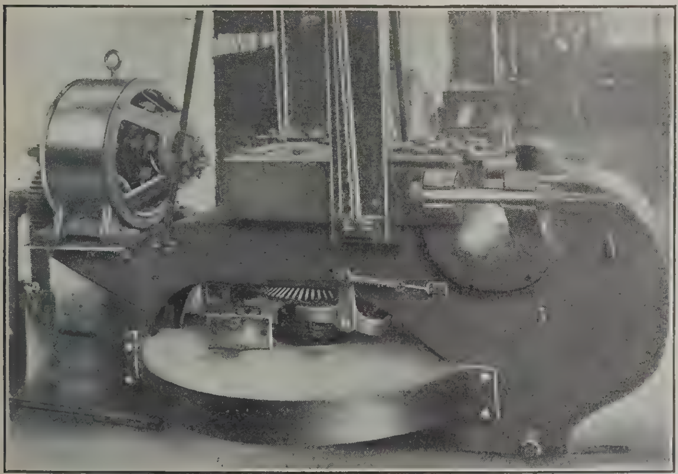

Fig. 8. Ten H. P. Motor on Horizontal Punch.

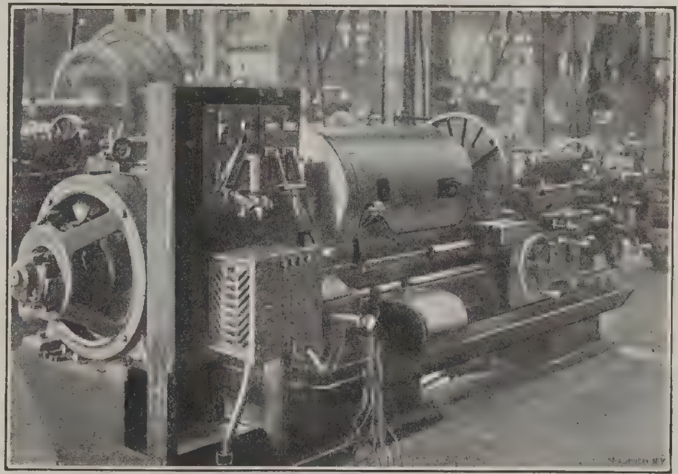

Fig. 9. Engine-lathe used for Crankpin Work, Driven by 7 1-2 H.P. Motor.

Besides the generating equipment and pumps there are two Ingersoll-Sergeant compound air compressors that furnish compressed air to the pneumatic hammers in the shops.

Fig. 3 illustrates a motor-generator set which supplies current for the yard and depot lights. It consists of a 115 horse-power Westinghouse type S motor direct connected to a 75 kilowatt, Westinghouse 2-phase, 60-cycle, 1,040 volt revolving field alternator operating at 900 revolutions per minute.

A standard Westinghouse switchboard, shown in Fig. 2, is provided with motor-generator panels, direct-current generator panels, feeder panels and a load panel and two blank panels providing for future extensions.

There are three motor-generator panels, two alternating-current and one direct-current or motor panel. The alternating-current generator panel is provided with one indicating wattmeter, one ammeter, one voltmeter, one type F oil switch, a rheostat, and the usual smaller instruments. The feeder panel is equipped with one power factor meter and two type

the new erecting shop and thence through underground conduits to the various buildings. The Westinghouse three-wire system of distribution is used for lighting and power, with an electro-motive force of 250 volts between outside wires, and 125 volts between each outside wire and neutral. There is a decided advantage in the flexibility of the voltage as incandescent and Cooper Hewitt lamps are operated on the 125-volt sides of the system and constant-speed 250-volt motors are connected to the main or outside wires while the variable speed motors utilize shunt field control.

Fig. 5 is a plan of the shops and gives the location of the various motors. It is particularly interesting as it shows the great diversity of motor applications.

The old erecting shop utilizes both group and individual drive, the group driven machines being divided into five sections and operated by five type S constant-speed motors, two of 30 horse-power capacity and three of 50 horse-power capacity. The machines in the fitting shop, which occupies one wing of

the erecting shop, are also group driven by a Westinghouse 30 horse-power, constant speed, type S motor. A complete list of the machine tools operated in each section is given below:

Section 1—50 Horse-power, Constant Speed Westinghouse Type S Motor.

Wheel press, 100 tons capacity.	53-in. vertical boring mill.
Wheel press, 300 tons capacity.	42-in. vertical boring mill.
Car wheel borer.	37-in. vertical boring mill.
Double car axle lathe.	36-in. upright drill.
Single car axle lathe.	28-in. upright drill.
4-spindle drill.	24-in. pillar shaper.
Horizontal boring machine.	32x32-in. x 8-ft. planer.
24-in. engine lathe.	1½x24-in. turret lathe.
80-in. driving wheel lathe.	90-in. quartering machine.
Two 16-in. engine lathes.	Duplex emery grinder.
18-in. engine lathe.	7-Spindle nut tapper.
15-in. engine lathe.	40-in. upright drill.
10-in. slotter.	Small flange punch.
No. 4 plain milling machine.	

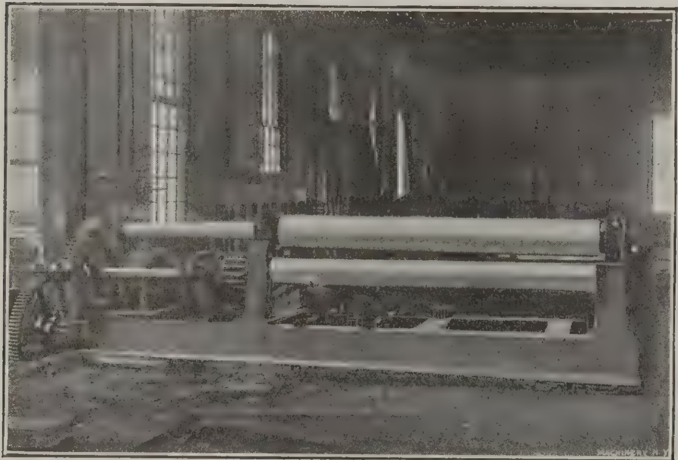

Fig. 10. Plate Rolls Operated by 10 H.P. and 15 H.P. Motors.

Section 2—30 H.P., Constant Speed, Westinghouse Type S Motor.

Two 16-in. engine lathes.	12-in. slotter.
1½-in. bolt pointer.	2-spindle centering machine.
60x60-in. x 19-ft. planer.	Slab milling machine.
5-ft. radial drill.	40-in. drilling, facing and tapping machine.
4-ft. radial drill.	Duplex emery grinder.
18-in. slotter.	Triple head slotter.
Two 2-in. double bolt cutters.	40-in. upright drill.
1½-in. staybolt cutter.	

Section 3—50 H.P., Constant Speed, Westinghouse Type S Motor.

42x42-in. x 18-ft. planer.	Horizontal boring machine.
Ring turret lathe.	14-in. engine lathe.
48-in. upright drill.	Two 16-in. engine lathes.
42-in. engine lathe.	42-in. vertical boring machine.
30-in. engine lathe.	40-in. upright drill.
24-in. engine lathe.	32x32-in. x 8-ft. planer.
Crank planer, 20x20-in. x 24-ft.	5-ft. radial drill.
2x26-in. turret lathe.	Double-head traverse shaper.
36-in. engine lathe.	No. 4 plain milling machine.
36-in. engine lathe.	26-in. engine lathe.
Horizontal boring machine.	30-in. engine lathe.

Section 4—50 H.P., Constant Speed, Westinghouse Type S Motor.

16-in. engine lathe.	No. 17 Landis grinding machine.
24-in. engine lathe.	42-in. vertical boring machine.
24-in. pillar shaper.	36-in. upright drill.
Friction drill.	28-in. upright drill.
36x36-in. x 10-ft. planer.	48-in. upright drill.
36x36-in. x 8-ft. planer.	36-in. engine lathe.
32x32-in. x 8-ft. planer.	30-in. engine lathe.
20-in. engine lathe.	2—Fox turret lathes.
18-in. engine lathe.	86-in. vertical boring machine.
16-in. engine lathe.	Duplex emery grinder.
24-in. engine lathe	
Cylinder boring machine.	

Section 5—30 H.P., Constant Speed, Westinghouse Type S Motor.

2x26-in. turret lathe.	Key-slot milling machine.
20-in. American brass lathe.	30-in. engine lathe (piston rods).
24-in. engine lathe.	36x36-in. x 10-ft. planer.
18-in. slotter.	

Fitting Shop—30 H.P., Constant Speed, Westinghouse Type S Motor.

28-in. upright drill.	40-in. upright drill.
30-ton arbor press.	15-ton arbor press.
36x36-in. x 8-ft. planer.	2-spindle centering machine.
37-in. vertical boring machine.	Buffing wheel.
Three 18-in. engine lathes.	Small emery grinder.
Two 16-in. engine lathes.	Surface grinder.
30-in. engine lathe.	Guide grinder.
11-in. bench speed lathe.	Polishing tape and wheel.
24-in. pillar shaper.	Swing grinder.
20x20-in. x 24-ft. crank planer.	Friction drill.

In addition to the group driven machines in the erecting shop, there are a number of individually driven machines operated by both constant and variable speed Westinghouse type S motors, as follows:

Constant Speed Motor-driven Machines.

One 20-horse-power motor driving a planer.
One 13-horse-power motor direct connected to 600-ton wheel press.
One 7½-horse-power motor for moving tail-stock of driving wheel lathe.

Variable Speed Motor-driven Machines.

One 7½-horse-power motor operating vertical miller for side rods.
One 20-horse-power and one 6-horse-power motor operating 90-inch boring mill.
One 20-horse-power motor operating driving axle lathe.
One 7½-hores-power motor operating crankpin lathe.
One 40-horse-power motor operating 90-inch driving wheel lathe.
One 25-horse-power motor driving truck tire lathe.

The list of Westinghouse type S variable speed motors and the machines they drive is a typical illustration of their application and a practical demonstration of their ability to increase output, as the time and labor necessary to shift belts or change mechanical speed devices is minimized, and a piece of work can be machined continuously from the smallest to the largest diameter without interruption.

The speed of these motors is controlled by varying the field strength, and, as this may be done while the machine is in operation, it affords an easy and convenient method of speed regulation always under the immediate control of the operator, the controller being conveniently placed within his reach. The variation of field strength is effected by means of a resistance placed in the shunt field circuit of the motor, which decreases the shunt field current and causes a decrease

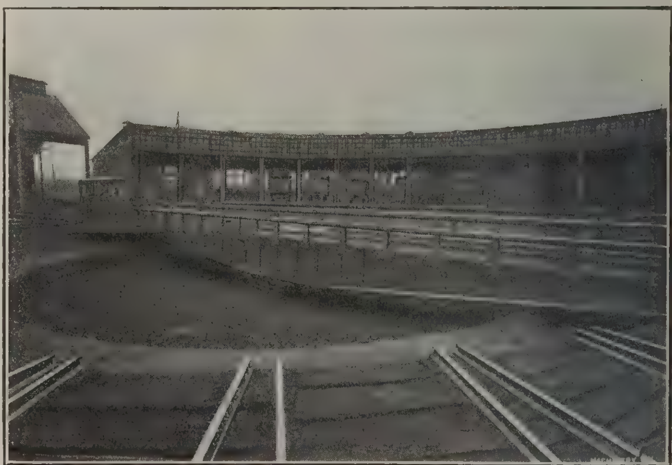

Fig. 11 Turntable Driven by 7 1-2 H.P. Motor.

in the field strength and an increase in speed, producing an extremely simple and effective means of varying the speed of either a shunt or a compound-wound motor.

One of the most prominent characteristics of this method of control is the simplicity and low cost of control apparatus made possible by the extremely small current which is handled. A second marked characteristic is the increase of speed with decrease of torque, when used as an adjustable speed motor, the horse-power output remaining practically constant throughout the whole speed range, which makes it peculiarly adapted to machine tool driving. This system involves the use of a minimum amount of auxiliary apparatus, thus materially reducing the first cost of an installation. The regulation of motors operating by shunt field control is good, which is of special importance in the operation of machine tools and in service of any class where constant speed is de-

sirable and where the torque varies between wide limits. The efficiency of motors operating at variable speeds remains practically constant over the range of speed.

Having considered the erecting shop equipment, the smaller shops next receive attention, the motors and the machine tools they operate in each department being given in their respective places.

Tool Room—20 H.P., Constant Speed, Westinghouse Type S Motor.

Yankee twist drill grinder.	15x15-in. x 20-ft. crank planer.
Duplex emery grinder (8-in. wheels).	16-in. toolroom lathe.
No. 4 Universal milling machine (Brown & Sharpe).	No. 3 Landis universal grinding machine.
No. 4 Universal Milling Machine (Cincinnati Milling Machine).	Sellers tool grinder.
	Reamer and cutter grinder.
	Gardner disk grinder.

Carpenter Shop—50 H.P., Constant Speed, Westinghouse Type S Motor.

Hollow chisel mortiser and boring machine.	12-in. rip saw.
Gaining machine.	42-in. band saw.
2-spindle shaper.	12-in. cutting-off saw.
Molding machine.	Single horizontal borer.
24 x 14-in. x 9-ft. Daniels' planer.	Tenoning machine.
Plain mortiser and borer.	15-in. turning lathe.
8x14-in. planer, 3 cutters.	15-in. swing vertical borer.
18-in. rip saw.	4-in. pipe cutter.
	3-in. pipe cutter.

Blacksmith Shop—30 H.P., Constant Speed, Westinghouse Type S Motor.

2—Power hammers.	2½-in. bolt header.
Light bar shear.	Alligator shears.
Small bolt header.	Bar iron shears.
1½-in. bolt header.	Hot saw.

50-horse-power constant speed type S motor direct connected to No. 9 Sturtevant fan.

Round House Machine Shop—20 H.P., Constant Speed, Westinghouse Type S Motor.

16-in. engine lathe.	40-in. upright drill.
26-in. engine lathe.	Duplex emery grinder.
32x32-in. x 8-ft. planer.	15-ton arbor press.
24-in. pillar shaper.	

Miscellaneous Applications.

One 70-horse-power Westinghouse type S constant speed motor driving fan for round-house heating system.
One 10-horse-power Westinghouse type S constant speed motor driving fan for new erecting shop heating system.
One 7½-horse-power variable speed Westinghouse type S motor operating round house turntable.
One 50-horse-power constant speed motor operating coal conveyor in locomotive coaling station.
One 30-horse-power constant speed Westinghouse type S motor operating ash conveyor for removing ashes from locomotive ash-pit.
One 7½-horse-power Westinghouse motor operating alligator shears for cutting up sheet scrap. This installation is located at the scrap bins in the shop yards.
One 25-horse-power motor operating transfer table.

The preliminary studies and final report, showing the benefits which would be the result of electrically equipping these shops, were made by the Westinghouse Electric and Manufacturing Company in conjunction with the motive power department of the Erie Railroad Co. The results have more than borne out the promises made to the management.

The installation of the new electrical equipment presented many engineering problems, but the work of transformation was carried on without any interruption to the service, and it reflects great credit to the contractors, Westinghouse, Church, Kerr & Company, who installed the plant, and Mr. George T. Depue, master mechanic of the Erie Railroad Company, who has charge of the Hornell shops.

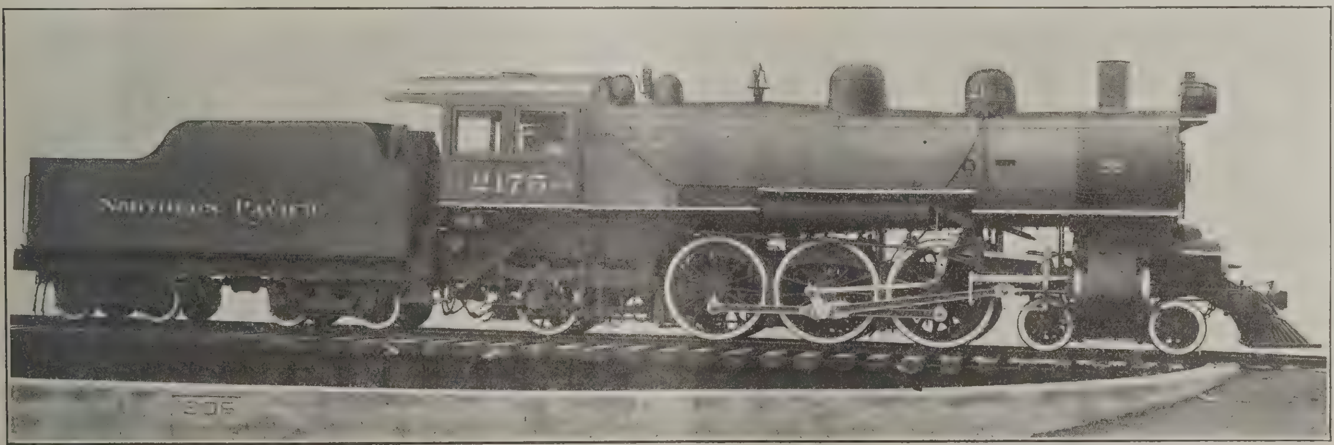

Fig. 1. Cole Four-cylinder Balanced Compound Locomotive for the Northern Pacific Railway, 40,000th Locomotive built by the American Locomotive Co.

Boiler Shop—7 1-2 H P., Constant Speed, Westinghouse Type S Motor.

Two Hartz flue welding machines.
Two flue cutting machines.

Direct-driven Machines Operated by Constant Speed, Westinghouse Type S Motors.

One 7½-horse-power motor driving 20-inch punch and shears.
One 25-horse-power motor operating plate rolls.
One 10-horse-power motor operating horizontal punch.
One 7½-horse-power motor driving bevel shears.
One 10-horse-power motor operating 36-inch punch and shears.

In connection with the boiler shop equipment there is a flue rattler which is located outside the building and is operated by a 20-horse-power type S motor. It is 48 inches in diameter and 22 feet long, and has a capacity of 175 to 200 flues. An average of five lots per day are cleaned, the exact time for each rattling depending upon the water used in the boilers. The longest flue is 21 feet, and they vary from 1½ to 2½ inches in diameter.

Tank Shop—20 H.P., Constant Speed, Westinghouse Type S Motor.

36-inch single shear.	36-inch single punch.

In addition to the belt-driven machines there is a 10-horse-power and a 15-horse-power constant speed type S motor geared to plate rolls.

COLE FOUR-CYLINDER BALANCED COMPOUND LOCOMOTIVE FOR THE NORTHERN PACIFIC RAILWAY.

A party of editors and newspaper men in company with Mr. G. M. Basford of the American Locomotive Co. visited their Schenectady Works, November 2, to inspect a Cole four-cylinder balanced compound Pacific (4—6—2) type locomotive built for the Northern Pacific Railway, which has the distinction of being the company's 40,000th locomotive. This number includes the total output of all the constituent companies now owned and controlled by the American Locomotive Co., namely: Schenectady Locomotive Works, Schenectady, N. Y.; Brooks Locomotive Works, Dunkirk, N. Y.; Pittsburg Locomotive Works, Pittsburg, Pa.; Rhode Island Locomotive Works, Providence, R. I.; Richmond Locomotive Works, Richmond, Va.; Rogers Locomotive Works, Paterson, N. J.; Dickson Locomotive Works, Scranton, Pa.; Locomotive & Machine Co., Montreal, Canada; Cooke Locomotive Works, Paterson, N. J.; Manchester Locomotive Works, Manchester N. H. The oldest company represented is the Rogers Locomotive Works, founded in 1831 to build cotton, woolen and flax machinery. The first locomotive built by Rogers was the *Sandusky*, for the Mad River & Lake Erie R. R. Co., in 1837.

The 40,000th locomotive is one of an order for two of this

type. (See RAILWAY MACHINERY, June, 1904.) It combines the latest and most important development in locomotive design in this country, but no untried features. The important features are the four balanced compound cylinders, boiler with combustion chamber, and Walschaerts valve gear.

The arrangement of cylinders employed in the application of the balanced and divided principle is the Cole type with the high-pressure cylinders ahead of the low-pressure and, in this case, inclined at a slight angle (about 4 degrees) so as to clear the leading truck. The location of the high-pressure length of high-pressure connecting-rod of 91¼ inches was obtained.

Inclining the high-pressure cylinder avoids the difficulty inherent with four-cylinders in the same transverse plane on this type of locomotive. It would otherwise have been necessary in order to get a good length of high-pressure connecting-rod to either increase the distance between the center of the cylinder and the forward driving wheels 30 to 36 inches, involving a similar increase in the length of boiler and tubes or to make use of the bifurcated design of high-pressure con-

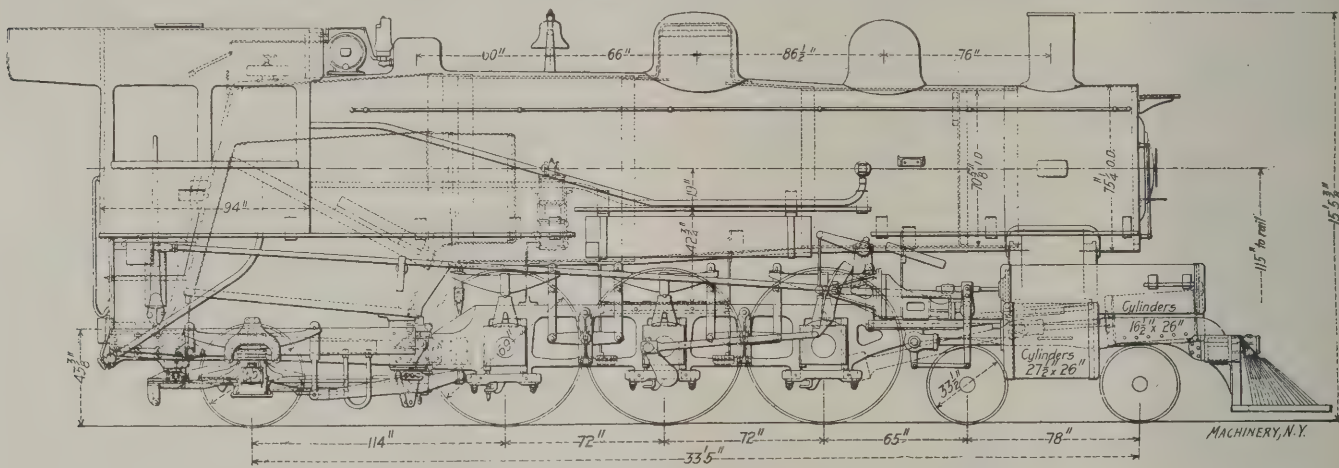

Fig. 2 Side Elevation of Cole Four-cylinder Balanced Compound Locomotive.

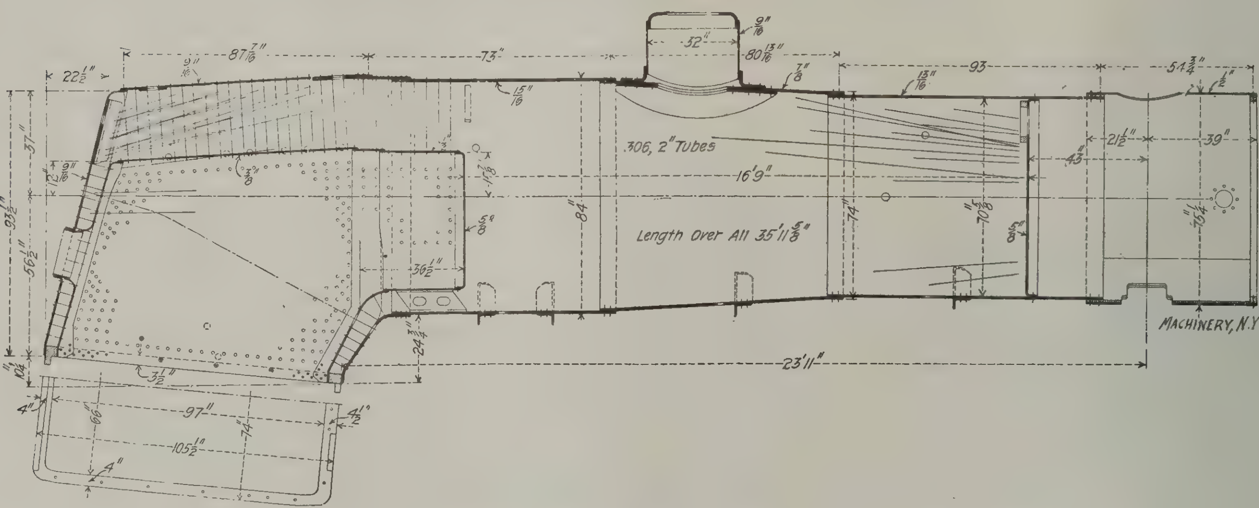

Fig 3. Boiler of Cole Four-cylinder Balanced Compound Locomotive, with Combustion Chamber.

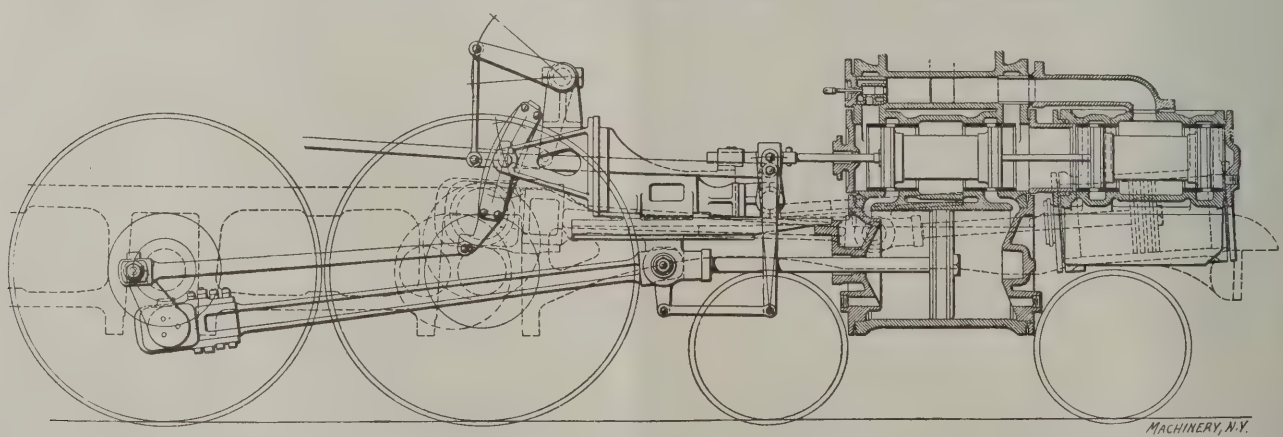

Fig. 4 Walschaerts Valve Gear, and Section through Low-pressure Cylinder and Valve Chamber.

cylinders ahead of the low-pressure cylinders is for the purpose of getting sufficient length for high-pressure connecting-rod to permit of its connection to the forward axle. The outside or low-pressure cylinders are connected to the middle axle and thus the application of the power developed in the four cylinders is distributed between two axles. By increasing the distance between the center of the cylinders and the forward driving axles 12 inches and extending the front end of the boiler, keeping the length of the flues the same as in the simple Pacific engine without combustion chamber, a necting-rod straddling the front axle. It is desirable to avoid the latter alternative on account of the weight and cost of such construction and its inaccessibility in case of repairs, and, as just pointed out, it is considered better to divide the power between two axles rather than to confine it to one.

The purchasing of a balanced compound locomotive by the Northern Pacific Railway is considered as being further evidence of the confidence of railroads of this country in the advantages of this design of the balanced type. These briefly are as follows: The approximately perfect balance of the recipro-

cating parts combined with the perfect balance of the revolving weights; permissible increase of weights on driving wheels on account of elimination of hammer-blow; increase in sustained horse-power at high speeds without modification of the boiler; sub-division of power between four cylinders and between two axles; reduction of bending stresses on the crank axle due to the fact that only half the turning moment is transmitted through each axle; light moving parts which will minimize wear and repairs.

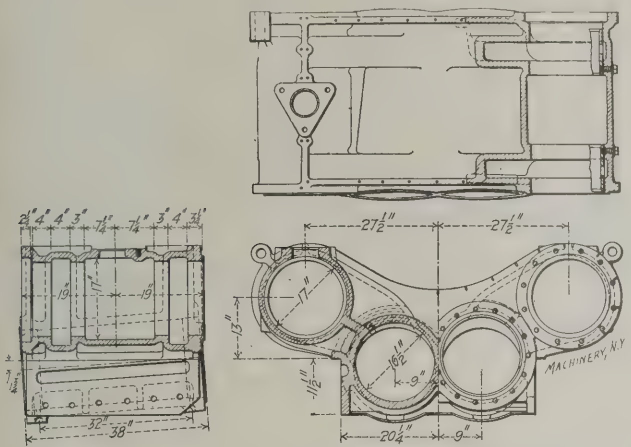

Fig. 5. Cross-section of High-pressure Cylinder and Valve Chamber.

In this present example the increase of weight on the driving wheels on account of the elimination of the hammer-blow is 11,000 pounds over that of the Northern Pacific simple engines. As to sustained horse-power, tests taken on the New York Central four-cylinder balanced compound Atlantic type locomotives at the Louisiana Purchase exposition showed that with identically the same size of boiler a compound engine developed from 20 to 30 per cent greater horse-power at high speed than the original simple engine. In actual service the compound engine developed 1,688 I. H. P. at 57 miles per hour, and 1,980 I. H. P. at 75 miles per hour, while the original simple engine developed only from 1,400 to 1,500 I. H. P.

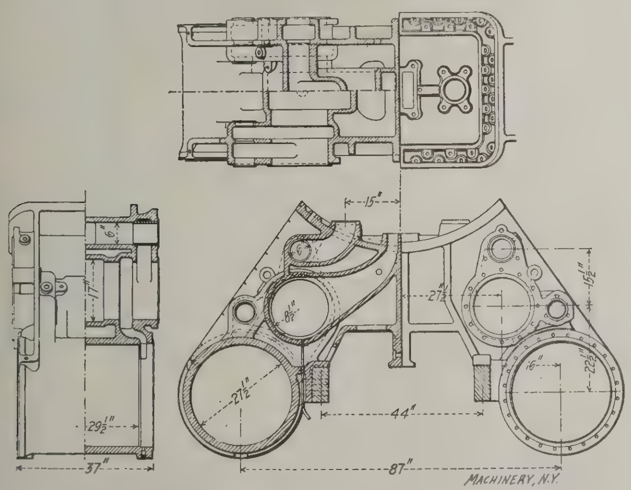

Fig. 6. Cross-section of Low-pressure Cylinder and Valve Chamber.

This locomotive is interesting also in that it contains a combustion chamber and is in line with the trend of practice on the Northern Pacific where the use of the combustion chamber has been found to reduce boiler troubles. The Northern Pacific Co. have recently had 70 locomotives built with combustion chambers, these being illustrated in RAILWAY MACHINERY in the September issue. The reduction in boiler troubles is attributed to the fact that the ends of the flues being removed from the hottest part of the fire, flue leakage is minimized. The combustion chamber also gives ample room to work on the flues without removing the brick arch and this means a saving in money and time. The fact that this construction does permit of flue work being done without affecting the brick arch is more advantageous in more ways than one. The brick arch, as everyone knows, is a promotor of good combustion but its use on locomotives has been discouraged as it is very expensive to maintain, if it must be removed every time the lower flues need attention. Hence it might be said that the combustion chamber makes the brick arch a practical feature of modern locomotive construction. The combustion chamber also materially increases the heating surface of the firebox and gives an increased firebox volume, which tends toward better combustion. Although the combustion chamber reduces the tube heating surface it is thought to be more than offset by the increase in firebox heating surface; a locomotive with a combustion chamber steams equally as well as a similar engine without a combustion chamber and with greater actual heating surface. A thorough trial of the combustion chamber on the Northern Pacific Railway has demonstrated the fact that where these conditions are found it greatly reduces boiler repairs and this we all know constitutes a large item in the cost of locomotive maintenance.

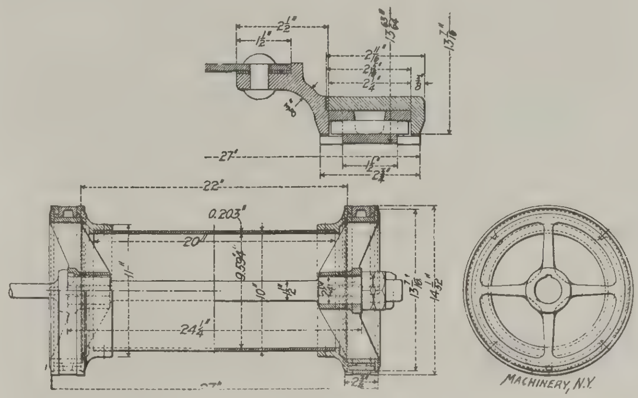

Fig. 7. Piston Valve with Boiler Tube Body.

As to the Walschaerts valve gear which is a prominent feature of this locomotive, this is now so widely introduced into American practice that it has ceased to be a novelty. Its practical advantages are conceded, and no doubt they will make it indispensable on large heavy locomotives of which this is an example. To review these advantages it may be stated as compared with the Stephenson link motion it is much more accessible for inspection, lubrication and repairs; it is lighter in construction; has less friction of parts; and affords a better opportunity than the Stephenson link motion for the introduction of strong frame bracing. This feature has been taken advantage of in the 40,000th locomotive. Not only is there a strong brace between the frames above the second axle but the frames are strongly tied together by a steel casting forward of the first axle. This casting is so constructed that it not only acts as a frame brace but it carries the rockers for the valve motion and also supports

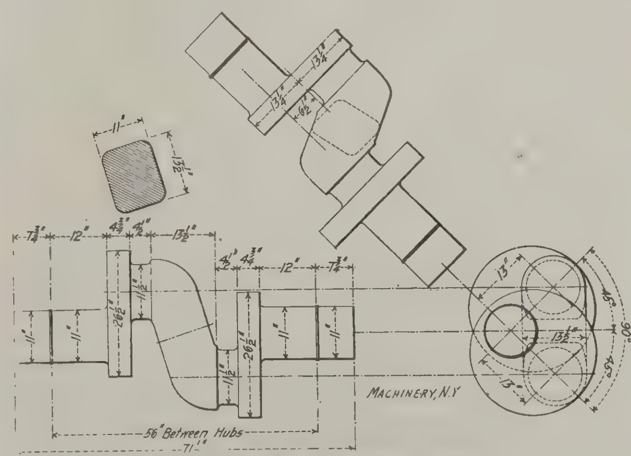

Fig. 8. Crank Axle, Forward Drivers.

the guides. A great deal of attention was given to the design of this feature and it is considerably of a novelty in American locomotive construction. Following are the principal dimensions of the locomotive:

Cylinders, compound piston valve; diameters, 16½ inches and 27½ inches; stroke, 26 inches; piston-rod diameter, 3¼ inches; piston packing, 2 cast iron snap rings.

Valves, type, piston; travel, 6 inches; steam lap, 1 inch; setting in lead, ¼ inch full front and back; exhaust clearance, high pressure, 5/16 inch; low pressure, ⅜ inch.

Gage, 4 feet 8½ inches; wheel-base, driving, 12 feet; rigid, 12 feet; total engine and tender, 62 feet 10 inches.
Weight in working order, 240,000 pounds; on drivers, 157,000 pounds; total engine and tender, 380,500 pounds.
Axles, driving journals, main, 11 x 11½ inches; others, 9½ x 12 inches; engine truck journals, diameter 6½ inches, length 12 inches; trailing truck journals, diameter 8 inches, length 14 inches; tender truck journals, diameter 5½ inches, length 10 inches.
Boxes, driving, main, cast steel; others, cast steel.
Boiler, type, extended wagon top; outside diameter first ring, 72¼ inches; working pressure, 220 pounds; fuel, bituminous coal.
Heating surface, tubes, 2,667.0 square feet; firebox, 232.9 square feet; arch tubes, 8.9 square feet; total, 2,908.8 square feet.
Firebox, type, wide; length, 96 inches; width, 65¼ inches.
Grate, style, rocking; grate area, 43.5 square feet; thickness of crown-sheet, ⅜ inch; tube-sheet, ⅝ inch; sides, ⅜ inch; back, ⅜ inch.
Water space: front, 4½ inches; sides, 4 inches; back, 4 inches.
Crown staying, radial.
Tubes: material, charcoal iron; number, 306; diameter, 2 inches; length, 16 feet 9 inches; gage, No. 11 B. W. G.
Exhaust pipe, single nozzles 5⅜, 5⅝, and 5⅞ inches.
Smokestack, diameter 18 and 20 7/16 inches; top above rail, 15 feet 5½ inches.
Brake, driver, Westinghouse-American combination; truck, Westinghouse-American combination; trailer, Westinghouse-American combination; tender, Westinghouse; air signal, Westinghouse J.; pump, 9½ inches R. H. on L. H. side; two reservoirs 18½ x 102 inches.
Tender, frame 13-inch channel steel; tank, style, water bottom; capacity, 7,000 gallons; fuel, 12 tons.
Wheels, driving diameter outside tire, 69 inches; centers, diameter, 62 inches; material, main, cast steel; others, cast steel; engine truck diameter, 33½ inches; kind, Standard Steel Works; trailing truck diameter 45 inches; kind, American Locomotive Co. cast steel spoke; tender truck diameter, 33½ inches; kind, Standard Steel Works cast iron plate.
Engine truck, 4-wheel swing center, wrought iron frame.

THE PINKUS RAILWAY—AN EARLY PNEUMATIC SCHEME.

A. R. BELL.

In the early days of railroad construction there were many attempts made to invent devices for propelling vehicles by mechanical means other than by steam locomotives. The atmospheric system was tried in 1847 and continued in use for about a year. The reason for it being discarded was, of course, due to the trouble and expense of working. The initial cost of equipment, however, was then claimed to be lower than ordinary rails with steam locomotives.

The means of propulsion consisted of a cylindrical tube, three feet in diameter, in which an air-tight piston moved, arranged midway between and a little below the level of the rails. The tube was laid the full length of the railway and had a smooth internal surface, the sections having air-tight joints. A stationary steam engine was used to pump a partial vacuum in the tube on one side of a piston, and the atmospheric pressure acting on the other side, pressed it forward and pulled the vehicle on the rails. As will be seen by the illustration the piston was not coupled direct to the passenger coach but to a trolley on the rails called a "dynamic traveler." This trolley served the purpose of raising and reseating the air-tight covering to the conduit as the piston progressed. At distances of about five miles along the

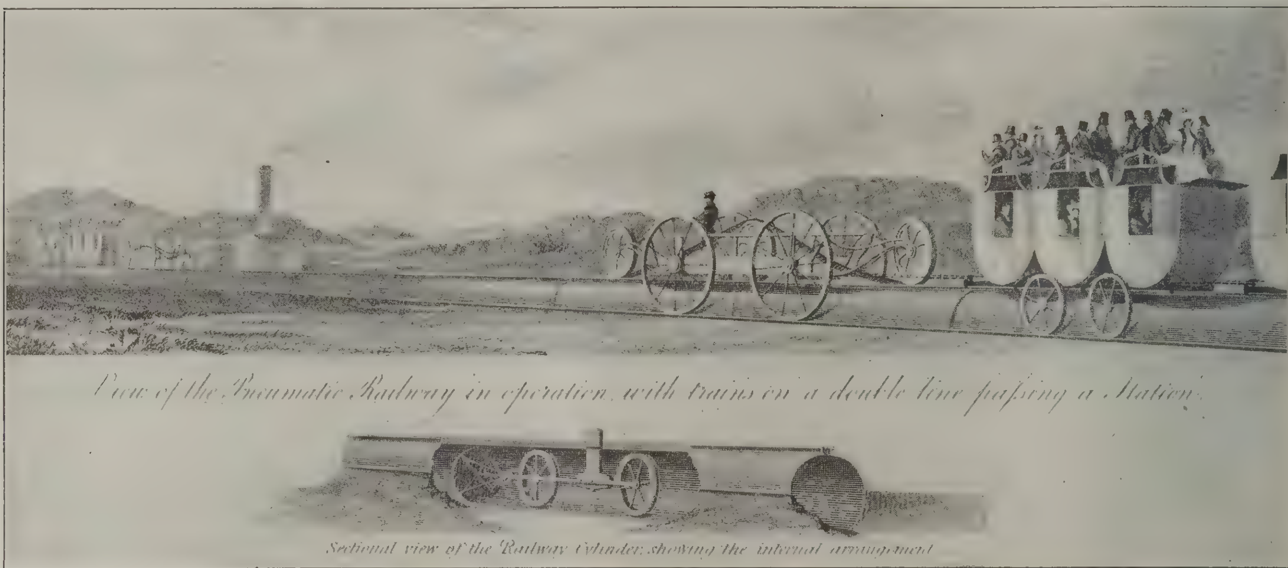

Fig. 1. Pinkus Pneumatic Railway in Operation, and Sectional View of the Cylinder—From an Old Print.

line, station valves were provided dividing the tube into sections so that more than one vehicle could be propelled along the same set of rails. For the purpose of checking the speed or stopping, an arrangement was devised for opening a valve in the piston, thus partly or fully destroying the vacuum in front of it. The continuous valve along the opening of the conduit was made of tarred felt, greased and rendered as flexible as possible in order to travel over the trolley wheels easily and form an effective air-tight joint.

* * *

We mentioned in the September, 1906, issue of RAILWAY MACHINERY that the number of locomotives equipped with Schmidt superheaters was 1,150. This figure was the number

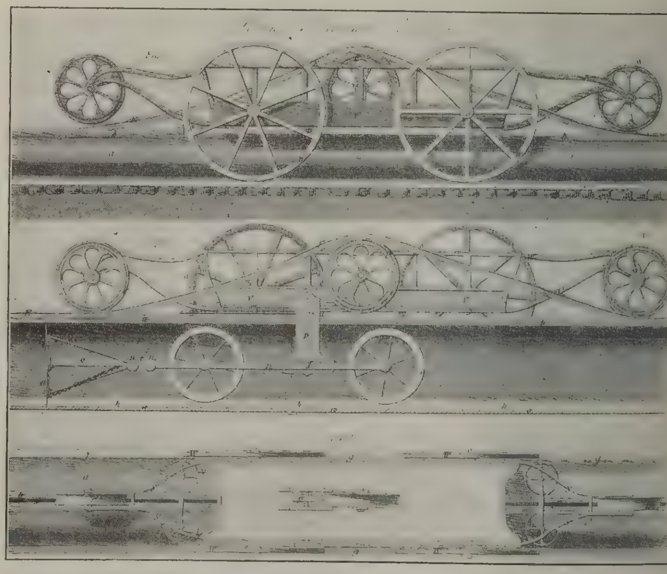

Fig. 2. Side Elevation, Side Section and Plan of the Pinkus Pneumatic Railway.—From an Old Print.

brought up to June, 1906. As an evidence of the rapid extension of this feature of improved locomotive boiler design it is of interest to know that under date of October 10 Mr. Schmidt informs us that the number of locomotives equipped and in the course of construction having the Schmidt superheater has increased to 1,664. Fifty-one railroads are now using it, mostly in Continental Europe.

SUB-PRESS WORK AT THE SLOAN & CHACE SHOPS.

The sub-press die is an old device dating back at least one and possibly two generations, and having its origin in watch and clock factories where its ability to perform blanking operations of the most delicate nature was early recognized and fully appreciated. That this tool, though familiar in the field just mentioned, has yet capabilities in other directions which have not hitherto been fully recognized, is the impression that must be strongly borne upon an appreciative mechanic who is acquainted with the work being done in the shops of the Sloan & Chace Manufacturing Co. of Newark, N. J. This firm has for many years built precision machinery for watch makers, fine tool makers and others, whose work requires great accuracy. It was over thirty years ago that they brought out their first line of bench lathes; their line now comprises, besides the lathes and the numerous attachments used on them, automatic pinion cutters, automatic gear cutters, drilling and tapping machines, bench milling machines, and many other tools of a more highly specialized nature, especially used in watch and clock making. Small sub-press dies had been built more or less from the beginning, but within the past few years this part of the business has been developed until it equals in importance the building of machinery.

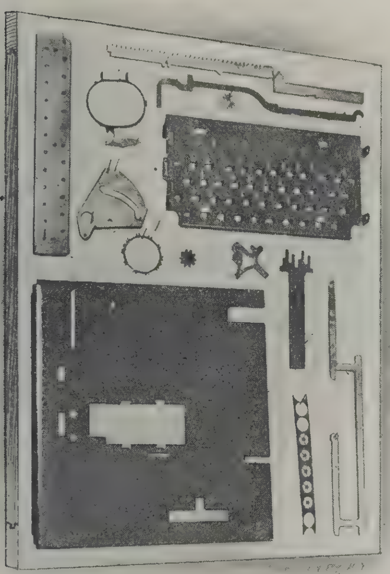

Fig. 1. Examples of Sub-press Work.

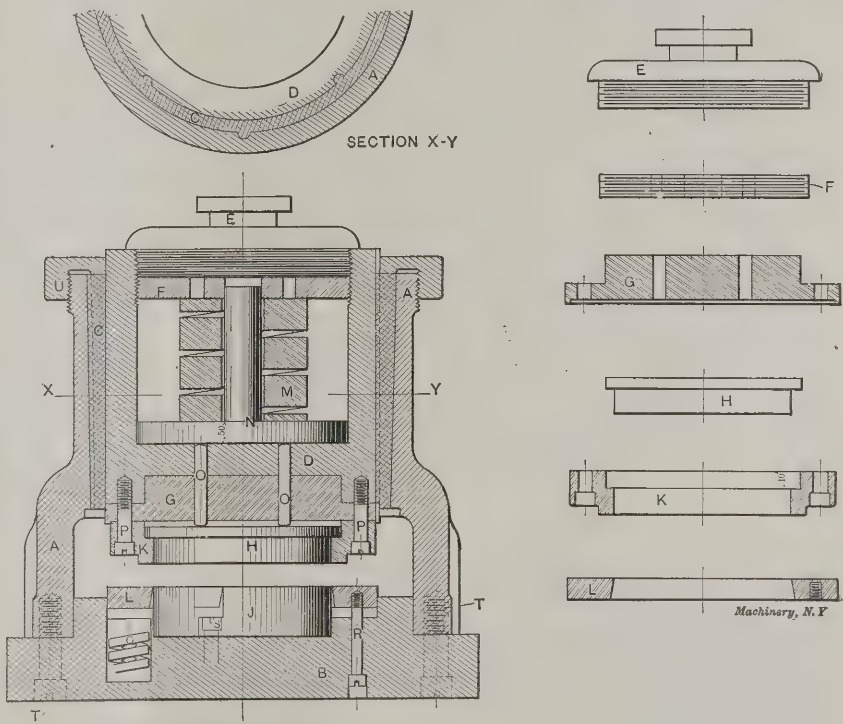

Fig. 2. Construction of Typical Sub-press.

A section of a typical blanking sub-press of the common cylindrical type is shown in Fig. 2. It is doubtless familiar to most toolmakers, so will need but a few words of description. To base *B* is screwed and dowelled the cylinder *A* lined with babbitt, as shown at *C*, this lining being provided with ribs which engage corresponding grooves in plunger *D* which works up and down within the babbitt lining under the action of the ram of the press in which it is used. Nut *U* furnishes an adjustment for tightening the babbitt lining to take up all slack due to wear, as fast as it is developed. The die is usually the upper member, while the punch is placed in the base. *K* is the die, screwed and dowelled to plunger *D*; accurately fitting the opening in this die is the shedder *H*, which is normally forced downward with its face flush with the face of the die by the action of spring *M*, which acts through the piston *N* and pins *O*. A similar construction is used in the bottom member. *J* is the punch, screwed and dowelled to the base. *L* is the stripper, surrounding the punch and accurately fitting it, and held firmly at the upper extremity of its movement by the pressure of the springs *Q*; it is restrained with its face flush with that of the punch by the heads on stripper screws *R*. Thus it will be seen that the faces of the punch with its stripper and the die with its shedder may be ground off smooth and flush with each other, presenting to the eye the appearance of two solid plates of metal, the division between the fixed and spring supported members not being visible if the fitting has been well done.

With this construction in mind, the details of the punch and die shown in Fig. 3 will be readily understood. Similar letters in each case refer to similar parts, but only the members of the device actually working on the metal are here shown. The outline of the punching which is to be made will be understood from the outline of the punch and its stripper, as shown in the plan view. There are two small holes, *c c*, and one larger hole, *b*, in the blank. For punching these small holes, in addition to the simple arrangement shown in Fig. 1, openings are necessary in the punch, and small piercing punches have to be placed within the aperture of the die, passing through holes in the shedder; the holes in the punch are continued through the base of the sub-press so that the waste material drops through beneath the machine. The piercing punches in the upper member are held to die pad *G* by holding screws *g* which draw these parts up into their tapered seats against the shoulders formed on them for the purpose. The fitting at all the cutting edges is done with great accuracy. The punch *J* fits die *K* very closely; the shedder *H* is fitted to the die very closely; the stripper *L* is fitted to the punch, and small punches *f* are accurately aligned and closely sized to their corresponding openings in the face of main punch *J*. Disappearing pins are shown at *h h*; they are used to guide the strip of stock, and are pressed down by the descent of die *K*, returning under the action of their springs as the ram ascends.

It will be understood of course that the sub-press is a complete unit, with punch and die and ram guiding surface always in place, so that no setting is necessary. The workman only needs to place the sub-press on the bed of the punch-press, insert the button on cap *E* in the holder provided for it in the face of the ram of the machine, and strap the base of the tool to the bed of the machine. He is then ready to commence work at once without any need for wasting time in matching up his dies, it only being necessary to adjust the length of the stroke to the proper amount. This is one of the advantages of the sub-press. Another of them will be immediately recognized upon considering the action of the parts on the strip metal from which the blank is punched. With the work in place, die *K* and with it small punches *f* descend, the latter passing through the stock until they almost meet the corresponding cutting edges in the lower member. As soon

as shedder H strikes the stock its motion is arrested, and it remains behind until the blank is separated, being meanwhile powerfully pressed upon the work by spring M. As the stock, while being sheared, is pressed down around the blank, it carries with it stripper L which also, by the influence of springs Q, exerts a heavy pressure on the stock. The whole area of metal being thus firmly held between plane surfaces, there is no danger of buckling or distortion of the stock as would otherwise be likely. As the ram moves upward again the blank is still firmly held on the stationary top of punch J by the shedder H. The stock, however, is carried upward

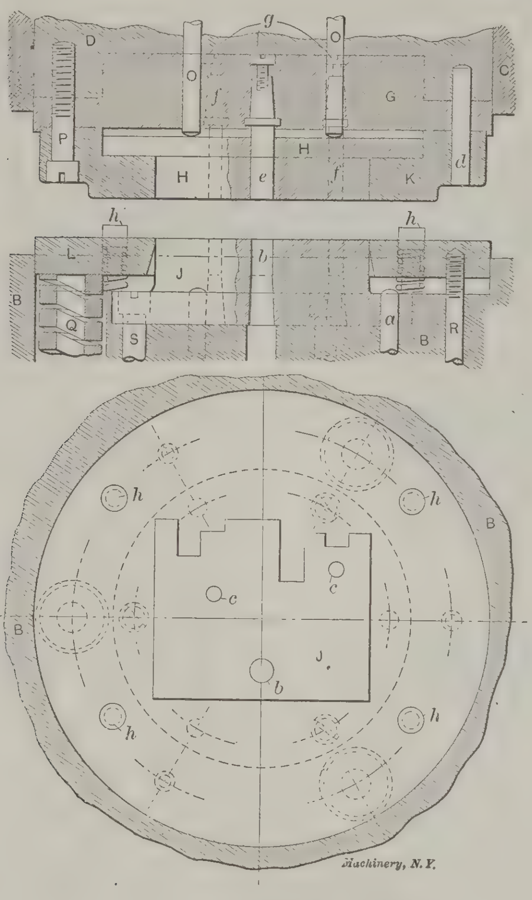

Fig. 3. Construction of Sub-press Punch and Die.

with die K by stripper L, forcing the stock back over the punching again until the movement of the stripper is arrested by the heads of screws R, at the time when the face of the stock is flush with the top of the punching. The work is thus pushed back into the stock in the same position that it occupied before it was severed from it and in many materials when the work has been nicely done, it is difficult at a careless glance to believe that anything has been done at all, both sides presenting a flush smooth surface where the parting occurred.

This condition is taken advantage of oftentimes in clock manufacturing. Gear blanks, for instance, are punched out from strips of metal and inserted back in their places again, minus, of course, the stock which has been punched out to form the arms and the hole for the "staff" or little shaft on which it is mounted. These strips, thus prepared, are then taken to machines where the staffs are inserted and fastened, it being much easier to handle the little wheels in this way than if they were severed and handled in bulk. A strip of stock thus treated is shown in the photograph reproduced in Fig. 1, the second one from the right at the bottom of the group; five of the pieces are shown in place in the stock while three have been pushed out. Besides the advantages of permanent setting of the punch and die and the holding of the stock to prevent distortion, which allows very narrow bridges of material to be left between wide openings, the suitability of the device for delicate work such as the piercing of small holes in thick stock will be appreciated by reference to Fig. 3. It will be noted that, no matter how small punches e and f may be, no portion of their projecting ends is at any time left unsupported laterally by shedder H or by the work. The shedder, pressing down firmly on the work, supports the end of the punch at the point where the pressure is applied. It is thus possible to use a very much more slender punch for a given thickness of stock than can be used in any other way. In Fig. 1, where a number of samples of sub-press work are shown, the topmost piece with the rack teeth in it, which is about 0.050 inch thick, has at its left hand end four 0.025 inch holes pierced through it. It will be seen that the thickness of the stock in this case is twice the diameter of the hole punched. Such a ratio has perhaps been undertaken with ordinary punches and dies, although the writer does not remember ever having seen the ratio of 1.5 to 1 exceeded; and in that case the hole in the die was considerably larger than the hole in the punch with the result that the pierced hole was very much tapered, the scrap coming out in the form of a conical plug. In the die under discussion, however, no allowance of this kind is made, the hole in the die being a very close fit to the punch, with the result that the hole pierced in the blank is as nearly a perfect one as could easily be obtained by any means short of reaming or grinding.

Another advantage of the sub-press, dependent in part on the accuracy of alignment provided, and the corresponding accuracy in fitting which can be given to the cutting edges, is that the work is remarkably free from fins and burrs. A consideration of the action of the press will show that there is practically no chance for burrs to form in a piece even where they would in an ordinary blanking die. It is of course necessary for the die to descend until the punch has all but entered it, if clean work is to be produced. There appears to be a slight difference in the practice of different operators in this respect, although this difference in practice would be expressed in the dimensions of only 0.002 or 0.003 inch, perhaps. Some of them adjust the stroke so that the die does not quite meet the punch. Others prefer to have them meet and even enter by an infinitesimal amount.

Attention has already been called to two of the samples of work shown in Fig. 1. The small parts there illustrated are within the ordinary range of the sub-press as used in this shop, but it is safe to say that there are many die-makers who consider themselves familiar with this tool who have yet to see dies built on this principle large enough to blank out such a piece as the largest one shown, which is quite 14 inches square. Nor is this the limit possible. The writer saw here dies of this type being made for heavy armature work, blanking out armature segments measuring possibly as high as 26 or 28 inches across extreme dimensions. The same advantages that obtain in the smaller presses, result from the use of the larger ones. There is a saving of time in setting up the tools; there is a possibility of punching small holes in

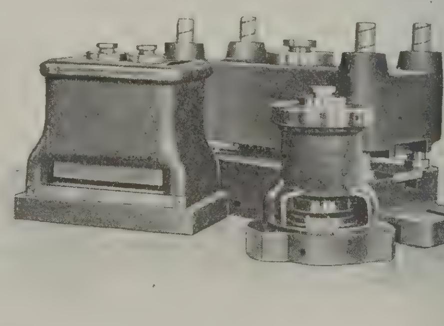

Fig. 4. Three Forms of Sub-presses.

thick stock or of leaving narrow bridges of metal between openings of considerable area; the dies, owing to their accurate and permanent alignment, may be fitted to each other much more closely, produce work that requires less finishing and comes more nearly to dimensions than can be done in any other way. At the same time, the construction effects a great increase in the life of the die, making it unnecessary to grind it anywhere nearly so often as would otherwise be the case. The only disadvantage that can be set off against these advantages is the increased cost, and it appears to be conceded that even with this consideration the balance is strongly in favor of the sub-press die.

Of course the larger sizes of these tools are not made in the familiar circular form illustrated in Fig. 2. Fig. 4 shows three different styles. The one at the rear has the sliding head guided by four vertical posts carefully ground and lapped to fit cast iron bushings. This is the construction used on heavy work. At the left is shown one in which the plunger is rectangular in shape. This works in a bearing lined with babbitt the same as the cylindrical form shown at the right of the cut and outlined in Fig. 2, although the bearing is not adjustable. The cylindrical form is used for the smaller sizes.

The making of a sub-press die requires all the skill of a and such holes as may be called for in the blank are transferred to die pad *G*. This is done by punches with outside diameters ground to fit the holes in the templet, and provided with sharp points concentric with the outside. The pad after being thus prick-punched, is put on the faceplate, the slight punch marks are carefully indicated, and holes are carefully bored to a taper to fit the punches which are to be inserted in them. The punches are finished by grinding on centers after they are hardened. They are supported at the shank by a male center, while the opposite end is temporarily ground to a point which revolves in a female center in the

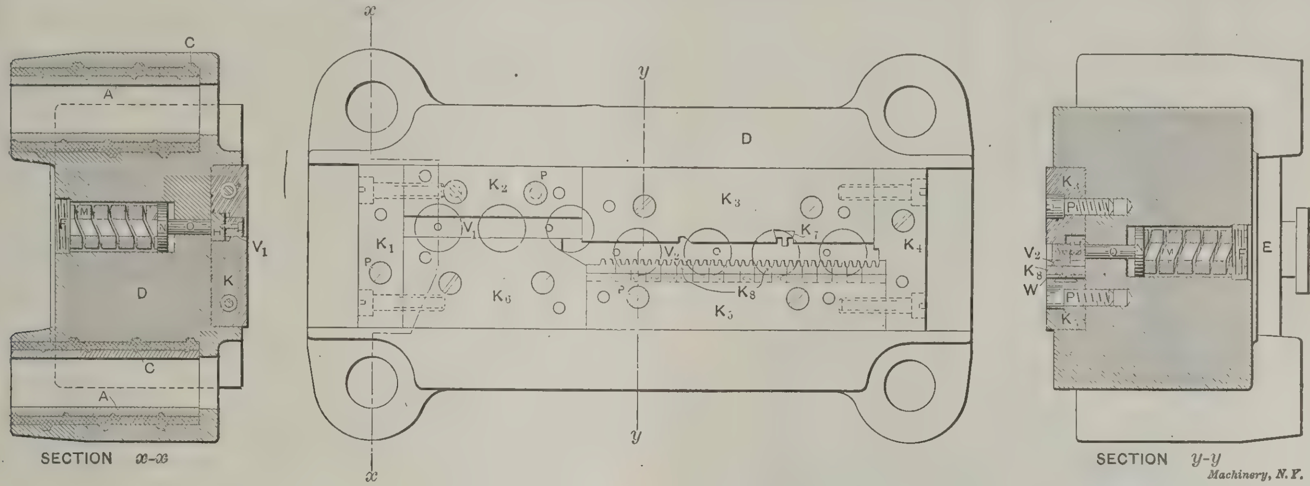

Fig. 5 Plan View and Section of Upper Member or Die of Sub-press shown in Fig. 7.

first class toolmaker. The method pursued by some, at least, of the men who are engaged in this work at the factory mentioned is about as follows: Taking the die shown in Fig. 3 as an example, the base *B* and cylinder *A* are machined and fitted together according to methods that would naturally be pursued by any good mechanic. The inner surface of the cylinder is grooved so that babbitt may be securely locked in place. Plunger *D* is then machined, and the outer surface ground and fluted with semi-circular grooves. Especial pains are taken to have these grooves parallel with the axis of the plunger in both planes; if this is not done the die may be given a slight twisting movement instead of the perfectly straight forward one that is required, since upon these grooves other end of the grinder. The punch may thus be ground all over with the assurance that the pointed end is true with the exterior—a necessary provision as will appear later.

It might be noted here that no draft is given to any of the cutting edges of these tools, since they do not enter each other, at least not to any appreciable extent, and since the stock in entering and leaving the cutting edges is positively moved, no clearance is necessary and the die cuts practically the same kind of a blank at the end of its life that it did at its birth. Shedder *H* is fitted to die *K* and the holes for the punches are transferred to it in the same way as for the die pad, by means of carefully machined prick punches which fit the holes in the models, these prick punch marks being afterward indicated

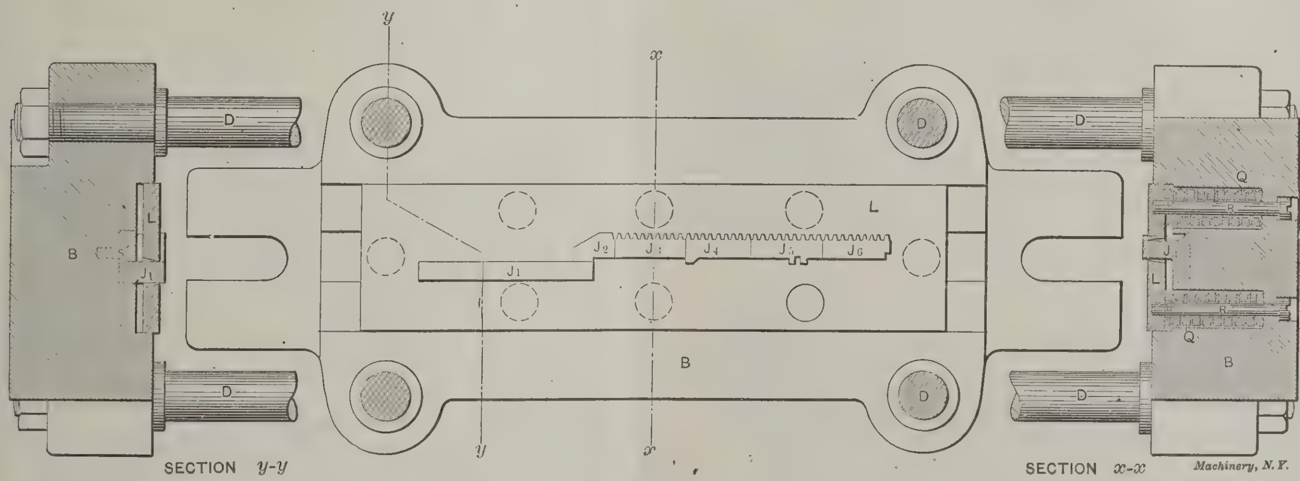

Fig. 6. Plan View and Section of Lower Member or Punch of Sub-press shown in Fig. 7.

depends the angular location of the punch and die with relation to each other. The plunger is now inserted within the cylinder and, with proper precaution, the space between them is filled with babbitt which flows into the grooves in the cylinder and those in the plunger as well, locking with one and guiding the other. After being cooled, the plunger is pumped up and down to insure a perfect bearing and the nut *U* is screwed down until all slack is taken up. Die *K* is now made to accurately fit the templet or model furnished the toolmaker as a sample. After it has been completed, it is hardened and fastened in place. Then the model is inserted within it, to run true on the faceplate. The punch is now worked out a very slight amount larger in all its outlines than the die. The model is laid upon it, the holes transferred to it as in the case of the other parts, these holes being then indicated and bored out, but not ground in this case, being left three or four thousandths smaller in diameter than finished size. The punch is fastened in place in the base, lining up as nearly as possible with the die. The ram is forced downward in a screw press until the punch enters the die very slightly, cutting a thin chip from its sides to bring them to the shape required. The punch is then worked down to this point all

around and again entered in the die a short distance further, the operation being repeated until the two parts fit perfectly.

In finishing the holes in the punch, after the hardening process plugs are driven in each of them as shown in Fig. 8. The punches f still with their ends pointed concentric with their outside surfaces, are fastened in position in the upper member, and the ram is brought down until these punches mark slight centers in the top of the brass plugs, when the ram is again raised and the punch J removed. The punch is then strapped to the faceplate and each of the small plugs is

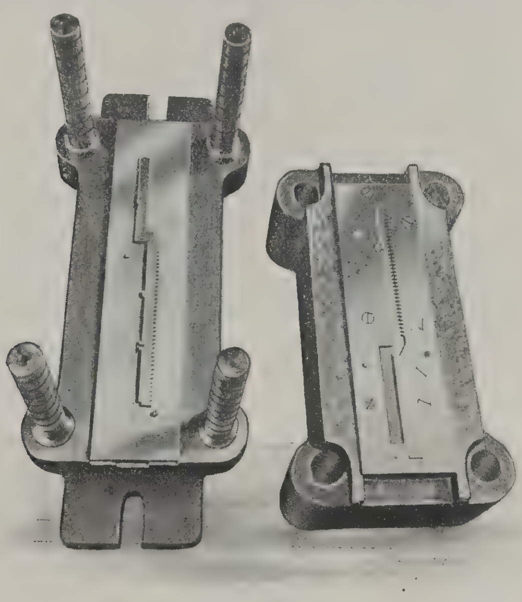

Fig. 7. A Good Example of Sub-press Construction.

in turn indicated from the prick punch marks, when it is removed and the hole is ground to size with a steel lap charged with diamond dust in an internal grinding fixture. The stripper is fitted to the punch in the usual manner. With the parts thus made and fitted great accuracy is obtainable.

A die of the four-posted type is detailed in Figs. 5 and 6, Fig. 6 showing the lower member or punch while Fig. 5 shows the upper member or die. This sub-press is used in making the piece with rack teeth shown in the upper right-hand corner of Fig. 1. A slightly different method of procedure is followed in this case than with the sub-press just described. The punch and die are finished before the upper and lower members are lined up with each other. When the time comes for doing this the punch is entered in the die, the two parts being parallel with each other as to their faces, when bushings A are slipped over the posts until they rest in the bottom of the cast counterbores in die holder D, Fig. 5. This counterbored space has had packets gouged out in the sides for

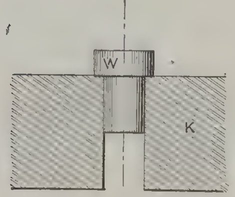

Fig. 8. Plug for Centering Holes for Grinding.

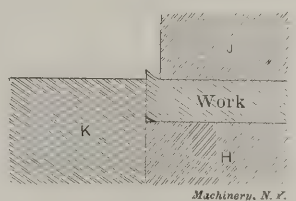

Fig. 9. Action of Badly-fitting Punch and Die.

the babbitt to flow into and lock with. The grooves shown in the posts in Fig. 4, are not yet cut in Fig. 6, they being still smooth and true as the grinding left them. The space C being poured full of babbitt and allowed to cool, the punch and die are permanently aligned with each other without possibility of shifting. The posts are then removed and the spiral grooves for oil distribution are cut in them.

One of the noticeable points about this die, as shown in Fig. 6, although the work is so closely fitted in the tool itself that the eye is scarcely able to distinguish the construction, is the fact that the section of the cutting edge which shears out the rack teeth is built up of small segments, each containing two teeth only, these segments being dovetailed into the larger piece, K_5. Each of these small pieces, K_8, is secured by two dowels which pass through from side to side of K_5, locking the parts firmly together. This costly and difficult construction was necessitated by the demand for accuracy in the spacing of the teeth. With the sectional construction shown the parts are not affected sensibly in the hardening. That piece K_5 may not be warped out of shape; it is ground to size in all its surfaces, top, bottom, sides and even in the dove-tail, so that when completed its plane surfaces are straight and parallel. The dove-tails of the die sections K_8 are next machined to fit this and inserted, being then spaced the proper distance apart. The holes in K_5 are then continued through pieces K_8, which are taken out and hardened, and returned to be dowelled in place. It will be seen that this die is constructed on the sectional plan throughout. This makes it possible to finish on the surface grinder most of the cutting edges. Troubles due to distortion in hardening are thus entirely avoided. The proper end measurements between vital points in the model are also preserved by leaving a slight amount of stock where two sections of the die come together, the parts being ground away at this point until the proper dimensions are obtained.

In the few cases where the grinding wheel will not finish the cutting surface, great use is made of diamond laps, these being in the form of steel sections of proper contour to fit the part of the die they are working in, these steel pieces being charged with diamond dust and reciprocated vertically

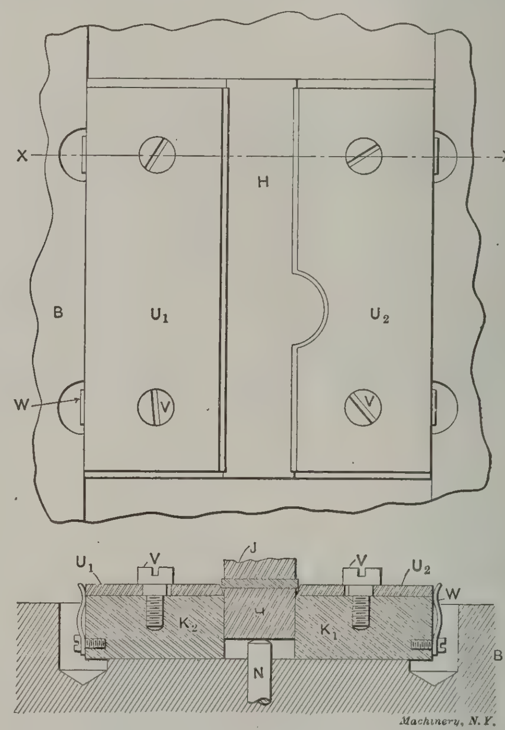

Fig. 10. Shaving Die with "Nest" for Locating the Work.

in filing machines, of which a large number are used in this shop. The little dove-tail in which part K_7 is inserted, for instance, was finished in this way. The back of the dove-tail is perpendicular but the two sides slope somewhat from the vertical forming a wedge-shaped opening enlarged toward the rear. Section K_7 is then driven in from the rear, finished off, and ground with its front face flush with the rest of the die. In Fig. 7, which shows this sub-press, this little section has not yet been finished off, so that it is seen to project above the remaining part of the die.

This is the first operation or the blanking punch and die. The pieces produced are afterward subjected to the action of a shaving die, the original blanks being left with 0.002 or 0.003 stock for this purpose which is trimmed off in the final operation. The punch for this first or blanking die has the rack section subdivided into four parts only, which are matched up carefully with the sectional die just described. In the shaving die, however, this punch is built in sectional form as described above for the blanking die, so that great refinement in measurements is secured.

The sub-press just described is that shown at the back of Fig. 4 and opened up in Fig. 7. Its action is exactly identical with the smaller one just described; it has all its advantages and presents the same deceptive appearance of perfectly homogeneous surfaces in the punch and die when it is completed. In the illustration the shedder and stripper springs have been slacked up in order to show the outlines of the cutting edges, but this is not the normal condition.

A feature of the shaving die system, to which reference has been made, is the use of a "nest" to locate the work. In this trimming operation the punch is in the upper member and the die in the lower one. On the surface of the die, of which an example is shown in Fig. 10, are placed steel guiding plates, U_1 and U_2, which form the nest referred to. They have their edges shaped to the outline of the piece to be operated upon and they are pressed inward by flat springs *W* at the outer edge, being allowed a slight lateral movement although retained from sidewise displacement by shoulder screws *V*. The holes through which these screws pass are slotted to permit this; the end of the slot limits the inward movement of the plate. As shown in the enlarged views, Figs.

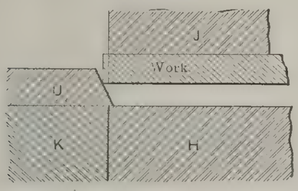

Fig. 11. "Nest" with Work in Place.

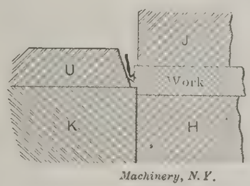

Fig. 12. Work being Trimmed in Shaving Die.

11 and 12, the inner edges of these plates are bevelled backward so as to form a recess in which the work may be located. The descent of the punch forces the plates out, which, as they are displaced, still guide the work so that it is properly centered over the die. These beveled edges of the plates have the further advantage of curling the chip out of the way where it does not clog the tool and may be easily cleaned off. The shedder coming up from below and removing the work, closes the lower opening effectively so that the whole device is chip tight.

Even greater accuracy is advisable in the fitting of the punch and die in this shaving sub-press than is necessary in that used for blanking only, if it is desired to produce clean work free from burrs. The necessity for this will be appreciated upon examining Fig. 9, which shows in magnified form the action of the cutting edges. If the punch *J* does not match up closely with the edge of die *K*, the stock is bent upward leaving a sharp burr, while the punch impresses the outline of its cutting edge on the top surface of the blank.

Mr. Haney, the general manager of the Sloan & Chace Mfg. Co., has ambitions for this branch of the firm's product which are by no means modest. It is his aim to build the greater part of the dies made in this country for purely manufacturing purposes. The idea of having the tool work of a manufacturing firm done by an outside party has a number of commendable features about it. Suppose a new concern is about to enter in business as a manufacturer of typewriters. There has to be an enormous initial expense for tools and, as a part of it, the buying of a great many costly machines, the establishment of a large toolmaking department, together with the hiring and organization of an efficient toolmaking force—an exceedingly difficult undertaking. In general it entails an amount of worry and expense which can only be appreciated by those who have been unfortunate enough to have actually met these conditions. Where it is not necessary to have a larger toolroom equipment and organization than is required for keeping tools in repair and for making occasional additions to the line as slight changes are made, a large part of the time, expense, and worry might be avoided. This is where the independent toolmaking firm has its strong hold. Filling orders for a great number of different concerns, they can have a nearly constant volume of business, a constantly used equipment of fine machinery, and an efficient corps of diemakers, working under the assurance that their jobs are permanent ones; this would not be the case were they working for a new firm just starting in business, who then require many more men in making these tools than they will to keep them in repair and make occasional changes.

It is evident that manufacturers have begun to look at the matter in this light, for the firm of which we are speaking has more of this work on hand at the present time than it can attend to, some of their contracts being of a size that is startling both as to the number of tools and their money value. The only factor which hinders a rapid growth of this business to many times its present size is the fact that it has so far been exceedingly difficult to get men who are capable of doing the work that is required of them. Almost all of the workmen have learned the business in this shop, some of them having been there for many years. Of the many who have come in response to advertisements and in the ordinary course of their wanderings, only a few have been found who are able to meet the demands made upon them. The firm is preparing in the near future to institute an apprenticeship system with the hope of educating bright boys to be capable and efficient diemakers.

* * *

STRAIGHTENING RACKS MADE FROM COLD ROLLED STEEL.

The phenomenon of skin tension in cold rolled steel is one with which all shop men are familiar. This process of working the steel develops permanent stresses in the outer portion of the metal, and if this outer portion is taken off on one side of a square bar, for instance, the stresses in the opposite and untouched side will be sufficient to draw the stock into an arc of a circle. This condition is met with in cutting racks in square cold-rolled stock, a practice in common use at the present time, since it avoids the necessity for planing the four sides of the work as would have to be done if machinery steel were used. After the teeth are cut in these racks, they are so distorted that drastic treatment has to be applied to bring them back to a condition in which they are fit for use.

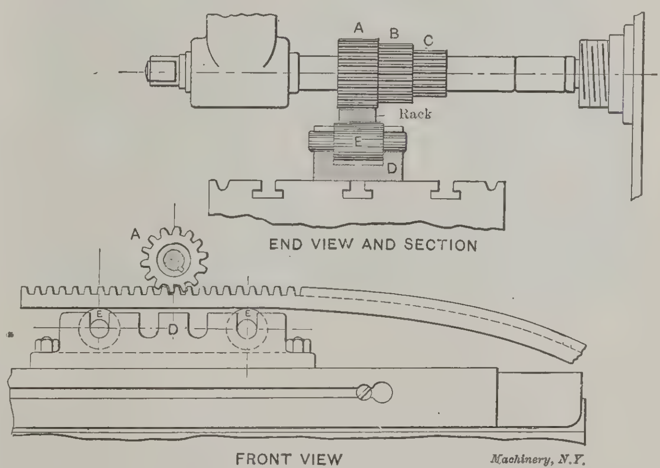

Fig. 1. Straightening Cold-rolled Racks in the Milling Machine.

Fig. 1 shows the principle of a device for this purpose which has been used for some time by the R. K. Le Blond Machine Tool Co., Cincinnati, Ohio.

A plain miller, which stands near the rack cutter, is made use of. An arbor is mounted in the spindle, carrying, ordinarily, three gears, *A*, *B*, *C*, of the pitches most commonly used. On the table is clamped a channel casting *D*, which is provided with four slots in each side, in which may be placed the rollers *E*, which are made of about the dimensions shown. The use of the device will be readily apparent. The rolls are dropped into place at such a distance apart as best suits the work in hand, and are brought in line with the proper gear on the arbor, which is then located centrally between the two rollers. The rack is now fed in between the rollers and the gear, and the table is brought up until pressure enough is exerted on the rack to straighten it. The spindle is revolved slowly and the rack feeds through and is bent back into shape again by the pressure between the rolls and the pinion. The gears *A*, *B* and *C* are so proportioned that they bear on the tops of their teeth as well as on their sides. This prevents stretching the racks when in mesh with the gears. Were this

not so, the wedging action of the gear teeth, under heavy pressure, would spread the rack teeth and increase the pitch, lengthening the rack to some degree at least.

While this arrangement worked well on small racks, when it came to the heavier ones the straightening imposed a strain of several tons on the spindle, and it took about 3 horsepower to drive the work through the rolls. This was too severe service to give the miller, and a special machine was therefore designed, working on the same principle but better adapted for its intended use. The machine consists essentially of a bed *A* (mounted on suitable legs of ordinary pattern) to which is cast the bracket *B* carrying the main spindle *C* of the machine; the bracket in its design resembles the column of a Stiles pattern punch press. At *D* is a block adjustable for the desired height through hand wheel *E* and the attached gear train *F G* and elevating screws *H*. These elevating screws run in nuts seated in counterbores in the bed of the machine. Pulleys *J J*, driven in opposite directions by open and crossed belts at suitable speed for the work being done, run loosely on shaft *K*; either of them, however, may be clutched to the shaft by moving handle *L* to the right or left, as may be desired. This handle operates an internal clutch similar in construction to the well-known device used on the double back gears of the Le Blond milling machine. To shaft *K* is keyed a worm, which in turn drives worm wheel *O* and through it spindle *C*. On the end of the spindle may be mounted any one of the gears *P*, which are made in pitches ranging from 5 to 14 to agree with the rack which is to be straightened. Rollers *Q*, which furnish a support for the rack, revolve in seats in block *D* in a manner exactly similar to the device illustrated in Fig. 1. As in the previous case four different slots are provided so that the distance between the rolls may be varied to suit the stiffness of the rack being straightened. The operator stands at the right of the machine in Fig. 2 with his hand on the controlling lever *L* and runs the rack back and forth, bringing up the rolls meanwhile with the handwheel *E* until the rack has been straightened. The handwheel is graduated in thousandths of an inch to allow the wheel to be brought to the same point each time when running through a lot of similar racks. The details of this device, which are very well worked out, can easily be gathered from a study of the drawings, which are shown in Fig. 2 complete in every respect save that the dimensions are omitted.

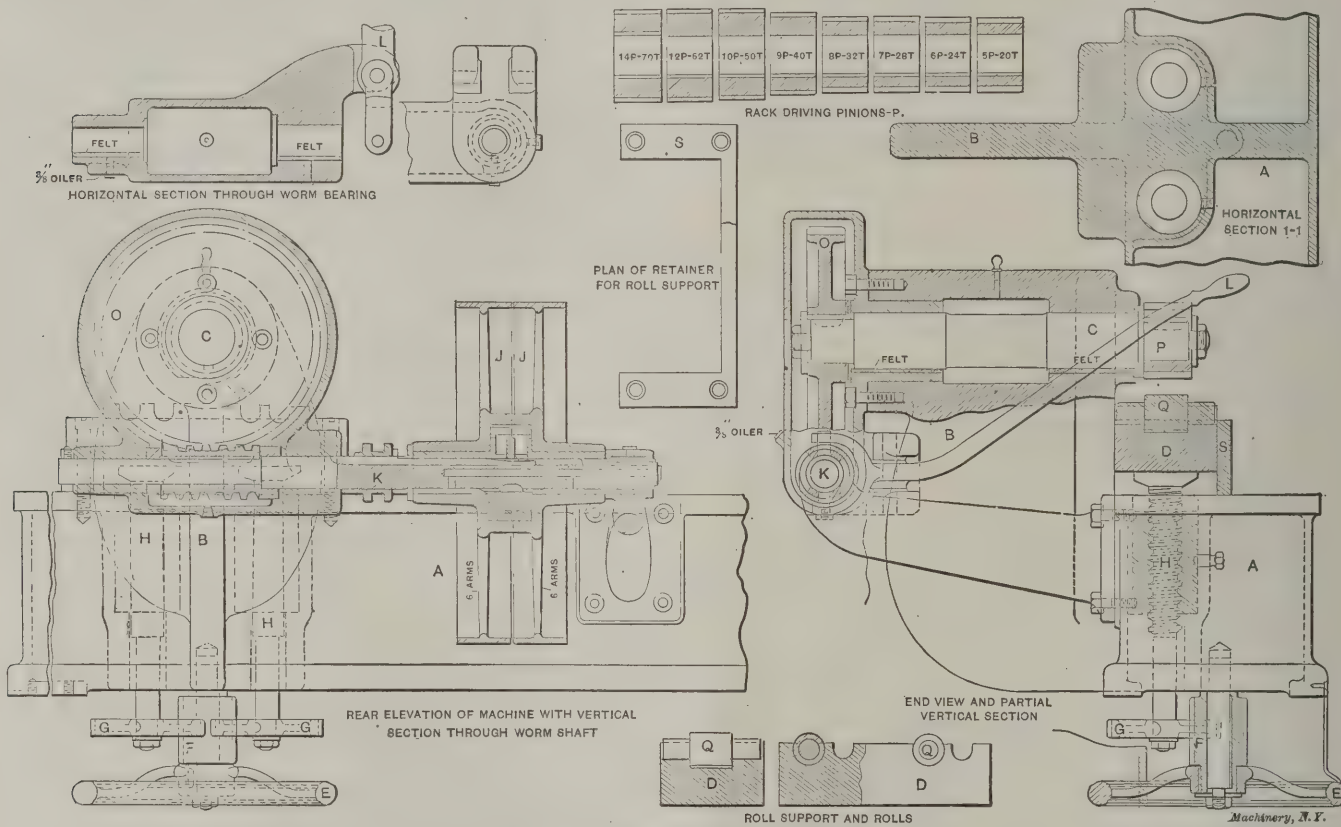

Fig. 2. Machine for Straightening Cold-rolled Steel Racks.

ENDURANCE RECORD OF TAPS.

In a comment on the endurance record for taps which appeared in the November issue, Samuel Hall's Sons, New York, say that they have an average of a ¾-inch tap tapping 10,400 nuts ¾-inch thick; and a 1-inch tap tapping 9,300 nuts 1-inch thick.

William H. Haskell Mfg. Co., Pawtucket, R. I., say: "We do not think that the number of holes tapped as mentioned by your correspondent is exceptional, as we should consider, that unless a tap of the size mentioned tapped a considerably larger number of holes than is mentioned by you, that the tap was faulty. We know that our taps tap more than 10,000 holes, but how many more, we cannot tell."

The Boston Bolt Co., Boston, Mass., say they would not consider that these taps did any specially large amount of work inasmuch as 10,000 holes in cast iron is not much work for a tap to do. Their explanation is that under favorable conditions a tap should tap at least 25,000 nuts of wrought iron, and they imply that the same tap should be good for a greater number of holes in cast iron than in wrought iron. "The number of holes we could tap probably depends upon the quality of the stock, on the temper of the tap, and also how much stock the tap has to remove. We should not be surprised if under some conditions a 1-inch tap would tap 40,000 nuts. We have no exact data to which we can refer but certainly if a tap did not tap 10,000 pieces we would consider it inferior."

The Garland Nut & Rivet Co., Pittsburg, Pa., say that in tapping iron and steel nuts they could not approach the record made by Mr. Sallow's taps.

The Graham Nut Co., Pittsburg, Pa., say the tapping of nuts is largely regulated by the speed of the tap and consequently the tap sometimes suffers on that account. They consider about 5,000 inches a good average for nut taps. This would be equal to about two-thirds the record made by Mr. Sallow's taps.

* * *

The excellence of the design of the sister ships *Lusitania* and *Mauretania* of the Cunard Steamship Co. is made publicly evident from the fact that the company has been awarded a grand prize for these models at the Milan Exposition. The prize awarded extended also to other models of the company's well-known steamers.

ADJUSTABLE FORMER FOR BEVEL GEAR PLANING.

G. L. H.

It is a well-known fact that in order to correctly plane the teeth of a bevel gear the cutting point of the tool should work toward the apex of the pitch cone. Bevel gear planers are built on this principle, the tool rest slide being hinged at one end in the apex of the pitch cone of the gear being cut (or at least arranged so that the tool will travel toward that point), the other end being supported on a former which determines the shape of the tooth. This principle is illustrated in Fig. 1. A convenient method of cutting ordinary bevel gears by the use of a comparatively small number of formers is described in the following paragraphs.

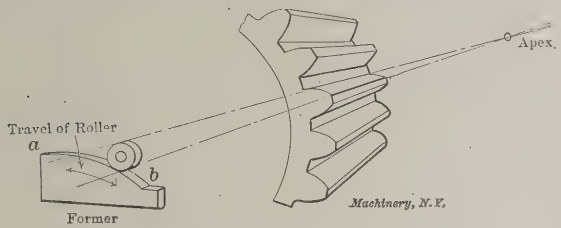

Fig. 1. The Principle of the Bevel Gear Planer.

Bearing in mind the fact that to a given circle there corresponds one and only one shape of involute, one can readily see by referring to Fig. 2 that a pair of formers, one for the upper and one for the lower side of the tooth, would serve for all gears if they could be set at any desired distance, H, from the apex of the pitch cone. If the shape of the former is the same as that of a gear tooth whose pitch radius is R, it will be suitable for cutting the bevel gear indicated by a full section, as the curvature of the gear tooth will be reduced from the curvature of the former in the same proportion as R is to r; but a bevel gear of any other pitch cone angle and number of teeth, for instance the one shown in part only, having a pitch cone angle A_1, can be cut with the same former, if only this former be set in the new pitch cone at such a distance, H_1, from the apex that the new pitch radius, R, is the same that it was before. The number of teeth in either of the gears is immaterial so long as the templet is long enough. A long tooth will use the whole of the templet from a to b, as shown in Fig. 1, while a shorter tooth, such as that represented as

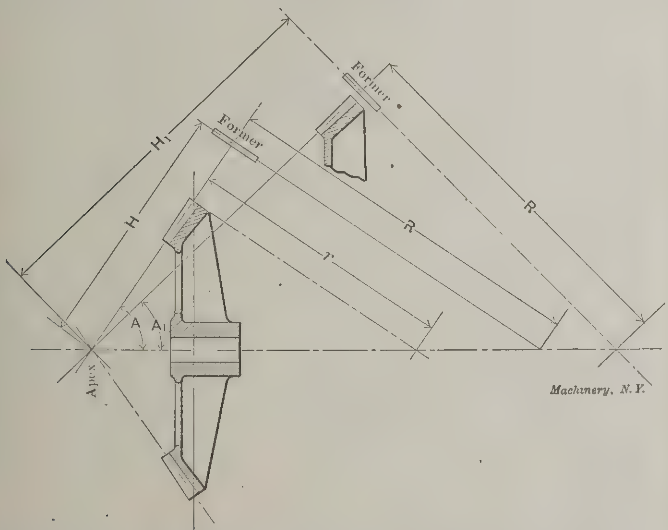

Fig. 2. Planing Gears of Different Angles with the same Former.

being cut, will only use as much of the former as is indicated.

As stated, it would be possible for one former to cover the whole range of pitch cone angles A, but since on any given machine, distance H has but a limited variation, this necessitates a series of formers in order to include all the gears capable of being cut on the machine. Suppose we have a machine on which a former can be set between 30 and 45 inches from the apex. Let H and H_1 in Fig. 2 represent these two extremes of distance, respectively. It is apparent from this diagram that $\frac{R}{H} = \tan A$. If 2 inches is the smallest value for R to be used on this machine we can, by using it in the above formula with different values of H between 30 and 45, obtain the corresponding values of A which, when laid out on the diagram, Fig. 4, will be represented by the curve $c\,d$. This diagram has, however, been extended, giving a minimum value to H of 20 inches and a maximum value of 55 inches. In a similar way all the other curves are found, the values of R for each succeeding one being chosen so that each curve intersects the 45-inch line at about the same value for the pitch angle that the preceding curve intersects the 30-inch line, thus always covering the field between 30 inches and 45 inches, the assumed limits of the machine.

Take, for example, a bevel gear with a pitch angle of 30 degrees; according to the diagram the 21-inch former, or a former made for a radius, $R = 21$ inches, is the one to be used, and the reading of the diagram shows that it should be set about 36¼ inches from the apex. If the machine allows a shorter or longer adjustment of the former than that assumed above, the 31½-inch former at about 54 inches or the 14-inch former at 24¼ inches from the apex would give the same tooth form. When the pitch radius of the former exceeds 200 inches the involute for any ordinary pitch of tooth is practically a straight line, and a former laid out accordingly may be set at any distance from the apex.

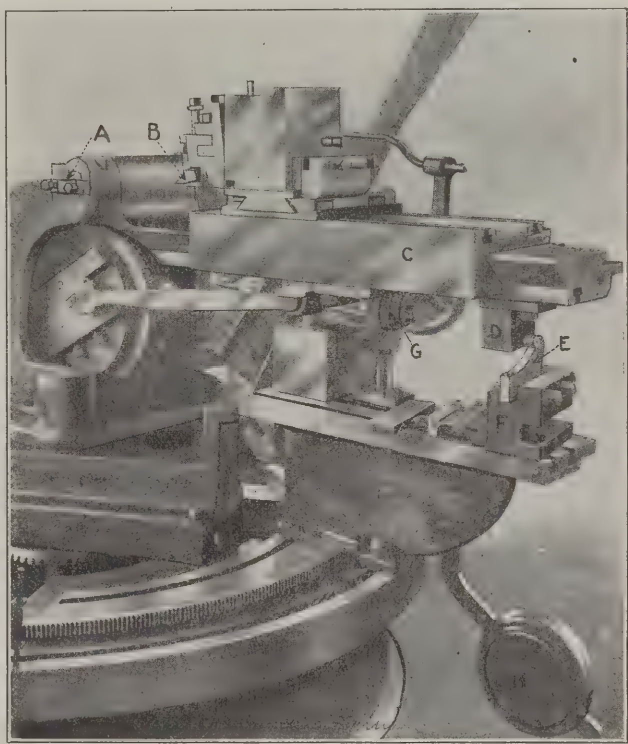

Fig. 3. Gear Planer Arranged with Adjustable Former.

In the above remarks involute formers only have been considered. Owing to the fact that the cycloidal curves vary not only with the pitch radius, but with the pitch as well, and consequently with the number of teeth in the gear, a simple diagram as shown above cannot be obtained for cycloidal formers.

Fig. 3 shows a tool slide and its controlling mechanism on a Gleason gear planer. At A is the apex of the pitch cone of the gear, the point toward which the tool B always travels. C is the reciprocating slide on which the tool is mounted. At D is the block carrying the former roller which follows the outline of former E; F is the support for the former. Both F and D are readily adjustable between the limits, in this machine, of 30 and 45 inches, as explained above. Counterbalance H supports a post and short track on which runs roller G attached to the support for the cutter slide. This serves to take a large part of the weight of the mechanism off of the former, thus making the guided parts more sensitive and easily handled.

[The scheme described above by our contributor allows the use of a smaller number of formers than would otherwise be necessary and practically makes allowance for the errors that

would be introduced in cutting, in the usual way, a gear whose pitch angle was about half-way between those of the two nearest formers. So far as we know, however, the make of planer to which this idea may be applied is not built at the present time in such a way that the distance from the former to the apex is adjustable. The machine shown in Fig. 3, on which the idea worked very nicely, is evidently of an old design. In the later machines, as we understand the matter, dimension H in Fig. 2 is constant for any given machine, and the formers are made to fit this dimension, being cut in a generating machine by a milling cutter, on a spindle which is pivoted to swing about the apex of the pitch cone in the same way that the tool slide does.—EDITOR.]

* * *

Aluminum may within the near future enter into serious competition with copper for the transmission of electricity for lighting, traction and power purposes. While the electrical conductivity of aluminum is only 63 per cent of that of copper, the specific gravity of the metal is less than one-third of that of copper, and thus conducting wires of aluminum, although of larger sectional area than those of copper with equal conductivity, will still be less than one-half the weight of the latter. It follows, therefore, that even if the price of aluminum were double that of copper, which it is not, a bare conductor made of aluminum would still be somewhat cheaper than the copper conductor. With insulated conductors there will be some difference owing to the additional insulation material made necessary by the larger area to be covered. —*Practical Engineer.*

THE WORLD'S SUPPLY OF IRON ORE.

Some time ago a prominent Scandinavian metallurgist predicted a famine in iron ore in about 100 years' time. In the United States this famine was to occur within thirty or forty years at the present rate of consumption. This, however, was not founded on a basis of the consideration of all the facts in the case. There is in existence a great amount of iron ores at the present time not considered worth using, because of their impurities. In the future, however, if the supply of the purer iron ore now used should prove to become less abundant, it is safe to predict that these ores will be largely used to make up the world's supply. This is true no less of America than of Europe. A number of mines were closed thirty or forty years ago in England because cheaper and better iron ore cut them out of the market, but when this supply of cheaper and better ore will be exhausted, the old mines will most certainly be reopened. An English metallurgist claims that three counties in England would supply that country at the present rate of consumption with ore for 200 years, and that considering all the iron ore possible to be used, Great Britain would have enough to last for 1,000 years without importation, provided that the consumption would not rise above the present rate. Probably similar statements would be true of the United States, and it is in all likelihood too early to commence to contemplate what to do when the world's supply of iron is exhausted. Methods are constantly being perfected for cheaper ore reduction, and while the quality of ore which will be used in the future may be poorer, the price of iron itself need not necessarily rise to any great extent.

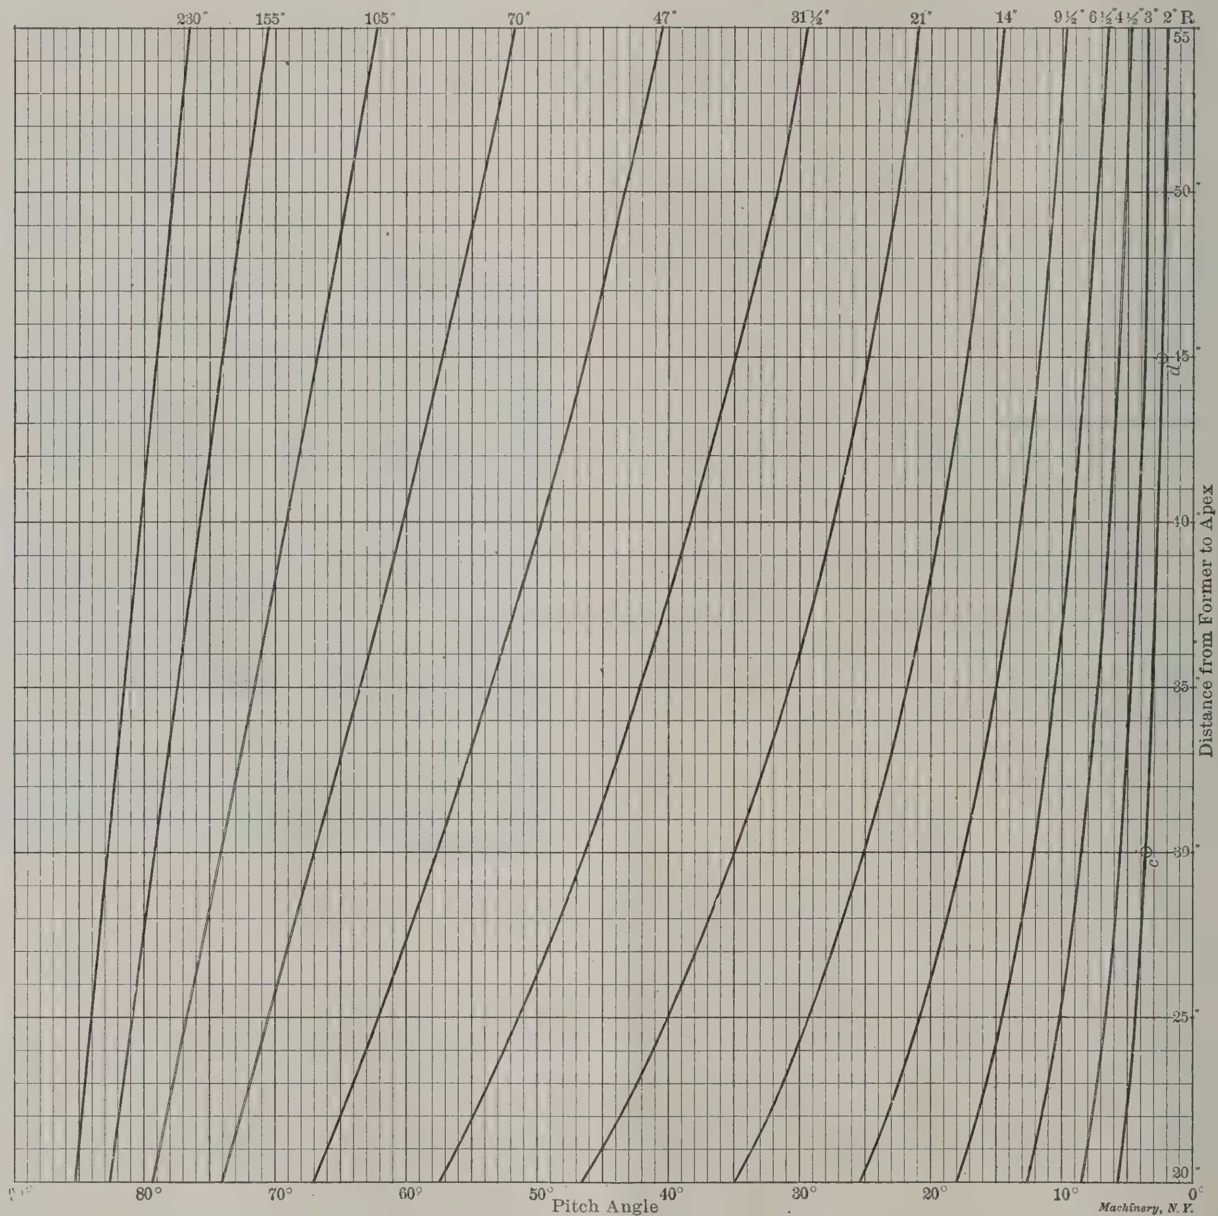

Fig. 4. Diagram for Selecting Formers.

DRILL JIGS.—2.

E. R. MARKHAM.

Holding Devices.—It is necessary to hold the work solidly in the jig without any chance of its changing location. Should the location change after one or more holes are drilled, and before all are drilled, it would cause a variation that would in all probability spoil the piece of work. When but a few pieces are to be drilled with a jig it is not generally considered advisable to make jigs with fastening devices, the work being held in place with a clamp, as shown in Fig. 7. In order to do away with any possibility of change of loca-

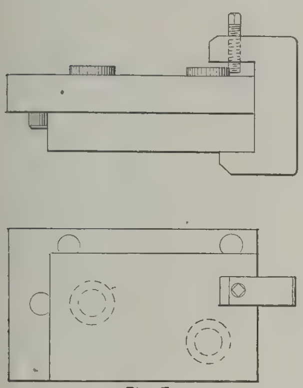

Fig. 7

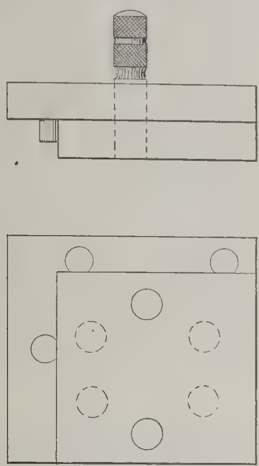

Fig. 8 *Machinery, N.Y.*

Means for Holding Work in Drill Jigs.

tion, a pin is forced through the jig hole and the hole in the work after drilling the first hole. If many holes are to be drilled in a piece it is advisable to have two pins. After drilling a hole in one end of the piece, force in a pin, then drill a hole in the opposite end, and place a pin in this hole, as shown in Fig. 8. The pins in opposite ends of the piece will prevent its slipping when the rest of the holes are drilled. Many different forms of fastening devices are provided, the design depending on the class of work. One of the most positive methods consists of a screw which passes through a stud or some elevation on the jig, and presses against the work, forcing it against the locating points, or stops, as they are called. The screw may have a knurled head, as shown

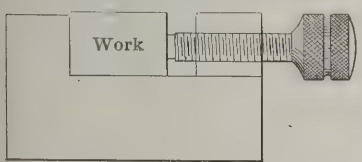

Fig. 9

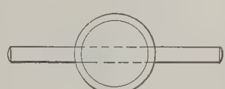

Fig. 11

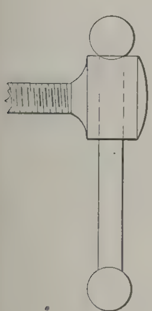

Fig. 12

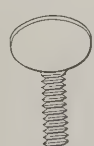

Fig. 10
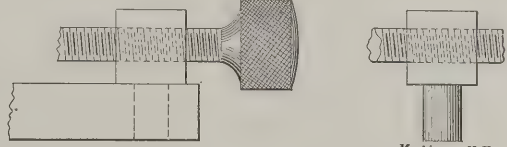
Machinery, N.Y.

Means for Clamping Work in Drill Jigs.

in Fig. 9, or a thumbscrew may be used, Fig. 10. Sometimes it is necessary to exert greater pressure than can be applied by means of a screw of the ordinary form. Then, it is possible to make a screw with a round head, drill a hole through it, and through this hole pass a piece of wire as shown in Fig. 11. By this screw sufficient pressure can be applied. When it is necessary to exert a greater amount of power than would be possible by the use of a pin of the length shown in Fig. 11, one may be used that will slide freely in a hole in the head of the screw. A ball placed on each end prevents its falling out. By getting the full length of the pin on one side of the screwhead as shown in Fig. 12, a much greater amount of power is obtained. At times the stud which supports the screw may interfere with the placing of the work in, or the removal of the work from the jig, or it might be necessary to turn the screw for a considerable distance each time the work was placed in or taken out of the jig. In such cases a stud could be provided that could be removed from the jig when the screw was relieved of its tension against the piece of work. Such a stud is shown in Fig. 13.

The more common method of fastening work is by means of a cam of suitable form. Cams of the ordinary design are not as powerful as the screw, but they have the advantage of being more quickly operated, and in the case of light work where but little strength is required, they answer the pur-



Machinery, N.Y.

Fig. 13. Clamp Screw Mounted in Removable Stud.

pose much better. The designer should bear in mind that a few seconds' time saved on each piece of work amounts to a large saving in a day when a number of hundred pieces are placed in and taken out of a jig. And in these days of competition every means of saving time consistent with quality of work should be considered. When the work bears against two points—one on the side and one on the end—the cam should be designed so that its travel against the work will force it against both, rather than away from one. Fig. 14 shows a piece of work held by a cam which, by means of the handle, forces the work inward and in the direction of the arrow, thus holding it against the locating pins *a a* and the end stop *b*. In order to get as much pressure as possible with a cam, it is necessary to have the portion that bears against the work when it is against the locating surfaces nearly concentric with the screw hole. This being the case, it is obvious that the pieces must be very nearly of one size, while in the case of a screw binder any amount of variation may be taken care of. Thus it will be seen that a screw may be used where a cam would not answer. However, it is advisable to use a cam in preference to a screw when possible, but at times the piece of work may be subjected to repeated jars which would tend to turn a cam, thus loosening the work. In such cases a screw is preferable. If a cam would be in the way when putting in or taking out work, it may be made removable as

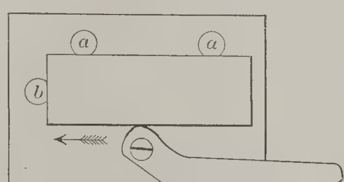


Fig. 14

Fig. 15
Machinery, N.Y.

Cam Clamp for Drill Jigs.

shown in Fig. 15. At times a tapered piece of steel in the form of a wedge may be used to hold work, as shown in Fig. 16.

When many pieces are to be drilled in a jig made in the simple form shown in Fig. 17, the drill wears the walls of the holes, enlarging them sufficiently to render accuracy out of the question. Where jigs are to be used enough to cause this condition, the stock around the walls of the hole may be hardened, if the jig is made from a steel that will harden. If made from machinery steel, the stock may be casehardened sufficiently to drill a large number of pieces without the walls wearing appreciably. This, however, would not answer when accuracy is essential, as the process of hardening would have a tendency to change the location of the holes.

When the jig is to be used for permanent equipment, or

where many holes are to be drilled, it is customary to provide bushings—guides—made of tool steel and hardened. These are ground to size after hardening, and being concentric, may be replaced, when worn, by new ones of the proper size. It is the common practice to make bushings for drill jigs on the same general lines as shown in Fig. 18, the upper end being rounded to allow the drill to enter the hole readily.

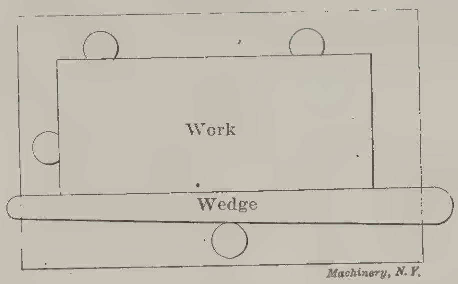

Fig. 16. Wedge Acting as Clamp in Drill Jig.

A head is provided, resting on the surface of the jig; the portion that enters the hole in the jig is straight, and is ground to a size that insures its remaining securely in place when in use.

If the hole is sufficiently large to admit a grinding wheel, it is ground to size after hardening. In such cases it is, of course, necessary, to leave the hole a trifle small—0.004 inch—until it is ground. If the hole is not large enough to allow of grinding, or if there is no means at hand for internal grinding, the hole may be lapped to size by means of a copper lap, using emery or other abrasive material, mixed with oil. When the hole is to be lapped rather than ground, leave a smaller amount of stock to be removed by the operation, say 0.001 inch or 0.0015 inch. After grinding or lapping the hole to size, place the bushing on a mandrel and grind the outside until it is a pressing fit in the hole. While on the mandrel be sure to grind the under portion of the head, *a*, Fig. 18, to insure its being true with the body. Before starting to grind the outside of the bushing, test the mandrel for truth. This should be done *after* placing the bushing on it rather than before.

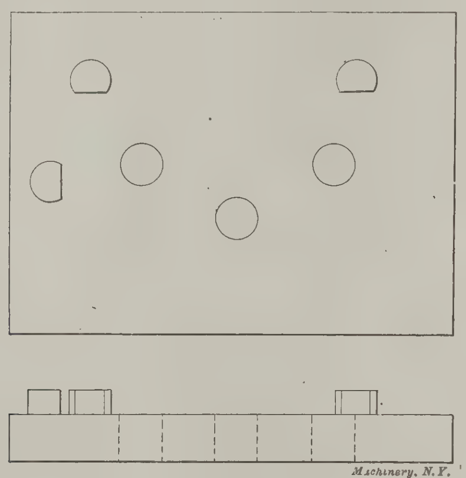

Fig. 17. Simple Form of Drill Jig without Bushings.

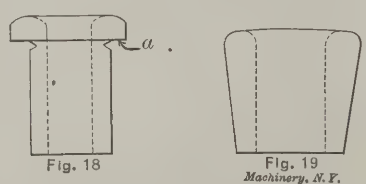

Bushings for Drill Jigs.

It is the custom in some shops to make the outer portion of bushings tapered, as shown in Fig. 19. Unless there is a sufficient reason for so doing, this is to be avoided, as the operation of making a tapered hole, unless it is bored on the taper with an inside turning tool, is not likely to produce a hole, the axis of which is at the desired angle to the surface of the jig. The outer portion of the bushing can easily be ground to the desired taper, but there is the liability of a particle of dust getting in the hole when placing the bushing in the jig. A tapered bushing, in order to get the proper taper, necessarily costs a great deal more than a straight one, and cannot answer the purpose any better, and probably not as well.

THE AUTOMOBILE SALESMAN AND HIS GOODS.

A. P. PRESS.

I send you a little yeast to lighten up the heavy matter; not that it is indigestible, but even a mechanic has more "wheels" than he can digest, sometimes. I am well aware that this is out of your line, and if you wish to throw it back on me, do not be afraid to do so; there will be no hard feelings.

You will remember I wrote you a year or two ago about the automobile (steam) salesman, and his expanding valve that kept the steam on the engine at any desired pressure, regardless of what the boiler might indicate, and also about his dividing line in the center of the boiler, so that if one-half burned out, you had the other half to come home on. I came across him again the other day; he was seated in a good-looking car of a well-known make, in the midst of an admiring crowd to whom he was extolling the virtues of the "auto."

"You see, boys, it is like this. This car ain't a circumstance to some of the new ones we are putting out, and while I ain't allowed to say much about it, I will say this: Our new model for 1908 is fitted with a chuck on the end of the engine shaft with lathe and mill attachment, so that no matter what happens, all you have to do is to put the drill in the same and make your own repairs, wherever you may be. Oh! I forgot to tell you; there is a vise, too, on the end of the tonneau. You see it makes you absolutely independent of any garage or machine shop. Then, the hydraulic cushions are new things——"

"Our new model for 1908 is fitted with a chuck on the end of the engine shaft with lathe and milling attachment."

"Pneumatic, you mean, don't you?"

"No! No! I mean hydraulic. Each cushion is made watertight and pumped up full. It makes the nicest seat you ever saw in your life. Then, it is connected with the cooling system from the radiator, so it keeps the seat cool in summer and warm in winter. I tell you what, it is great. Then, there is another one; we ain't saying much about it yet; it is for use out on the western prairies. It is fitted up with a cornshelling and bobbin-winding attachment. There is one farmer boy who has half paid for his, going around to houses and winding up bobbins at five cents per spool.

"One of the 'freaks' that we built on a special order is for a chicken fancier, who wanted to get clear of using gasoline. There is a large coop placed on the rear of the tonneau to hold about one hundred hens, and then every spoke in the wheel

is hollow. These are connected with a trap nest in the coop, so that the eggs run down through the hub and out into the spokes, just the same as that well-known 'perpetual motion' machine you have all heard about. The momentum of the eggs rolling out into the spokes keeps the thing going at a fair rate of speed."

"Yes," said one of the bystanders, "but what becomes of the eggs?"

"Catches them in a basket down at the bottom, and by the time he gets to town he has enough to pay for the automobile," said the salesman, as he slipped in his high gear and chugged away.

TABLET COMMEMORATING THE LOCATION OF THE HIDE AND LEATHER TRADES IN NEW YORK CITY.

The accompanying cut shows the bronze tablet mentioned in the business items for November, which was unveiled in New York October 27 in commemoration of the location of the hide and leather trades. This part of the city, known as the "Old Swamp," has been the home of the hide and leather trades for over a century. The site chosen for the tablet is the wall of the Schieren Building at the corner of Cliff and Ferry Sts., directly east of the Post Office. In the early days this locality was the site of numerous tanneries, these being the foundation of the present hide and leather industry in New York, and the industry still clings to this part of the

Bronze Tablet in the Wall of the Schieren Building, New York.

city, although the tanneries and the malodorous swamp have long since disappeared. The bronze tablet calls attention to the former existence of the tanneries on the site, stating that in excavating for the foundation of the building old tan vats were found in a good state of preservation containing tan-bark over one hundred years old. The tablet was unveiled in the presence of several hundred men connected with the hide and leather trades of New York and vicinity, and a luncheon was afterward served in the Schieren Building. An article on the Schieren Building and the manufacture of belting as conducted in the Schieren factory, was published in the May, 1906, issue.

* * *

It has become a custom with a great number of people to make an estimate of a country's prosperity from the amount of that country's exports. The fallacy of making an estimate of the prosperity of a country on such a ground is most easily apprehended if we compare the per capita exports of some European countries with the per capita exports of our own. There is no doubt whatever but that the general prosperity of the United States far exceeds the general prosperity of any European country, still the per capita exports of Germany and France have, at least up to the end of the last fiscal year, been both larger than the per capita exports of the United States. The per capita exports of the United Kingdoms are nearly twice as large, the per capita exports of Switzerland two and a half times, of Belgium three times, and of the Netherlands seven times as large as that of the United States. This seems to indicate that the country's prosperity does not entirely depend upon the amount of foreign exports, although this may be an important factor. It depends upon the internal conditions in the country, and American manufacturers do well in recognizing, that while the foreign trade may be an important item, the greatest possibilities for the building up of the industrial activities of this country are within the country itself. Whatever can be done to further our foreign trade is greatly important, but still more important is the establishment within our own borders of such conditions as will most greatly tend to increase the progress of our manufacturing.

SINGLE PULLEY DRIVES.

WM. F. GROENE.

The editor's request in Machinery several months ago for opinions on the "all gear" or "single pulley" drive, certainly relates to a subject on which discussion is timely. The question is one of the most important attracting the attention of machine designers to-day. The writer has recently made an extended tour through all the principal tool shops of the country, and with very few exceptions it is the opinion among builders and users that the single pulley drive will largely supersede the cone drive; and undoubtedly as soon as the present rush of business is over a great deal of attention will be given to tools of this design. Still for certain conditions it is doubtful whether we will find anything better than our old servant, the cone. The two principal advantages possessed by the single pulley drive are:

First, a great increase in the power that can be delivered to the cutting tool owing to the high initial belt speed. The belt speed always being constant, the power is practically the same when running on high or low speeds. The cone acts inversely in this respect; that is, as the diameter of the work increases, for a given cutting speed, the power decreases. As a second advantage, the speed changes being made with levers, any speed can be quickly obtained.

To these might be added several other advantages. The tool can be belted direct from the lineshaft; no countershaft is required; floor space can be economized. It gives longer life to the driving belt; cone belts are comparatively short-lived, especially when working to their full capacity. There are, however, some disadvantages to be encountered. Any device of this nature where all the speed changes are obtained through gears, is bound to be more or less complicated. The first cost of the tool is greater. There is also more waste of power through friction losses. A geared drive requires more attention, break-downs are liable to occur, and for some classes of work it cannot furnish the smooth drive obtained with the cone. Most of these objections, however, should be offset by the increased production obtained.

To the designer the problem presented is one of obtaining an ideal variable speed device, something that mechanics have been seeking for years with but poor success, and it is doubtful whether we will get anything as good for this purpose as the variable speed motor in combination with double friction back gears and a friction head. There are, it is true, some very creditable all-gear drives on the market in which the problem has been attacked in various ways. Still there is lots of room for something better. In the writer's judgment the ideal single pulley drive should embody the following conditions.

1. There should be sufficient speed changes to divide the total range into increments of say between 10 and 15 per cent.

2. The entire range of speeds should be obtained without stopping the machine.

3. Any speed desired should be obtained without making all the intermediate changes between the present and desired speed.

4. All the speeds should be obtained within the tool itself, and no auxiliary countershaft or speed variators should be used.

5. Only the gears through which the speed is actually being obtained should be engaged at one time.

6. The least possible number of shafts, gears and levers should be used.

There are few subjects in machine tools which admit of so many combinations, arrangements and devices. The writer shows in Figs. 1 to 6 inclusive, some sketches taken at random from a large collection. All of these, except Fig. 6, have the number of teeth and the speeds marked. Each has some good points but none of them possesses all the points referred to above. The only excuse for publishing them is to show what a vast number of designs can be devised. One of them, that shown in Fig. 1, has been built, a number of machines have been running for over a year, and they give very good results. In Fig. 7 is shown the way the idea was worked out as applied to a 20-inch Le Blond lathe.

[The design for the headstock shown in Fig. 7 needs little explanation since the drawing shows the parts quite clearly.

The friction clutch on the driving shaft Z, which alternately engages pinions H and J, is of the familiar type used in the Le Blond double back-geared milling machine. Sliding collar D operated by handle S moves the double tapered key E either to the right or left as may be desired, raising either wedge W or W', which in turn expand rings X or Y within the recess in either of the two cups, F and F'. Either of two rates of speed is thus given to quill gear K and the two gears L and M keyed to it. On the spindle is a triple sliding gear which may be moved to engage P with M, O with L (as shown in the drawing) or N with K, thus giving three changes of speed when operated by lever T. The six speeds obtained by the manipulation of levers S and T are doubled by throwing in the back gears, giving 12 speeds in all.

In comparing the merits of a series of gear drive arrangements like that shown in Figs. 1 to 6, how would it do to apply the "point" system in determining the most suitable one? The number of points that are to be assigned to a device for perfectly fulfilling any one of the various requirements outlined by Mr. Groene would be a matter requiring "selective" control is assigned 10 points. The fourth consideration, requiring that all speeds shall be obtained within the tool itself is a positive requirement. If it is not met, the mechanism is out of the contest, so this question need not be considered in our table of points. Fifteen points are suggested for the requirement that the gears not in use shall not be running in mesh. The sixth requirement reads "The least possible number of shafts, gears and levers should be used." It is suggested that this be divided, giving 20 points to the question of the ratio of the number of changes obtained to the number of movements required of the operator to obtain them, and giving the same number of points to express the ratio of the number of changes obtained to the number of gears used in obtaining them. The sum of these points added together is 100, which may be considered as representing the ideal design.

In filling out the table, since No. 1 has only 12 speeds or half the number required, we will give it only one-half the number of points, dealing similarly with the other designs up to No. 6, which is perfect in this respect. The machine has

Six Examples of Possible Geared Head Arrangements selected at random from a large number of Similar Sketches.

nice discrimination. So the method outlined below is to be taken as being suggestive, rather than authoritative. Our contributor's first requirement is that there shall be sufficient speed changes to divide the total range into increments of between 10 and 15 per cent. The six schemes he proposes do not all, unfortunately for our proposal, take in the same range of speed; considering, however, that they were each to be designed to give from 9 to 240 revolutions per minute to the spindle as in case No. 1, and that a 15 per cent increment is to be allowed, the number of changes required can be found in the usual way by dividing the logarithm of 27—, the total speed ratio required ($240 \div 9 = 27$—) by the logarithm of 1.15, which is the ratio of the geometric series desired. This gives 24 speeds, about, as needed to meet the requirements. Suppose we assign 15 points to a machine having 24 speeds. Let us set this down in its proper place in the table, given on the following page. For the second qualification, that the machine shall not have to be stopped, we may assign 20 points to the ideal machine. The principle of to be stopped to throw in back-gears. Assuming that this would not have to be done in 70 per cent of the changes, we get a uniform value of 14 for this consideration for all the cases. The feature of selective control is only about two-thirds realized in any of these designs, since the triple sliding gear used in all of them, in moving from one extreme to the other, passes through an intermediate position which is not required at the time. We may therefore assign the value 7 to each of these designs on this account. As to the question whether the gears not in use are running idly in mesh, all the designs are nearly perfect. The values set down in this table are suggested by this consideration. In considering the number of movements required to effect the number of changes obtained, the throwing in of the back-gear is credited with four motions, the stopping of the machine, unlocking of the spindle from the gear, the throwing in of the back gears and the starting of the machine. The 20 points of the ideal machine are then multiplied by each of the ratios obtained by dividing the number of changes by the number

of movements and the number of points found are set down as shown. For the last item twice as many changes as there are gears employed is taken as a maximum which can probably not be exceeded. With this as a standard the ratio obtained by dividing the number of changes by the number of gears used is employed to calculate the number of points.

A SUGGESTED TABULATION OF THE MERITS OF THE VARIOUS DRIVES PROPOSED.

Requirements.	Perfect Design.	No. 1	No. 2	No. 3	No. 4	No. 5	No. 6
No. of changes required compared with No. obtained..	15	8	8	8	8	10	15
Stopping of machine........	20	14	14	14	14	14	14
"Selective" control........	10	7	7	7	7	7	7
Gears not in use, must not be in mesh	15	13	13	13	15	15	13
Ratio of No. of changes to No. of movements	20	15	15	15	13	12	14
Ratio of No. of changes to No. of gears.............	20	10	9	9	9	16	18
Total	100	67	66	66	66	74	81

Adding the number of points obtained in each column we find that No. 1 has 67, No. 2, 3, and 4 each have 66, while No. 5 has 74, and No. 6, 81.

The comparison has been undertaken in this way with the understanding that all the arrangements are susceptible of being embodied in a practicable design. That arrangement No. 6 is practicable is strongly to be doubted. Our contributor has not given us the number of teeth in the various gears used, and it is far from probable that he could obtain with this arrangement a series of speeds in geometrical progression by moving in regular order the three levers required. Nos. 4 and 5, while otherwise well arranged, are open to the objection that sliding gears rotating at high rates of speed are used. This, if valid, constituted a disqualifying objection similar to that mentioned in relation to Mr. Groene's fourth requirement. The first three cases in which a friction clutch instead of sliding gears is used on the driving shaft are therefore much to be preferred for this reason. Of these first three cases, our tabulation shows that case No. 1 has a slight advantage, and Fig. 7, in which this arrangement has been applied to a 20-inch lathe headstock, shows that the scheme is a simple and satisfactory one, so far, at least, as one can judge from a drawing.

As before remarked, the suggestion that the merits of these arrangements be tabulated and determined mathematically is a tentative one only and we are willing to withdraw it in the event of determined objections on the part of experienced designers.—Editor.]

* * *

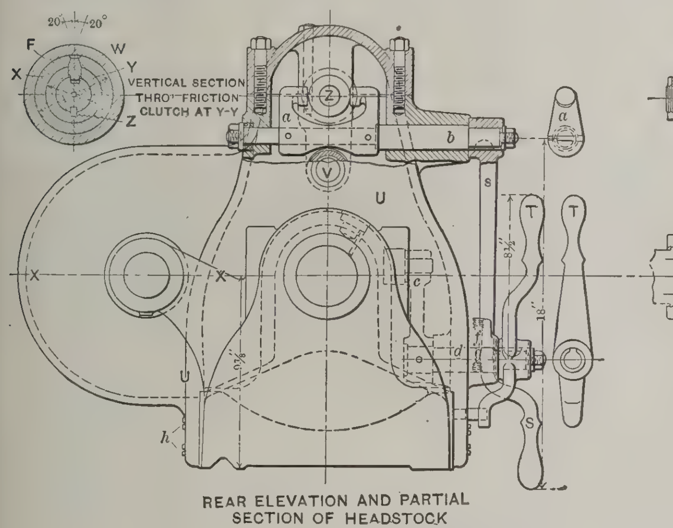
So far steam turbines of the Parsons type have been manufactured to give a total of 870,000 H. P. Of this 200,000 H. P. come on American builders, and 350,000 H. P. on the original Parsons' Works in England.

TAPPER TAPS.

ERIK OBERG.

The name tapper tap as understood by toolmakers and tap manufacturers is applied to one of the two kinds of taps used for tapping nuts in tapping machines. It is often confused with the expression machine tap, which properly designates the second kind of taps used for this purpose; the machine tap, however, differs from the tapper tap in a number of particulars, most important of which are the number and the form of the flutes, the relief of the threads and the general design. The tapper tap is the earlier of the two, and is simpler in its details. It is not adapted for the same hard usage as would be a machine tap, but is largely used for tapping nuts for general purposes in material which is not of too tough a structure.

The general appearance of the tap will be seen from the cut, Fig. 3. It consists of a threaded portion, *A*, chamfered on the top of the thread for a distance, *B*, and a shank, *C*, which as a rule is not provided with a square on the end,



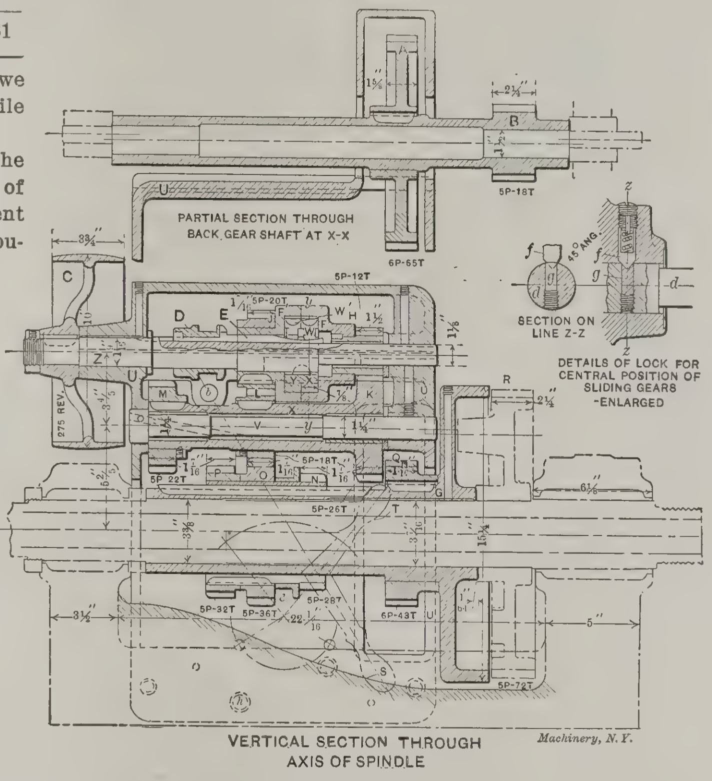


Fig. 7. The Scheme shown in Fig. 1 applied to the Headstock of a 20-inch Lathe.

this being unnecessary, because the tap is usually held firmly in a chuck by its circular shank. Some manufacturers using these taps prefer, however, to have the shank flatted on two sides, enabling them to secure a firmer hold on the tap in the machine. The diameter of the shank should be at least 0.015 inch smaller than the diameter at the root of the thread, in order to permit the threaded nuts to slide freely over the shank.

In turning and threading tapper taps, as well as any other taps, it must be remembered that the straight part of the threaded portion must be left a certain amount over the standard size. The screw which is to fit the nut threaded by the tap is usually made of a standard diameter, and the nut therefore must evidently be somewhat in excess of this in order to permit the screw to enter and to allow for slight unavoidable differences in the lead of the thread between the screw and the nut. The amount which a tap should thus be left over the standard diameter is largely a matter of judgment, inasmuch as this amount must vary according to whether a tight, free or loose fit is desired between the screw and the nut made by the tap. For general purposes, however, the tap should be made between the limits of from 0.0005 inch to 0.0015 inch oversize before hardening for sizes not over one-half inch diameter, from 0.001 inch to 0.002 inch for sizes between one-half and one inch, and from 0.0015 inch to 0.003 inch for sizes between one and two inches in

diameter. Tapper taps are rarely made in sizes larger than two inches. When larger diameters of taps are required for nut tapping, the taps should preferably be made on the principles of machine taps, the design and making of which the writer will return to in a later issue.

In fluting tapper taps it has been the practice to flute them practically the same as hand taps. It is, however, not necessary to make the lands as wide as on these latter taps, because there is not the same tendency for a tapper tap to deviate from its true course, the tapper tap being guided by the firm grip of the chuck, while a hand tap depends solely upon the lands of its threaded portion for guidance. The fluting of taps is one of the most important factors entering in their manufacture. The correct flute is a compromise be-

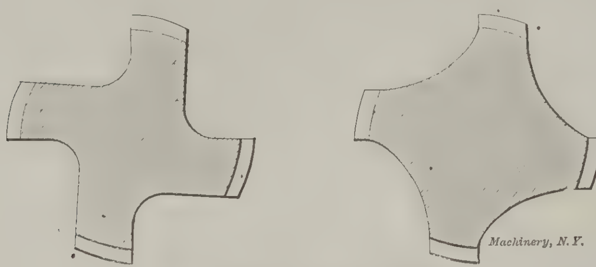

Fig. 1. Different Forms of Flutes.

tween a flute which will give the greatest amount of chip room and the greatest strength to the tap. Besides the flute must be of a shape easily produced, so as to limit the cost as far as consistent with good results, and must carry away the chips from the cutting edges in a manner offering the least resistance. The present practice is to provide tapper taps with deep straight-sided flutes having a small round in the bottom, as shown to the left in Fig. 1. This method, while it provides an abundance of chip room, is accompanied by some very grave disadvantages. The tap will crack more easily in hardening, it will not carry away the chips from the cutting edges as readily, and is not as strong as a tap fluted in the manner shown in the section to the right in Fig. 1. The making and maintenance of the cutters for producing this latter flute, however, is more expensive, and as the present practice of fluting is becoming fairly universal it is evident that the objections, while of a serious nature, do not outweigh the advantages gained. A tapper tap par-

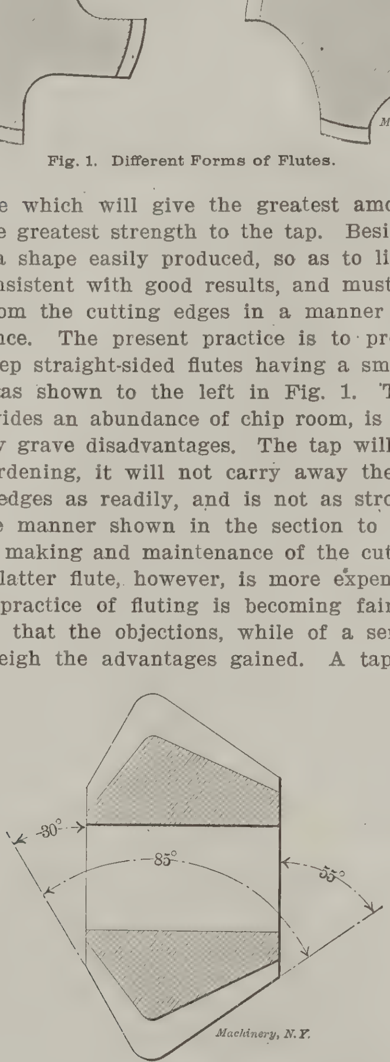

Fig. 2. Fluting Cutter for Cutting Flutes shown to the left in Fig. 1.

ticularly needs plenty of chip room because of its rapid cutting. The radius at the bottom of the flute ought, however, not be less than one-quarter of the diameter of the tap. Some persons well familiar with this kind of work claim that a radius of one-eighth of the diameter of the tap would serve the purpose equally well, besides giving a larger space for chips. It has been proven beyond doubt, however, that this slight difference in the radius at the bottom of the flute influences the endurance qualities of the tap very materially. In regard to the number of flutes there is some difference of opinion. The practice adhered to by prominent tool manufacturers is to give four flutes to all taps up to and inclusive of one and one-half inch diameter, and five flutes for larger sizes. The fluting cutter for straight-sided flutes should have an inclusive angle of 85 degrees, 55 degrees on one side, and 30 degrees on the other, as shown in Fig. 2.

The next question of importance is the question of the relief given to the thread. Tapper taps as a rule are relieved only on the top of the thread of the chamfered portion. They are not given any relief in the angle of the thread. The straight part, which performs no cutting, being nothing but the sizing part of the tap, should not be relieved, or, if relieved, the relief should be very slight in order to permit the tap to retain its size so much the longer. It may be remarked that if the tap is backed out through the nut no relief at all should be permitted on the parallel part of the thread, because of the liability of chips getting in between the land and the thread in the nut, injuring tap as well as nut. In hardening these taps they should be drawn to a temper of 430 degrees F.

The accompanying formulas and a table figured from them give the common proportions of length of thread and length of chamfered part of tapper taps. The length over all depends solely upon the kind of work the tap is to be used on. It is the common manufacturing practice to make these taps 11 inches long over all. The formulas are based upon the diameter of the tap as this is the most convenient working factor. It may be objected that the length of thread should rather depend upon the pitch of the thread than upon the

DIMENSIONS OF TAPPER TAPS.

D	A	B	D	A	B
$\frac{1}{16}$	$\frac{5}{8}$	$\frac{1}{4}$	1	$3\frac{3}{4}$	$1\frac{1}{2}$
$\frac{1}{8}$	$\frac{7}{8}$	$\frac{3}{8}$	$1\frac{1}{8}$	4	$1\frac{9}{16}$
$\frac{3}{16}$	$1\frac{3}{16}$	$\frac{7}{16}$	$1\frac{1}{4}$	$4\frac{1}{4}$	$1\frac{11}{16}$
$\frac{1}{4}$	$1\frac{7}{16}$	$\frac{9}{16}$	$1\frac{3}{8}$	$4\frac{1}{2}$	$1\frac{3}{4}$
$\frac{3}{8}$	2	$\frac{3}{4}$	$1\frac{1}{2}$	$4\frac{3}{4}$	$1\frac{7}{8}$
$\frac{1}{2}$	$2\frac{9}{16}$	1	$1\frac{5}{8}$	5	$1\frac{15}{16}$
$\frac{5}{8}$	3	$1\frac{3}{16}$	$1\frac{3}{4}$	$5\frac{1}{4}$	$2\frac{1}{16}$
$\frac{3}{4}$	$3\frac{1}{4}$	$1\frac{5}{16}$	$1\frac{7}{8}$	$5\frac{1}{2}$	$2\frac{1}{8}$
$\frac{7}{8}$	$3\frac{1}{2}$	$1\frac{3}{8}$	2	$5\frac{3}{4}$	$2\frac{1}{4}$

diameter. This is true to a certain extent, but if we limit the formulas to standard thread taps, there will be no cause for errors, inasmuch as the number of threads is in all standard systems dependent upon and stands in a certain proportion to the diameter. In the table the values are given approximately as there is no reason to work closer than to one-sixteenth or even one-eighth inch in regard to length dimensions of this character.

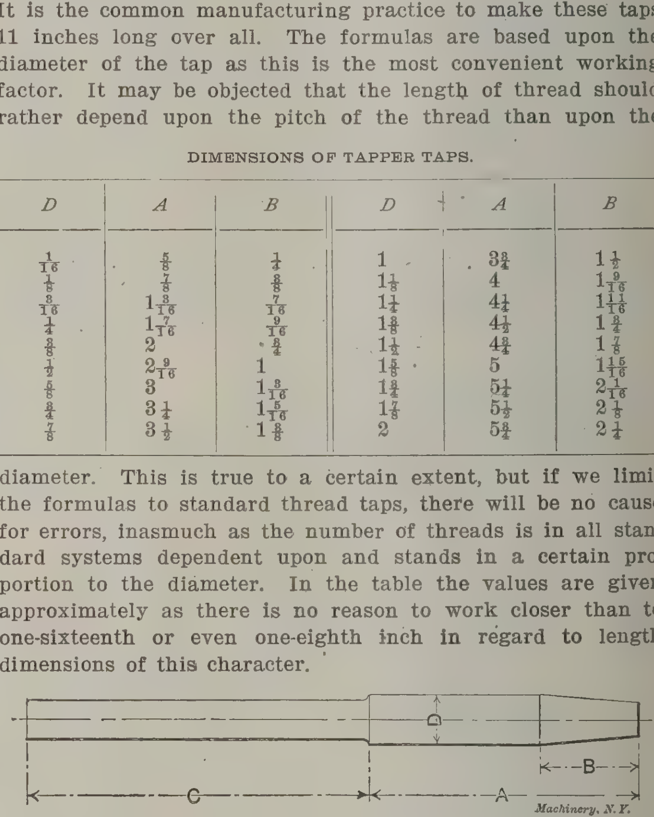

Fig. 3. General Appearance of Tapper Tap.

In the following formulas:

D = the diameter of the tap,

A = the length of the threaded portion,

B = the length of the chamfered portion.

For taps from 1/16 to 9/16 inch the following formulas are used:

$A = 4.5\,D + 5/16$,

$B = 1.75\,D + 1/8$.

For taps from ⅝ to 2 inches, use the formulas:

$A = 2\,D + 1\frac{3}{4}$,

$B = 0.75\,D + \frac{3}{4}$.

The diameter at the small end of the chamfered part should be from 0.005 to 0.008 inch below the root diameter of the thread on sizes smaller than ¼ inch in diameter, for sizes up to one inch about 0.010 inch below, and for larger sizes about 0.015 inch below the root diameter.

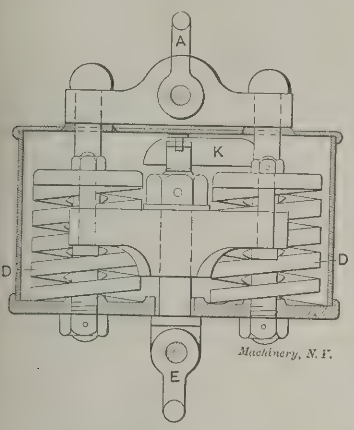
* * *

The bulletin of the Bureau of Labor for July is at variance with the generally accepted theory that prices have increased in a greater ratio than have wages during the last few years. This fact is proven by elaborate statistical tables. Whether the Bureau of Labor is right or not in its contention, may be open to discussion, but the fact remains that no statistical figures will be able to convince the salaried man or the wage earner that prices have not gone up out of all proportion to incomes.

ITEMS OF MECHANICAL INTEREST.

SAFETY DEVICE FOR CRANE CHAINS.

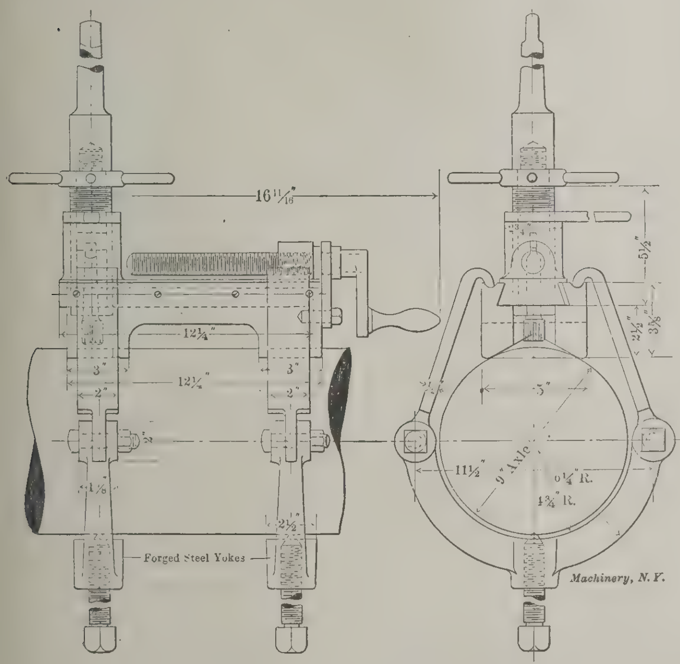
The accompanying cut shows an English device for preventing accidents due to failure of crane chains. These chains have, in many cases, been overloaded beyond their elastic limit, with fatal results. The cut shows an apparatus inserted at a convenient place in the chain, the upper portion of the chain being connected to the hook *A*, the lower to the hook *E*. By means of the springs *D* and suitable connections an electric bell *K* will give alarm whenever the chain is loaded beyond a certain limit, determined by primary adjustments of the springs and of the electric contacts. The springs, as is seen from the cut, are only in compression, so that any failure of the springs will not cause any damage, the load still remaining suspended. The principle of the design is plainly visible in the cut. The mechanism is dust-proof, being fully enclosed in a casing.



Safety Device for Crane Chains.

LOCOMOTIVE AXLE KEYSEATING DEVICE.

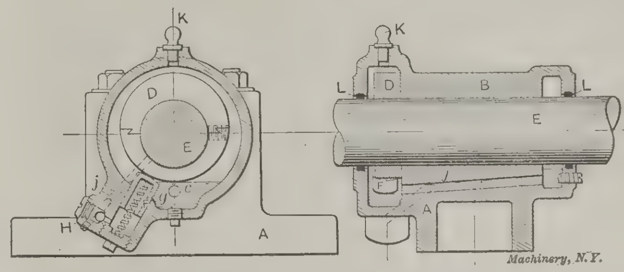
The accompanying cut shows a locomotive axle key-seating tool used in the shops of the Central Railroad of New Jersey, at Elizabethport, N. J., and depicted in the *Railway Master Mechanic*. As seen from the cut the device is fastened to the shaft in which the keyway is to be cut by means of two clamps, each consisting of a steel yoke and two clamping arms, these clamps holding the base of the device in position. A slide is provided which by means of a feed screw is moved back and forth in this base parallel with the axis of the shaft in which the keyways are to be cut. This slide carries a spindle bored to receive the Morse taper shank of an end mill, the spindle itself being provided with a Morse taper shank and driven by an air motor connected by a flexible shaft. The device has provisions for adjustments in all directions necessary. The cut shows plainly the design in detail. The usefulness of this tool will be appreciated by anyone who has had to cut out keyways for eccentrics in a hard steel axle, using a hammer and chisel and perhaps doing the job under the engine at that.



Locomotive Axle Keyseating Device.

A SHAFTING HANGER WITH FORCED LUBRICATION.

At the Olympia machine exhibition, which has been in progress for some months in London, Messrs. Geo. Richards & Co., Ltd., of Broadheath, Manchester, have been showing a pair of swivel adjustable bearings, using a method of self-lubrication, which is illustrated in the line cut of the pillow block shown herewith. *A* is the main casting of the block and *B* is the cap. The bearing formed by *A* and *B* has an annular recess at each end connected by the duct *c*. One of these recesses forms a chamber in which revolves split collar *D*, which is made fast to shaft *E* with a setscrew and forms one of the collars of the line shafting. The periphery of *D* is eccentric, and plunger *F*, which works in a hole in casting *A* and is pressed against *D* by the action of a stout spring, is constantly given a reciprocating motion. *F* is the piston or plunger of the pump which distributes the oil. At the extremity of its upward stroke, ports *g* are in communication with the reservoir of oil furnished for the supply of the bearing. This oil, through the action of a previously produced vacuum below the plunger, is drawn into the chamber beneath it. As the shaft revolves and *F* is forced downward ports *g* are closed and the oil within the cavity is pumped out past ball valve *H* through passage *j* to the center of the journal, where it spreads over the entire bearing, to the extent that the journal and bearing are kept entirely out of contact with each other. A pressure gage applied to duct *j* registers from ten to twenty pounds per square inch, depending on the speed of the shaft. As the plug moves upward again under the influence of the spring, the vacuum formed beneath it draws in a fresh supply of oil as soon as ports *g* are opened. The supply of oil is renewed through plug *K*. The bearing is made dust-proof and oil-proof by the insertion of leather washers *L L* at the ends of the bearing. The chamber for the supply of oil has sufficient capacity to lubricate the bearing for several months without any further attention.



Shafting Hanger with Forced Lubrication.

* * *

ADAPTING MACHINERY TO THE CAPACITY OF PACK ANIMALS.

One of the problems that sometimes confronts the machine designer is to make the construction so that no part shall exceed a weight of, say, two to three hundred pounds, or that which can be carried by a pack animal. This applies, of course, to mining machinery which has to be transported over mountains and into unsettled parts where roads have not been built. In some cases, however, it taxes the ingenuity to provide this, especially where the machinery is of such a nature that it must necessarily be integral. For example, the steel cables for hoisting have to be transported in full length as much as possible to avoid the defects of splicing. In such cases the matter is up to the manager of the pack train, but the method followed is very simple in scheme, although not always simple in the carrying out—if some of the animals are evil-disposed. It consists simply of uncoiling the cable and recoiling it at intervals to the required burro load, then leading to the next animal, where another coil is gathered, and so on until the whole cable is distributed among as many as are necessary to carry the total weight.

The postal department in Bulgaria has introduced automobiles for local transfer of mail, and found them to be of great advantage as well as economical for this purpose. It is proposed to extend the employment of automobiles to rural mail routes.

Entered at the Post-Office in New York City as Second-Class Mail Matter.

RAILWAY MACHINERY

A SPECIAL EDITION OF MACHINERY FOR THE RAILWAY SHOP, DEVOTED TO LOCOMOTIVE AND CAR EQUIPMENT AND MECHANICS.

Published monthly by

THE INDUSTRIAL PRESS,

66-70 WEST BROADWAY, NEW YORK CITY.

DOMESTIC SUBSCRIPTIONS, $2.00 A YEAR. FOREIGN, $3.00 A YEAR. SINGLE COPIES, TWENTY CENTS.

The receipt of a subscription is acknowledged by sending the current issue. Remittances should be made to THE INDUSTRIAL PRESS, and not to the Editors. Money enclosed in letters is at the risk of the sender. Changes of address must reach us by the 15th to take effect on the following month; give old address as well as new. Domestic trade is supplied by the American News Company or its branches.

We solicit communications from practical men on subjects pertaining to railway machine shop practice, for which the necessary illustrations will be made at our expense. All copy must reach us by the 5th of the month preceding publication.

DECEMBER, 1906.

WILL THE STEAM TURBINE BE USED ON LOCOMOTIVES?

When asked the question "Will the steam turbine be used on locomotives" it is unwise to make a negative answer. In all probability the idea will be tried—in fact we believe it has already been experimented with—but in the light of present knowledge there does not seem to be much encouragement for the use of the steam turbine for locomotive practice. In the first place the steam turbine only develops good efficiency when run in connection with a condenser, and this, obviously, is impossible with the locomotive. In the second place the gyroscopic effect of heavy masses, with horizontal axes, revolving at high speed on a locomotive would likely be serious in rounding curves at any but a moderate pace. The suggestion of providing two turbines running in opposite directions in order that one might offset the effect of the other, is unsound. The tipping effect or resistance to change of plane should be the same for the same weight and speed of revolving parts. Add to this the effect on the bearings of the resistance to change of plane, and the situation becomes extremely unpromising, especially when it is admitted that dynamos and motors must be interposed between the turbines and the drivers.

* * *

FALLACY OF THE "LOOSE WHEEL" AXLE.

One of the principal retarding factors in railway train operation is the frictional resistance of the trucks in rounding curves. This retarding effect is made up of flange friction against the outer rail, pivot and side-bearing friction, and the slipping of the wheels on the outer and inner rail, caused by the rigid connection of the wheels to the axle. To avoid the rigid axle connection of railway car-wheels, has been the object of numerous inventions, all of them practically worthless on account of the cost and complication introduced. But it is not generally known that this very feature of rigidity of connection is useful in keeping the trucks parallel with the track, paradoxical as it may seem. Some years ago the Sixth Avenue elevated railway in New York City tried a "loose wheel" truck with very unsatisfactory results. The truck had the serious defect, aside from its complication and high first cost, of being very easily slued on the track with the consequent ever-present danger of derailment. Any slight obstruction on one of the rails such as sand, snow, ice, etc., tended to make one wheel run behind the other and turn the truck at an angle. This obviously is something that does not happen with the rigid wheel construction which, consequently, becomes a really valuable feature. Notwithstanding its retarding effect on curves, it is probably safe to say that the rigid axle connection between opposing car-wheels is something that will never be changed. It has the merit of cheapness, simplicity and, as just pointed out, of preserving the alignment of the truck with the track. The principal objection to rigid connection—the resistance to rounding curves—is partly disarmed by coning the tread. Another point is that with a revolving axle the journal constantly tends to wear to a full bearing in its brass, while on the other hand a wheel revolving on a stationary journal always tends to wear out of full bearing.

* * *

EXTRA COST OF THE WALSCHAERTS VALVE GEAR.

At the September meeting of the New York Railroad Club the statement was made by one of the speakers that the locomotive builders charge fully $1,000 more for a locomotive equipped with the Walschaerts valve gear as compared with the same locomotive equipped with the Stephenson gear. We have since learned that this statement is not entirely as it appears on the face. It is true that more is charged for the Walschaerts valve gear, but the sum is not as great as that mentioned. It is pointed out that while the Walschaerts gear is lighter in construction than the other so far as the working parts are concerned, it requires heavier cylinder castings, however. With the Stephenson gear using piston valves the shape of the cylinder casting is a nearly straight slope from the outside of the cylinder barrel to the smoke arch, but with the Walschaerts gear the piston valve is set over to come in line with the vertical plane of the gear and this adds considerable to the weight of the castings. The additional weight may easily be as much as 2,000 or 3,000 pounds. Another point to be remembered is that the design of locomotives with the Walschaerts gear is such as to admit of additional bracing between the frames, and this is taken advantage of, and, of course, it adds to the weight and cost.

* * *

AMATEURISH SCIENTIFIC INVESTIGATIONS.

A description of some experiments made by a French aeronaut has been going the rounds in the popular technical press. This ingenious Frenchman, Archdeacon by name, has applied an air propeller to a motor cycle, his object in doing this being, as it is stated, "to compare propellers of different shapes as to their efficiency." The motor cycle used weighed 154 pounds, and it was fitted with a V-type Buchet motor rated at six horsepower. The total weight propelled was 334 pounds and the time occupied in covering 1 kilometer was 45 2-5 seconds, a speed which corresponds approximately to 50 miles per hour. We are given information as to the method in which the motor was geared to the propeller shaft which was placed at the front of the machine. Details of the construction of the propeller are given and the statement is made that the propeller was injured prior to the test and only hurriedly repaired so that still better results are hoped for later.

In general an experiment of this sort is undertaken for the purpose of obtaining data on some particular subject; but the first thing this simple-minded aeronaut did was to cover the vital point of his experiment with a mass of confusing conditions which at once made any definite conclusions impossible. Why the motor cycle? And why its use on a public highway with its unknown conditions of roadway and wind velocity, with the necessary variable weight of rider and lost work in tires and propelling mechanism? It reminds one strongly of the old-fashioned method once said to have been followed in China for roasting pigs; the pig was tied up in the kitchen and the house set on fire.

Sir Hiram Maxim, some years ago, investigated this very subject of air propellers with highly refined apparatus. The fan or air propeller was mounted at the end of a revolving frame work whose resistance to movement through the air and about its pivot was reduced to a negligible quantity. Care was taken that the air in which the propeller revolved should be as nearly free and unaffected by outside conditions as it was possible to make it. From such experiments, with every variable eliminated except the design of the propeller and its velocity in revolutions per minute, it was possible to get a direct result in pounds, read from the dynamometer, or in surface speed, read from the revolution counter. Heaven only knows what definite results one could ferret out from the information given in the motor cycle test described above, but perhaps the experimenter's prime object was to get his name in the papers. If so, he has succeeded—as witness these paragraphs.

THE CORRESPONDENCE SCHOOL IDEA.

The celebration of the fifteenth anniversary of the International Correspondence Schools, October 16, at Scranton, Pa., marked a mile-stone in the progress of a great idea—technical education by mail. Like most great movements this started in a very modest way; it originated with Mr. Thomas J. Foster, then the editor of a newspaper in Shenandoah, Pa., who introduced a method of teaching a course by mail which was designed to enable the coal miners of Pennsylvania to pass the required examinations for mine foremen. It included special home study text-books and a system of direction and correction of students' work. The success of this work was immediate, and it led to the formation of many courses, there being now over 200 courses of instruction, covering almost every branch of all the well-known trades and professions. Over 300,000 students have either fully completed courses or have completed various subjects of a course.

The correspondence school idea appeals with special force to men who, as they have come to mature years, have realized their lack of education, especially on technical subjects. To many young men, unfortunately, the word education has an empty sound. It means little to them save perhaps a smattering of the three R's. Having no incentive to wider knowledge and, consequently, few or no ideals, they have drifted along until opportunities or family responsibilities have awakened them to a sense of their need. To such who are truly ambitious the correspondence school idea may be a great help. It opens the door to self-help and explains the way, making it so easy that the ordinary man of average intelligence who is able to read and write can gain a specialized knowledge and an understanding of the theory of his industry which will qualify him to be a leader in it rather than an inferior workman. The practical nature of the instruction and the fact that it treats of the business with which the learner is already familiar, has made this system of education a powerful factor in the general uplift.

* * *

THE ROTARY GAS ENGINE.

In the Engineering Review section of the November issue space was given to an abstract of an article on the above subject without editorial comment. The article was in favor of the gas engine, using the unsound arguments that have been used time and time again to bolster up the case of the steam rotary engine. The strongest feature of the rotary engine and one that always appeals most to inventors is the absence of dead centers and the fact that in the reciprocating engine there is a varying crank effort beginning at zero and increasing up to the maximum at about half-stroke position, then decreasing to the time of exhaust. The rotary engine is held to be free from this "defect"; consequently a great gain of mechanical efficiency is claimed. In the article noted the following unreliable statement is made, bearing out this claim:

"The greatest advantage of the rotary over the reciprocating engine would be, that the power of each impulse is applied constantly on the tangent; hence, the turning moment would be always equal to the pressure at any point, while in the reciprocating type the turning moment varies for small close-connected engines approximately as given in the accompanying table:

	Pressure.
Beginning of stroke	0.00
⅛ of stroke	0.444
¼ of stroke	0.668
⅜ of stroke	0.84
½ of stroke	1.00
⅝ of stroke	0.75
¾ of stroke	0.60
⅞ of stroke	0.44
Full stroke	0.00

"This variation is due to the imperfection of the crank and connecting rod as a means of power transmission. The above factors coupled with the constantly varying pressure, which falls rapidly after the beginning of the stroke, make the average turning moment only about 0.45 of the average pressure on the piston. *The rest of the pressure, about* 0.55, *is simply lost in strains and friction.*" (The italics are ours.)

To quote Josh Billings, "this is 2 mutch." Did the author stop to consider that although the crank effort does vary substantially as claimed, the piston moves only about two-thirds the distance traversed by the crank, and that the volume swept up by the reciprocating piston is not more nor less than that swept up by the rotary piston for the same number of foot-pounds developed, neglecting friction? And, as to friction, the rotary engine is notorious in this respect. In fact it is the one great defect of the rotary engine, causing excessive wear and low mechanical efficiency. The prospects of success for the rotary gas engine seem even more remote than those of the rotary steam engine. What more could we say against it?

* * *

CONSULAR COMPLAINTS CONCERNING THE HANDLING OF FOREIGN TRADE.

There has appeared of late a great number of complaints from our consular service in regard to the manner in which American manufacturers treat their foreign customers and handle the export trade. These complaints seem to indicate that our European competitors are superior to us in every respect in regard to handling their foreign trade. Whether this supposition is founded on reasonable ground will be a second consideration. In fact it is impossible to review consular reports of any European country without finding that the consuls of those countries make similar complaints regarding the manufacturers of their respective countries. Instead of the American manufacturers solely being at fault it must be that manufacturers all over the world have not as yet acquired the ability of handling their foreign trade in the same expert manner as they take care of their domestic trade relations. We point out this fact, not with a view of impressing upon American manufacturers the opinion that inasmuch as the manner with which they handle their foreign trade may not be in any way inferior to the manner in which our European competitors handle theirs, they should feel satisfied with the results obtained and not try to improve, but simply because we consider that due justice ought to be given to our own country and its manufacturers. While there doubtless is good reason for improvements in many respects it does not seem justified to paint the American export trader fully as black as some of our foreign consuls have succeeded in doing.

There is, however, another complaint made by our consular service which we think to be far more justified, and which should not be disregarded by our manufacturers and merchants. Reports are frequently received from diplomatic and consular officers complaining of carelessness on the part of correspondents in the United States in failing to fully prepay the prescribed postage on letters and other mailable matter. This carelessness is not only annoying but is expensive to those receiving communications upon which the full amount of postage has not been paid, and has resulted in many cases in defeating the sale of American products abroad. It places an unnecessary burden on people who are making an effort to become acquainted with American goods and methods. Being compelled to pay penalties, even though small, does not tend to promote good feeling on the part of actual or prospective buyers. Under international postal agreements a penalty equal to double the amount of deficient postage must be paid by the party to whom the matter is addressed.

In offering a suggestion for overcoming the liability of mistakes in large establishments where all mail is handled by a special clerk it may be well to call the attention to the custom of several well organized houses who use special envelopes bearing the words "Foreign Mail" printed in the place where the stamp is to be affixed. This serves as a constant reminder to the mailing clerks that the domestic postage rates do not apply to the letters or packages so marked, and errors are thus easily avoided. Such a course might help to regain the good will of many foreign firms whose disaffection can be attributed to no greater and no other cause. The evil is evidently due to a lack of proper classification of mail matter in the offices of our merchants, and a simple method, like the one mentioned above, would probably prove to be an effective remedy.

ENGINEERING REVIEW.

CURRENT EVENTS, TECHNICAL AND MECHANICAL—LEADING ARTICLES OF THE MONTH.

Two-cent letter postage for each half-ounce became effective between New Zealand and the United States on November 1. This arrangement will no doubt bring the two countries into closer business relationship.

Two months ago the first section of the Pekin-Kalgon Railway was opened which will, when completed, connect the Chinese capital direct with Europe and will bring Pekin within twelve days of London. The most remarkable feature in connection with the building of this railway is perhaps that it has been constructed entirely by Chinese men working under a native engineer.

It has been suggested several times in engineering history to make use of the tides by allowing them to fill diked-in territory, to run out again through turbines. It happens, however, that land that can be diked in is very valuable for dairy purposes, as the soft mud makes excellent soil, and much more can be netted from the land than from the power. —*Power.*

A remarkable opinion with regard to steam turbines finds expression in the words of Dr. Riedler at the Berlin meeting of the Society of German Engineers when in discussing the development of the steam turbine he found occasion to say: "The turbine is no longer the motor of the future; it is the steam engine of the present." This opinion has so much greater weight, as Dr. Riedler himself has attained much of his professional eminence by reason of his success in the improvement of reciprocating machinery.

An interesting employment of paper relates to the production of gas-pipes. Manila paper cut in strips, of a width equal to the length of the pipes to be made, is put in a receiver filled with fused asphalt and rolled solidly and uniformly around a rod or core of iron until the desired thickness is obtained. After the pipe thus produced has been submitted to heavy pressure, the exterior is covered with sand and the whole cooled in water. The core is removed and the outer surface covered with a waterproof product. These pipes, it appears, are perfectly tight and more economical than metal pipes.—*The Mechanical World.*

Two parts of aluminum and one part of zinc form an alloy to which has been given the name "alzene." It is equal in strength to good cast iron and superior to it in the matter of elastic limit. It takes a fine smooth finish and does not readily oxidize. The color is white. It melts at a low red heat, and is very fluid, running freely to the extremities of the mold and filling small or thin parts. Great care must be exercised in melting it, particularly when mixing the two metals, in order to preserve its smooth working qualities. It is said to be somewhat brittle and hence unsuited to such pieces as require the toughness possessed by brass.—*Obermayer's Bulletin.*

The Giornale d'Italia, Rome, Italy, announces that the Midvale Steel Company, Philadelphia, has obtained from the Italian government an order for 2,100 tons of armor plate, valued at $1,000,000, for a man-of-war. The American company was in competition for the contract with five European firms, including the Krupps. Its tender was $180,000 less than that of the Italian Terni factory. Comments seem almost unnecessary, but it is evident that the time has passed when fiscal provisions are necessary in this country to keep foreign steel product out of the competition with our own steel mills. The above seems to amply indicate the latter's ability to successfully compete with European steel concerns even if "unprotected."

By reason of the ease with which the rotating member of a turbine revolves in its bearings, and the length of time that it will continue to run after the steam has been shut off, the frictional work of that form of engine is assumed to be very small. C. H. Wingfield calls attention to the fact that while there is no doubt about the friction *per revolution* being much less than in a reciprocating engine of equal power, the number of revolutions in a given time is much higher, and the friction of the turbine must be proportional to this greater number of revolutions before a comparison can be made. In other words, he asks, "Is the work expended per minute in overcoming friction less with a turbine than with a slower-running reciprocating engine of the same power?"—*Power.*

A two-cylinder 20-horsepower Maxwell automobile made a 3,000-mile run without its motor ceasing operation, the test ending in New York, October 31. The most of the mileage was made between Boston and Worcester, the round trip being 88 miles. This route was covered by two drivers, alternating at the end of every two trips. Then, in continuation of the run the car traveled to New York, back into Connecticut and again to New York, so as to complete the 3,000-mile distance. For fuel and lubrication 161½ gallons of gasoline, at 20 cents per gallon; 24¼ quarts of lubricating oil, at 20 cents per gallon; and 5 pounds of grease, at 15 cents per pound, were used. Other minor expenses brought the total nominal cost of operation for 3,000 miles up to $41.45.

As was mentioned in an article describing the new shops of the Western Electric Co. at Hawthorne, Ill., in the July issue of MACHINERY this company has provided storage bins for coal so arranged that the coal may be kept stored under water, this for preventing loss of heat units and spontaneous combustion. For the storage bins a plot 320 x 75 feet has been excavated to a depth of about 12 feet and lined and sub-divided by concrete walls into twelve 80 x 25 feet pits. The bottom is clay subsoil and the walls are carried about 4 feet above the ground. The pits can be flooded by means of a 12-inch water main. The longitudinal division walls are wide enough to carry the tracks on which the coal is delivered. It is removed from the pits by a steam shovel.

There has of late been a number of different formulas proposed for the rating of automobile motors. The Automobile Association of Central Europe has adopted a formula for four-cycle motors based upon a mean pressure of about 55 pounds per square inch and 900 revolutions per minute. This formula reads $N = 0.003\ id^2s$, in which N equals the number of horsepower to be determined, i the number of cylinders, d the diameter of the cylinders, and s the stroke. All dimensions are given in centimeters. If the dimensions are given in inches the formula would be $N = 0.0492\ id^2s$. The output as figured from this formula is rather low, however, depending upon the low mean effective pressure upon which the formula is based.—*The Horseless Age.*

After the great San Francisco fire, hundreds of tons of lead, zinc, and other metals owned by the Selby Smelting Company were found melted into a solid block at the base of the shot tower that was for many years one of the landmarks of the old city. The problem of recovering the metals, which were worth many hundreds of thousands of dollars, was a difficult one. The great mass could not be raised or broken up into fragments of a practicable size by any ordinary means. After removing several tons of bricks and débris, however, channels have been cut through the great block of metal by an electrical arc process. The bed of metal is from three to four feet thick, and covers the entire area of the ruins of the tower. The heat and light produced by the process are intense, though only ten volts are used for each implement. The men who are engaged in cutting the channels have their heads and faces covered with canvas to protect them from the blinding light. The metal is recovered in blocks weighing nearly a ton each.—*Scientific American.*

The opinion has frequently been expressed that Scandinavia, with its huge waterfalls, will before long be one of the most suitable places for large chemical works; indeed, it is claimed that with the future developments of electrochemical technology the greater part of the world's supply of soda, chlorates, nitrates, calcium chloride, and iron will be produced in the northern peninsula. Hence it is easy to understand the action of the Swedish and Norwegian governments in protecting the falls against foreign capitalists. Sweden has passed a law that the use of the falls is reserved to the State, while a bill is before the Norwegian Storthing in which it is prescribed that at least one-half of the capital laid out on the falls shall be Norwegian money, and the direction of the work be in the hands of Norwegians who are living in the land.—*London Nature.*

It is a common thing to find that many of our modern inventions and developments have been thought of a long time ago, but on account of various causes been forgotten. It may, however, surprise many, that a typewriter was invented and made two hundred years ago, during the reign of Louis XIV, in France, by one of his officials. The apparatus contained some of the principal details of our modern typewriters. Another fact of similar character is called to our attention by *The Engineering Magazine* for October, where we are told of the existence of a Scott graphophone in the "Musée du Conservatoire des Arts et Métiers" in Paris, the construction of which probably antedated the birth of Edison. Such cases do not decrease the honor of individual inventors, but only serve to prove that the human mind has constantly been active to solve certain problems which it has been reserved for our time to bring to a practical solution; that in fact, "nothing is new under the sun."

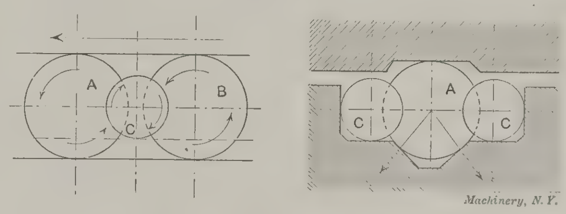
While the development of the use of steel cross-ties for railroad construction has not been very rapid in the United States, it may be of interest to know that metal ties were discussed in Germany as early as in the sixties, and that seventeen years ago nearly 10,000 miles of German railroad was laid with iron or steel foundation. In 1903, 11,500 miles of track were provided with metal cross-ties, this constituting more than one-fourth of the tracks in Germany. Indications point to the fact that the railroads in this country will before long earnestly consider a step of this kind for many reasons, among which we may mention the electrification of roads, necessitating a third rail and its supports, the abolishing of the grade crossings, calling for an abundance of viaduct work, and automatic train signalling which may call for a stronger support than can be provided for by wooden ties. It is evident that the expense of construction of railroads will increase with this improvement, but the traffic of the country is also increasing in such a degree that if the German railroads are able to afford this expense, there is no question but what the permanence of the track which this improvement would insure, will amply repay the railroads in this country for the increased amount of investment necessary.

THE CRYSTALLIZATION OF STEEL.

In an article in the *Iron Age* Mr. James H. Baker treats the subject of annealing and crystallization of steel. His statements in regard to the latter subject are very interesting. He claims that while there has been a great deal said about steel crystallizing when in use or when subject to vibrations and shocks, there is still room for doubt on this point. During experiments carried on by Mr. Baker, he has hammered steel for a long time cold and bent it back and forth slowly under a press until nearly destroyed, and on cutting and breaking the pieces there was no sign of crystallization. He claims that at times when steel used for industrial purposes breaks, as all things will when used enough, and its fractured area shows a crystalline structure, then it is always said to be "crystallized by use." But the fact is that the steel which when breaking shows a crystalline structure has been sent out from its place of production in a crystalline condition originally, and its use simply separates the faces of the crystals. Shortly, Mr. Baker seems to claim that there is no such thing as the crystallization of steel from shocks or vibrations. Cases where such occurrences have been suspected simply reduce themselves to a case where the steel has been defective from the beginning.

IMPROVED BALL BEARING.

The principle of spacing the individual balls of a ball-bearing by means of a second set of balls which carry none of the load of the bearing but serve only as spacers, has been applied in a new way by Mr. E. Denis, of St. Quentin, near Paris, France. Two sets of spacing balls are used, one on



Principle of Improved Ball Bearing.

each side, and tracks are provided for them to bring them central with the larger main balls. The sketch herewith, taken from *Le Genie Civil* shows the arrangement so fully as to require no further explanation. This form of bearing has been applied to the step-bearings of centrifugal dryers.

THE VALUE OF ALCOHOL FOR COMBUSTION ENGINES.

The Engineer, November 1, 1906.

With the enactment of the law on denatured alcohol, which is to take effect on January 1, 1907, experimental data on engines adapted to use this fuel are in order. The Model Gas Engine Works of Peru, Ind., have already had engines operating successfully with this fuel for a little more than a year. To adapt the "Model" engines for alcohol required no change whatever, with the exception of the compression, the fuel being admitted over a disk valve, thence passing through screens of perforated brass direct into the cylinder.

For its experimental work, the company used alcohol exported from Cuba. The company paid 10 cents a gallon, but was obliged to pay duty until it cost something over $3 a gallon delivered.

On trial it was found that alcohol was not nearly so volatile as gasoline, and therefore would stand a much higher compression. Various compressions were tried until a little more power was secured from a given sized engine than was possible with gasoline, the increase amounting to almost 10 per cent. The engine ran much more smoothly with alcohol, and there was no tendency for the heavy jar at the time ignition took place usually found in gaosline engines of high compression. This was accounted for largely in that the alcohol did not burn so rapidly.

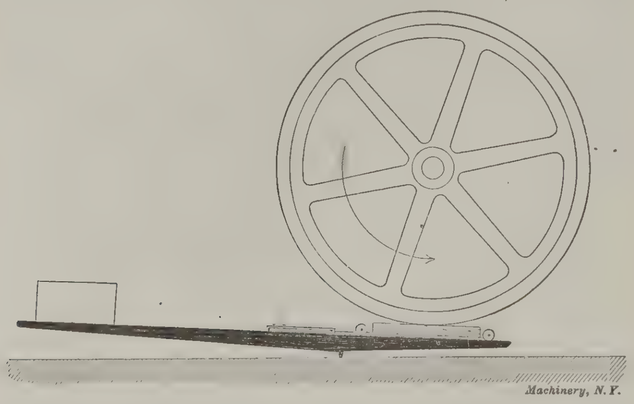
Very little difference was found in the consumption of alcohol as compared with gasoline. For the low grade alcohol which was tested the consumption was found to be approximately 1 gallon per horsepower for 10 hours, and this is practically the same result as secured with gasoline. Some writers are claiming that 1 gallon of alcohol will go as far as 2 gallons of gasoline for power purposes, but it is the company's belief that these people are not talking from actual experience, or have experimented with a higher grade of fuel than used by them.

It was also found that the engine would start practically as easily with alcohol as with gasoline, and was free from smoke and dirt. On the whole, the experiments seem to point out that alcohol is preferable to gasoline for power purposes with the gas engine, from almost every standpoint, where the price of both are equal.

A NEW DYNAMOMETER.

The Practical Engineer describes a very simple dynamometer recently brought out by an English concern. The object of the invention is to provide a measuring brake, which is portable and self-contained, and can be applied instantly to any engine or motor without previous preparation, and by which the power absorbed can be accurately and immediately meas-

ured with as little calculation as possible. This dynamometer, known as the Sellers, consists of a long lever carrying at one end a brake block running on small flanged wheels and attached to a spring balance fixed to the lever, as shown in the cut. The instrument can be used directly upon the flywheel. When not in use the brake is perfectly free of the flywheel, a great advantage when starting the engine or motor. The load is applied either by pressure of the foot or by placing



A New Dynamometer.

a weight on the long end of the lever, this weight being moved along to give a nice adjustment for steady running. There are no allowances or corrections whatever to be made, and by means of the table supplied with the spring indicator the power developed may be read off at once without any calculations.

THE STRENGTH OF IRON CASTINGS USED IN MACHINERY.

At the convention of the American Foundry Foremen, Professor C. H. Benjamin read a paper on the strength of cast-iron machine parts, in which he gave the results of many tests that have been made by him to determine by actual experiment the strength of castings of different forms. The information given by Prof. Benjamin will be found of decided value to designers, specially when engaged in developing some apparatus in which to save weight, or for some other reason, it is necessary to cut very close to the mark. In the following we have gathered what appear to be the most important parts of his address.

"In so simple a thing as a cast-iron beam of rectangular section, theory is more or less at fault in predicting the safe load. A series of experiments which I conducted several years ago showed me that the neutral axis of such a section was not stationary, but traveled gradually up from the center of gravity as the load increased. As the sections become more complicated the stresses due to the uneven cooling begin to appear and to still further embarrass the designer.

In the past dozen years I have conducted tests on a great variety of cast-iron members to determine the actual breaking load or pressure and compare it with that deduced by theory. There were tested in this way beams of various sections, cylinders, wheels, flat plates, gear teeth, pulley arms and rims, flywheels, rotary disks and high-speed pulleys of various types.

Cylinders usually break in a circular line just back of one of the flanges instead of splitting, as theory would indicate. Furthermore, the failures occur at pressure less than one-half those given by the usual formulas for their shells. This is probably due to pressure of blowholes or hot spots at the junction of shell and flange and to the bending moments caused by the pull of the cover bolts. Subsequent tests on cylinders whose flanges have been reinforced by brackets substantiate this conclusion. The cylinders all split from end to end under a pressure approximately two-thirds that given by the formula for their shells. The other third is accounted for by the bending due to lack of uniformity in the metal. A cylinder 10 by 20 inches, with a ¾-inch wall, would burst at a pressure of about 1,400 pounds per square inch, corresponding to a tensile stress of 10,000 pounds, whereas tensile tests showed the metal, a soft gray iron, to have a tensile strength of 14,000 pounds. Rectangular and square plates were tested, and the results were found to be remarkably uniform. The bursting pressure varied less than 10 per cent from that calculated by accepted formulas. The tests on gear teeth were made by applying a steady load on the testing machine, and were only conclusive as to the selection and not the absolute strength of different forms. The pressure was applied at various angles of obliquity, from 0 to 30 degrees, and two-pitch involute and cylindrical teeth were selected for experiments. The shapes varied from those of pinions to those of racks, and the following conclusions were reached:

1. The plane of fracture is approximately parallel to the line of pressure, and not necessarily at right angles to the radial plane.

2. Corner breaks are likely to occur even when the pressure is uniformly distributed.

3. Rack teeth are about twice as strong as those of pinions of 15 to 20 teeth, and involute teeth are from 40 to 50 per cent stronger than cycloidal.

The breaking pressure corresponded quite well to those calculated from the modulus of rupture of the iron used.

In testing the arms and rims of pulleys a steel belt was used, and a twisting moment thus applied to the pulley through the medium of levers and a testing machine. The pull on the tight side of the belt was graduated to twice that of the slack side, and the pulls were increased until one or more of the arms failed. The arms were slightly tapering and had twice the strength at the hub as at the rim. The fact that they broke sometimes at one end and sometimes at the other showed the ratio of the bending moments. The arm or arms nearest the tight side of the belt nearly always failed first, and we were justified in forming the following conclusions:

1. That on account of the springing of the rim the bending is unevenly distributed, so that about twice the average moment comes on the arm nearest the tight belt.

2. That the bending moment at the hub is about double that at the arm, as such pulleys are usually designed. The above ratios will be affected by variations in the relative stiffness of rims and arms.

Tests of Rotating Pieces.—The most fascinating and the most spectacular series of experiments have been those in which rotating pieces have been tested to destruction by high speed.

Wheels, models or flywheels without flanges were operated at a speed up to 400 feet per second, while those made in sections reached the speed of only 150 feet. Placing the joint close to the spoke did not appreciably strengthen the wheel, although steel tie rods between the joints and hubs increased the strength to some extent. English wheels, built on the bicycle wheel pattern, were the strongest wheels experimented with, giving a speed of 4,000 revolutions per minute. The large number of spokes permitted of no bending of the rim. All of the wheels experimented with were 24 inches in diameter.

A balance weight weighing 3½ pounds was located inside of the rim, and the wheel burst at 1,200 revolutions per minute. It should have withstood a strain of 2,000 revolutions.

From these tests we reach the following conclusions:

1. Any weight on the rim between the arms of a rapidly-rotating wheel, whether it be a flange, a balance weight or otherwise, is a source of weakness and danger.

2. When the weight is accompanied by a joint or any breaking of the metal at such a point the wheel is entirely unsafe at even ordinary belt speeds.

3. Solid rims of cast iron as ordinarily designed are almost entirely free from bending stresses, and will not burst at speed much less than 400 feet per second.

Tests on cast-iron disks have just been commenced, and so far the difficulties have been found greater than in any other series of experiments. The bursting speed of a disk is from one and a half to two times that of a ring, and this high speed, coupled with the severe shock of bursting, has affected the steam turbine used in making the experiments. So far three 18-inch disks have been burst at a speed of about 7,500 revolutions per minute. This corresponds to a rim speed of about 600 feet per second and to a stress near the center of about 12,000 pounds per square inch."

ANNEALING UNDER GAS.

Walter J. May, in *The Practical Engineer*, September 28, 1906.

Finished steel articles which have to be kept bright when annealed are rather difficult to deal with when charcoal packing is used, but when the annealing case or box is kept full of ordinary coal gas the trouble is overcome and the articles remain both bright and clean. The process is by no means an expensive one, while with ordinary care there is no danger attendant on working, no extremely high temperatures being required for annealing only. The quantity of gas used is small, as after the annealing case is filled, only a very small quantity need be passed through—enough to keep a No. 0 ordinary fish-tail burner alight being sufficient, and this would probably not be more than 2 cubic feet per hour. The time taken in the process of annealing from start to finish should not exceed two or three hours as a rule unless the articles dealt with were very heavy, and therefore it is scarcely likely that so much as 10 cubic feet of gas would be used in any one case.

Where the operator can regulate the heat it is possible to blue steel articles effectively, but as a rule this would require the use of a pyrometer, as a great number of men

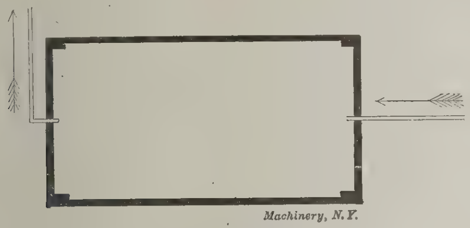


Diagram of Flask and Gas Supply for Annealing under Gas.

could not judge so low a heat as given from 520 degrees F. to 600 degrees F., as there would be no redness to go by. Clear mica sight holes might, of course, be used, but as the annealing flask would be dark inside, these would be of very little use in practice, while test wires would not advance matters much, as these would be blued before larger pieces of metal showed any change in color.

The method of heating the annealing flasks will be the one usually adopted in any particular place, but special flasks would have to be provided, whether they be of metal or fireclay. Probably those of cylindrical form would be best for many reasons, but this form is not absolutely necessary, as rectangular shapes may be more easily dealt with in some places. Anyhow, the same general plan for arranging the gas supply and the small exit pipe will be adopted, and this is approximately shown in the cut, each form of flask requiring its own special arrangement of fittings. Roughly, the flask is filled with the articles to be annealed, the cover luted on, and then it is placed in the furnace, after which the gas is connected and turned on, the air escaping by the exit pipe, which should be fitted with a No. 0 or No. 1 ordinary *iron* fish-tail burner. When the air has been driven out, the burner should be ignited and the supply of gas regulated to give just a small flame at the burner, and as the flask becomes hot probably a further reduction of the gas supply will be necessary. When the annealing is completed the gas supply will be disconnected, and the end of the supply pipe stopped, the exit pipe being stopped as soon as the flask is withdrawn, and then the whole can cool down before opening the flask, the articles not being exposed to the oxidizing influence of the air. Both for convenience and also economy in gas, it is well to have an *iron* stopcock on the exit pipe and an ordinary stopcock on the fixed portion of the inlet pipe, as by this means the flask can be sealed before it is taken from the furnace. This is a matter of detail which should be left to the common sense of the operator, however, and is scarcely worth mentioning where practical men are concerned.

Air must not be admitted to the annealing flasks while they are hot, or the gas will ignite, and under certain conditions explode with some violence, in which case damage would be done both to the furnace and to persons around, in all probability. All joints should be luted to prevent the admission of air as a matter of course, but the luting material will vary with the material of which the flask is made. The heat required for successful annealing, being between 1,300 and 1,500 degrees F., would be sufficient to ignite gas holding a certain proportion of air, but if air is not present the gas will only expand without ignition, and for this reason ordinary care must be used. Taken all round, for bright steel work, annealing under gas presents considerable advantages, but for rough work where finishing has not been done, the ordinary process is sufficient as a rule, and need not be deviated from unless for some special reason.

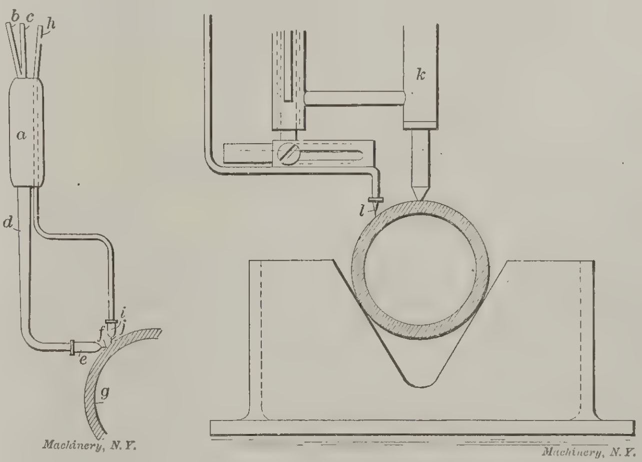
THE CUTTING OF STEEL BY THE COMBUSTION PROCESS.

S. D. V. Burr, *Iron Age*, November 1, 1906.

We are indebted to a Belgian engineer, Felix Jottrand, of Uccle, for the perfection of a process which, according to reports that have reached this side, is both rapid and economical and further is capable of wide application. The process depends upon the union of oxygen and iron and is founded upon the principle that when combustion has once been started it will continue as long as the proper conditions are maintained (see MACHINERY, Engineering Edition, July, 1906, page 590).

The first experiments were made with an oxy-hydrogen flame to bring the metal to a red heat; when this temperature had been reached the hydrogen supply was reduced and that of the oxygen increased, the idea being to produce combustion. It was found that this action was not violent enough; the oxidation was too slow, and the metal could not be made fluid enough to flow freely from the cut. Carried out in this manner the operation was intermittent. Combustion could only be maintained for a few seconds at a time and then the metal had to be again heated with the oxy-hydrogen jet. The kerf was of varying widths and its edges were rough, while the repeated heatings were too prodigal in the use of hydrogen.

Success was attained when two jets, one carrying the oxygen and hydrogen and the other the oxygen, were moved



Figs. 1 and 2. The Cutting of Steel by the Combustion Process.

along the mark. The first brought the metal to a red heat and the second provided the oxygen for combustion. The first jet was kept a short distance in advance of the second. Under these conditions the heat did not have time to be dissipated and the oxide was very fluid. Rapidity of cutting was assured, as the work was continuous. The expense of cutting was reduced, as there was no waste of gases, both the oxygen and hydrogen being used under the most efficient circumstances.

It is explained that the cutting of the metal is affected by a chemical action upon the heated part, the metal being raised to such a temperature as to enable oxidation to take place without fusion of the metal, while the oxides, which are more fusible than the metal itself, flow readily. The severance is perfectly clean as though the metal had been sawed.

The construction of the device will be understood from the accompanying illustrations, which are taken from the patent papers. When the work does not require any great degree of

precision, or when the contours to be cut are quite complicated, an ordinary blowpipe is employed, indicated at *a* in Fig. 1. This is provided with separate inlets *b* and *c* for the oxygen and hydrogen which open into the mixing chamber, *d*, from which leads the nozzle *e*, whence issues the heating jet *f* against the metal *g*. To this blowpipe is fixed the pipe *h*, which conducts oxygen under pressure to the nozzle *i*. This nozzle is arranged to follow closely in the path of the first, so as to direct its jet *j* upon that portion of the metal which has been brought to the proper temperature by the flame. This jet of oxygen produces a clean cut along the line and without appreciable loss of metal.

The second drawing, Fig. 2, shows the nozzles carried by a center *k*, which is applied to a pipe. It is evident that the same arrangement can be applied to a plate for circle cutting. Extending from the center is an arm at the lower end of which is a stud engaging with a slotted bar to which the gas pipes *l* are attached. By this means the device can be arranged to cut in circles of different diameters.

It is mentioned that the section cut is as clean as that left by a saw and the kerf is not over 2 millimeters (0.078 inch) wide in a plate 100 millimeters (3.93 inches) thick. The rate of cutting is 20 centimeters (7.87 inches) per minute for a plate 15 millimeters (0.59 inch) thick. The consumption of hydrogen and oxygen for this amount of work is only a few liters (1 liter = 61.022 cubic inches) of each. The line of cutting may follow any direction desired, and variations in the character of the metal have no influence on the cutting. The process is equally applicable to hard or soft steel and has been advocated for the dressing of armor plate.

HIGH-SPEED STEELS FOR WOODWORKING.

Iron Age, November 1, 1906.

Builders of woodworking machinery assert that they have demonstrated to their complete satisfaction that the high-speed steels are destined to bring about radical improvements in the woodworking industry, and some even go so far as to prophesy that it will be revolutionized in the near future. The tests made by one of the best-known and largest of the woodworking machine establishments brought out these general facts:

The rate of feed may be nearly doubled.

The cutting knives keep an edge from three to ten times as long as the old steels.

The knives may be ground with a better edge.

The sharpening of knives may be done to advantage without removing them from the head.

A slower speed of knife head is entirely practicable.

The most interesting and probably the most unexpected advantage obtained from the use of the new steels is the smoothness of the finish which they give to the work. This seems somewhat paradoxical to one who has employed them in working metal where they have been of little or no value in finishing work, though of exceedingly great importance in heavy or rapid production. Tests made, however, tend to show that in planing, for instance, it is possible to obtain, instead of a succession of knife marks, a clean, unmarred surface with a glossiness similar to that obtained in a sanding machine. Sample boards planed at the rate of 105 feet per minute showed this characteristic, and these boards included several varieties of both hard and soft woods. Sixty feet per minute is a high feed for carbon steels. Probably the reason for this better finish lies in the durability of the steel, which renders it possible to give the knives a keener edge with the knowledge that they will stand up to the work for a reasonable length of time. It is hoped by those who have experimented in this direction that under the new conditions still finer surfaces may be turned out by the planing machine at high rates of feed. As to the use of this steel for heavy reduction purposes, there should be some advantage in employing it as there is in metal working, but not so great a one. Here the old steels have been entirely satisfactory and seldom has a task been found beyond the temper of the cutting blades. For special purposes, such as in machining very hard woods, high-speed steel should prove valuable. As for the form of the knives, the toolholder is coming into vogue, the blades consisting of a thin, narrow strip, securely clamped to the head.

ELASTIC COUPLINGS.

Some kind of a spring drive has long been recognized as advantageous for machinery in which sudden and violent changes of resistance have to be overcome. The cut, Fig. 1, shows a coupling designed by Messrs. Rankin, Kennedy & Sons, Glasgow, primarily for use in motor cars and similar designs, and described in *Engineering* October 12, 1906. Its peculiar feature consists of a rubber disk for transmitting the power. This disk is provided with holes which receive

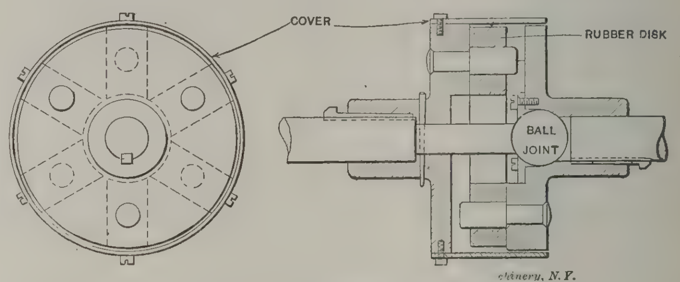


Fig. 1. Flexible Elastic Coupling.

the driving and driven pins projecting alternately from the faces of the coupling flanges. There are three pins in each flange. The flanges are prevented from longitudinal movement by a ball-and-socket connection. Consequently the shafts are free to adapt themselves to any want of alignment, but the ends cannot separate or close up on account of the ball joint. In motor cars where gear wheel transmission is used, the Kennedy coupler fitted to each end of the cardan shaft provides both a flexible and spring drive, and acts as a universal joint at the same time.

For chain drive the ball joint is dispensed with, as no flexibility is then required, and the coupling is designed as is

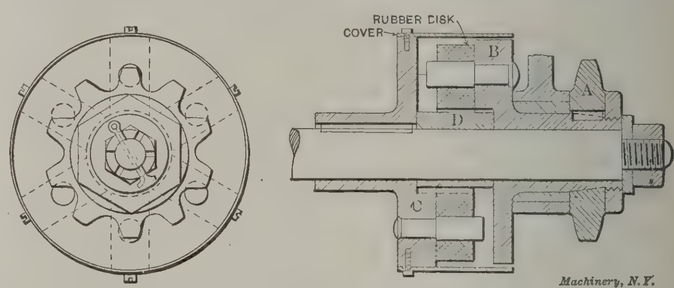

Fig. 2. Non-flexible Elastic Coupling.

shown in Fig. 2. Sprocket wheel *A* is fixed to the sleeve *B*, which turns loosely on shaft. The sleeve *C* is keyed to the shaft and each of the sleeves has three pins connecting them with the rubber disk. The collar *D* is inserted between the sleeves simply to keep them at a correct distance from one another.

UNIFORM NOMENCLATURE OF IRON AND STEEL.

At the Brussels Congress of the International Association for Testing Materials held in September, 1906, a report was presented on "The Uniform Nomenclature of Iron and Steel." The following definitions of the most important forms of iron and steel are given:

Alloy cast irons: Irons which owe their properties chiefly to the presence of an element other than carbon.

Alloy steels: Steels which owe their properties chiefly to the presence of an element other than carbon.

Basic pig iron: Pig iron containing so little silicon and sulphur that it is suited for easy conversion into steel by the basic open-hearth process (restricted to pig iron containing not more than 1.00 per cent of silicon).

Bessemer pig iron: Iron which contains so little phosphorus and sulphur that it can be used for conversion into steel by the original or acid Bessemer process (restricted to pig iron containing not more than 0.10 per cent of phosphorus).

Bessemer steel: Steel made by the Bessemer process, irrespective of carbon content.

Blister steel: Steel made by carburizing wrought iron by heating it in contact with carbonaceous matter.

Cast iron: Iron containing so much carbon or its equivalent that it is not malleable at any temperature. The committee recommends drawing the line between cast iron and steel at 2.20 per cent carbon.

Cast steel: The same as crucible steel; obsolescent, and to be avoided because confusing.

Cemented steel: The same as blister steel.

Charcoal hearth cast iron: Cast iron which has had its silicon and usually its phosphorus removed in the charcoal hearth, but still contains so much carbon as to be distinctly cast iron.

Converted steel: The same as blister steel.

Crucible steel: Steel made by the crucible process, irrespective of carbon content.

Gray pig iron and *gray cast iron:* Pig iron and cast iron in the fracture of which the iron itself is nearly or quite concealed by graphite, so that the fracture has the gray color of graphite.

Malleable castings: Castings made from iron which when first made is in the condition of cast iron, and is made malleable by subsequent treatment without fusion.

Malleable iron: The same as wrought iron.

Malleable pig iron: An American trade name for the pig iron suitable for converting into malleable castings through the process of melting, treating when molten, casting in a brittle state, and then making malleable without remelting.

Open-hearth steel: Steel made by the open-hearth process irrespective of carbon content.

Pig iron: Cast iron which has been cast into pigs direct from the blast furnace.

Puddled iron: Wrought iron made by the puddling process.

Puddled steel: Steel made by the puddling process, and necessarily slag-bearing.

Refined cast iron: Cast iron which has had most of its silicon removed in the refinery furnace, but still contains so much carbon as to be distinctly cast iron.

Shear steel: Steel, usually in the form of bars, made from blister steel by shearing it into short lengths, piling, and welding these by rolling or hammering them at a welding heat. If this process of shearing, piling, etc., is repeated, the product is called "double shear steel."

Steel: Iron which is malleable at least in some one range of temperature, and in addition is either (*a*) cast into an initially malleable mass; or, (*b*) is capable of hardening greatly by sudden cooling; or, (*c*) is both so cast and so capable of hardening.

Steel Castings: Unforged and unrolled castings made of Bessemer, open-hearth, crucible or any other steel.

Washed metal: Cast iron from which most of the silicon and phosphor have been removed by the Bell-Krupp process without removing much of the carbon, so that it still contains enough carbon to be cast iron.

Weld iron: The same as wrought iron; obsolescent and needless.

White pig iron and white cast iron: Pig iron and cast iron in the fracture of which little or no graphite is visible, so that their fracture is silvery and white.

Wrought iron: Slag-bearing, malleable iron, which does not harden materially when suddenly cooled.

THE MAZZA SEPARATOR FOR GASES—THE HIGHEST TEMPERATURE EVER ATTAINED BY MAN

Robert Kennedy Duncan, in *Harper's Magazine*, October, 1906.

Professor Duncan, who occupies the chair of Industrial Chemistry in the University of Kansas, contributed to the October *Harper's* a readable and instructive article on "High Temperatures and Modern Industry." A review is given of the increase in knowledge made possible by each increase in temperature afforded by successive discoveries, taking the reader from the bushwood fire of the savage, through the "good beach cole" of the alchemist, to the fiery furnace of the electric arc. Speaking of the importance of the oxygen blast in obtaining high temperatures, he thus describes two ingenious methods for obtaining it:

"As everybody knows, placing the 'blower' on the grate increases the per cent of oxygen passing over the fuel in a given time; it is the principle of the forced draft. But enormously better results may be obtained in another way. Since combustion depends upon the twenty-one volumes of oxygen in the air, why not increase its per cent by abstracting the inert and diluting nitrogen? This is being done to-day in two distinct ways. The first depends upon the use of liquid air. The boiling point of its constituent nitrogen is above that of its oxygen, and hence as its evaporation proceeds it leaves a liquid continuously richer in oxygen. Not only so, but Pictet and others following him have devised a "separator," by which the evaporating gases separate, because of their different specific gravities, in such a way that nitrogen passes off through one tube and oxygen through another. This method is one of completely demonstrated efficiency; it is attracting wide attention in France, and it may safely be predicted that in a few years it will enormously increase the output of the unit blast-furnace and high-temperature steels.

"The other method is a most curious one, and depends upon the hitherto unsuspected fact that it is possible to use centrifugal force in order to separate out a mixture of gases. The idea that with a revolving wheel it is possible to whirl out of the air nitrogen to one corner and oxygen to another seems almost absurd, and yet it is apparently capable of practical application.

"The 'Mazza Separator,' as it is called, contains a centrifugal wheel, which, revolving in the air at speeds from 1,200 to 2,200 a minute, is capable of concentrating the per cent of oxygen at the periphery. According to the experiments of Professor Schaefer, of the Technical School at Charlottenburg, the apparatus increases the per cent of oxygen in the air drawn from the periphery from twenty-one volumes to twenty-six. Again, according to an Italian firm of papermakers, who applied the separator to air furnished to their Cornish boilers, they saved throughout a month's working no less than 27.7 per cent of their coal. Of course, it is capable, also, of whirling hydrogen out of illuminating gas, and so increasing its luminosity; of whirling carbonic acid out of waste blast-furnace gas, thus making it more available for the new blast-furnace engines; and, in fact, if its actual industrial practice yields even a modest approximation to the enormous claims of its manufacturers, its use ought to result in striking economics in furnace practice."

As to the furthest point yet reached in the direction of high temperature, the author says: "According to a paper recently communicated to the Royal Society, Sir Andrew Noble has reached the highest point of temperature in terrestrial thermometry. He has accomplished this by exploding cordite in closed vessels with a resulting pressure of fifty tons to the square inch, and a temperature of no less than 5,200 degrees C. Sir William Crookes saw that one incidental result of this experiment should have been the formation of diamond—that is, if his calculations were correct. On working over the residues of the explosion chamber he has recently extracted from them small crystals that seem to be veritable diamonds. We see, then, that if men cannot control the conditions that make for large diamonds, they, at least, understand them. It is, in all likelihood, a matter of a comparatively short time when the diamond will have been conquered as absolutely as the ruby.

"With this final temperature of 5,200 degrees C. we have reached the limit of man's present attainment. On looking back, we see that every step in temperature he has so far taken has led him just so far along the path to universal conquest—the absolute conquest which he is destined ultimately to make. But in this phase of temperature alone he has far to go. We have had evidence from many sources that even in the sun, which is by no means the hottest of the heavenly bodies, and which yet possesses temperatures that transcend anything we know on earth, the very elements of matter lie there disintegrated into simpler forms. Such temperatures are the distant Alpine heights ever and ever so far higher than the slight ascent to which we have so tediously arrived."

ALUNDUM—ITS MANUFACTURE, CHARACTERISTICS AND USE.

Abstract of a description prepared by the Norton Co. in response to numerous requests.

No more remarkable advance in mechanical lines has taken place in modern times than the development of grinding. The field of the old grindstone was limited, and the sharpening of edged tools was almost its only use. But the introduction of the emery wheel made grinding a very important operation. The emery wheel has not only rapidly replaced the grindstone, but in many operations the work of the cold-chisel, the lathe tool, the file, and other steel-cutting tools is now done more efficiently by grinding.

Before the invention of the electric furnace, artificial abrasives suitable for grinding wheels were unknown. Wheel manufacturers necessarily depended upon natural products—chiefly corundum and emery. As emery occurs in considerable quantities in various parts of the world, it came to be recognized and used as the chief raw material for grinding wheels and other products employed in grinding metals. On this account the modern grinding wheel made of any abrasive is popularly known as the "emery wheel."

The Norton Company has during the past few years been operating an electric furnace plant at Niagara Falls, New York, in which has been developed and brought out a superior abrasive, known as alundum, and which is conceded to be one of the important electrochemical products made possible by the Niagara Falls power development. Eleven electric furnaces have been installed there, each capable of turning out three tons of alundum every twenty-four hours.

The process of making alundum consists in taking the purest amorphous oxide of aluminum found in nature, known as the mineral bauxite, and purifying and melting it in the electric furnace in a large, homogeneous bath or fluid mass. Upon cooling, this molten fluid solidifies and crystallizes in solid masses of alundum of great purity and absolute uniformity throughout.

Bauxite, the raw material from which alundum is made, is the purest naturally occurring amorphous oxide of aluminum known. This mineral was originally found at Baux, France, from which it derives its name, but purer forms are now obtainable in the United States. The best quality only is used in the manufacture of alundum, and in its preparation practically all impurities are removed. The high grades of bauxite used are of rare occurrence. The Norton Company, however, owns its own mines from which the purest grade is obtained.

The bauxite is heated in large preliminary heating furnaces to drive off the combined water, and is then melted directly in electric furnaces of special design. Bauxite was considered infusible until the invention of this process, no heat of combustion being able to melt it, the electric arc only being equal to this task.

The temperature, at which the furnace charge melts in one homogeneous mass, is above the limit by which temperatures are measured by any means known to science, and is variously estimated between 6,000 and 7,000 degrees F. The operation of these furnaces and the composition of the molten bath is under the control of the furnace operative. Exact quality and uniformity, which is so important in steel manufacture, is fully as important in the manufacture of alundum. The highest grades of steel are now being made in electric furnaces similar in design to the alundum furnace, because impurities can be removed at the high temperatures obtained by the electric arc, and the quality of the molten bath uniformly maintained. In the alundum furnace both the purity and uniformity of the alundum is assured. Each step in the process is under the close supervision of expert chemists.

The large masses of molten bauxite are allowed to cool and crystallize in great ingots of purified crystalline alundum. Beautiful crystals are found in the center of these masses, showing nearly all the variety of colors found in the ruby and sapphire, of which alundum is the commercial, artificial product. The rarer colors of light pink, blue and purple found in the rarer oriental gems are sometimes noticed in small crystals. The ingots of alundum are broken up into small pieces by means of powerful crushers. It is then passed through series of rolls to reduce it to the various sizes of grain, which are finally separated by passing over sieves of different mesh to prepare it for manufacture into Norton grinding wheels, rubbing and sharpening stones, etc.

The solid massive alundum, while resembling the purest natural corundum in chemical composition, has the remarkable quality of being considerably harder than the natural product. This is due to the perfectly fluid condition in which the mass is melted, the control of its composition, the rate and method of its cooling and crystallization by which it receives its temper, the absence of water of combination (which almost invariably exists in natural corundum), and the pure and even state in which the fluid mass crystallizes.

The introduction of alundum in the field of grinding has been remarkably successful and rapid. The requisites sought for and attained in this abrasive are extreme hardness and sharpness, combined with uniformity and proper temper. These, alundum has in the highest degree.

To have sharpness in order to obtain the most satisfactory results—so far as rapid and continued cutting is concerned—a peculiar quality is necessary. There must be a fracture which will give a number of sharp-cutting points. This is obtained in alundum to better advantage than in any other abrasive material.

In the matter of hardness the recognized standard is the diamond, which is No. 10 in the scale of hardness; nothing that man has yet discovered or made equals the diamond in hardness. The term "hardness" is, therefore, a comparative term, the hardness of a mineral being ascertained by its ability to scratch another mineral of a known degree of hardness, or to be scratched by such a mineral.

Pure crystalline corundum, represented by the best sapphire or ruby, has always been the standard of No. 9 in the scale of hardness. This is readily scratched by alundum; in fact, alundum powder is used for cutting and drilling rubies and sapphires for watch jewels, etc.

After numerous careful tests, comparing alundum grains with other abrasive grains, including the diamond, alundum is found to exceed 9½ in the scale of hardness where the diamond is 10.

By "temper" is meant its strength of grain and the character of its fracture under grinding pressure. An alundum grain is remarkably tough and will stand more crushing pressure before breaking than any other abrasive grain, but when it does break down it breaks with a sharp, crisp fracture, giving a fresh, keen-cutting edge. This is a most important quality in an abrasive.

The purity and uniformity of alundum far surpasses that of any other abrasive. Purity, besides resulting in greater hardness and better temper, is necessary in the bonding of the grain into wheels, in order to secure accurate and uniform results, and uniformity is necessary to secure constant efficiency and accuracy of grade and temper in a wheel, so that wheels can be accurately duplicated at any time and maintain their standard of work.

Uniformity is one of the most important requisites in an abrasive. The ability to duplicate a grinding wheel is essential to efficient results from its use. In grinding wheels the abrasive grain of given size is bonded together to produce a certain grade or temper for a certain kind of work. This means that the bond, which holds the grains together, must be harder or softer according to the particular work required of the wheel. Different grades are required for different materials to be ground; cast iron, steel, brass, glass, bone, leather, wood and other substances demand wheels of special grade which must be duplicated to make the grinding operation continuously efficient. It is for this most important reason that great stress is placed on evenness in quality of the abrasive itself. Grades cannot be duplicated accurately without having a known and dependable factor in the uniformity of the material composing the wheel; and this important requisite is to the highest degree found in alundum.

Alundum and the process of making it were awarded the Grand Prize at the St. Louis Exposition. The individuals responsible for its invention and development were honored with diplomas and medals for their part in this most notable, practical invention.

APPRENTICESHIP IN THE UNITED STATES.

Abstract of Report of Apprenticeship Committee of the National Machine Tool Builders' Association, 1906.

At the fifth annual convention of the National Machine Tool Builders' Association at the Hotel Breslin, New York City, October 9, Mr. E. P. Bullard, Jr., presented the final report of the Apprenticeship Committee, which had been directed to make a thorough analysis of the systems now in use throughout the United States, and to make suggestions for the guidance of the association in taking such action as might be advisable in the direction of uniform apprenticeship requirements. The following paragraphs give an abstract of the essential features of the report.

A series of letters containing fourteen questions was addressed to 51 machine tool builders and 41 other manufacturing concerns employing machinists. Replies were received from 49 machine tool builders and 26 from concerns engaged in other lines. The following were the questions asked:

No. 1. Do you indenture apprentices to the machinist's trade?

No. 2. Have such apprentices proven satisfactory from a commercial standpoint?

No. 3. What is the approximate ratio between the number of apprentices and machinists employed?

No. 4. Have graduate apprentices of your works been advanced to positions of authority while in your employ?

No. 5. Is difficulty experienced in securing a sufficient number of intelligent apprentices?

No. 6. Are applicants required to have a specific amount of previous school training?

No. 7. Are courses of instruction provided for apprentices during their term of service?

No. 8. Is attendance on these courses compulsory?

No. 9. Are apprentices under the charge of a special instructor while employed in the works?

No. 10. Are apprentices permitted to work on either the premium or piece-work systems?

No. 11. Are small tools provided for their use free of charge?

No. 12. Are inducements of either shorter time or increased pay offered to technical graduates to learn the machinist's trade?

No. 13. Do you indenture apprentices to the various branches of the trade, such as lathe work, planer work, etc.?

No. 14. Is any provision made for these special apprentices to become regular apprentices, should they desire, after having completed their special apprenticeship?

The following synopsis, taken verbatim from the report, gives the results of this inquiry:

1. The majority of Machine Tool Builders have established apprenticeship systems, which are in more or less satisfactory operation. A smaller percentage of the allied trades have some system, but one large industry, the automobile manufacturers, with one exception, employs no apprentices.

2. Apprentices have proven satisfactory from a commercial standpoint.

3. The approximate ratio between the number of apprentices and journeymen employed by The Machine Tool Builders is about 18 per cent, whereas the allied trades do not average over 13 per cent.

4. Graduate apprentices have been advanced to positions of authority in many shops. Some concerns state that their foremen come almost entirely from this class.

5. All reports indicate that difficulty is experienced in securing a sufficient number of intelligent apprentices. It seems, however, that the question of wages and time of service have little effect on this question.

6. But few concerns require a specific amount of previous school training, the majority requiring a common school education only.

7. As a general rule courses of instruction are not provided for apprentices.

8. Those who do provide such a course make attendance compulsory.

9. Apprentices are usually under the direct charge of the foreman of the department.

10. About 50 per cent of the concerns employing apprentices permit them to work under either the premium or piece work systems.

11. Thirty-three per cent provide small tools free of charge.

12. Thirty-three per cent offer special inducements to technical graduates, but state that they find it difficult to secure them.

13. Twelve per cent state that apprentices are taken to the various branches of the machinist's trade.

14. But a small percentage of the above make provision for special apprentices to become regular apprentices after having completed their special course.

This problem then resolves itself into the following:

Having an insufficient number of skilled workmen, we can only increase this supply by teaching the machinist's trade to an increased number of boys. Finding difficulty in procuring a sufficient number of boys for this purpose, we must offer inducements which will attract them to the trade.

We would therefore suggest: First, the drafting of uniform apprenticeship contracts, covering both regular and special apprentices, same to be binding both to the employer and employee, the former to be obliged to properly instruct the latter in the branch or branches of the trade specified in the contract, and we suggest that the articles of indenture provide sufficient guarantee on the part of the apprentice for the satisfactory completion of his time of service, the wages paid to be optional with the individual employer. We believe this point is essential, as it is apparent from our investigation that apprentice wages vary in different sections of the country. It would seem advisable, however, to have a uniform term of service in all cases to be based on the time found necessary, by previous experience, to properly teach the branch or branches of the trade specified in the contract.

The number of apprentices employed in any shop should be limited only by the ability of the employer to properly instruct them.

Graduate apprentices should be advanced wherever possible, and preference given them in making promotions.

Special apprentices or those indentured to one branch of the trade only should have a common school education, and regular apprentices, or those indentured to the full trade, to have at least a grammar school education.

Courses of instruction for apprentices during their term of service should be provided, where practicable, and attendance upon such courses, where provided, be made compulsory. High school and technical graduates should be exempt from special study during their term of service. A special instructor should be provided where practicable.

Apprentices should be permitted to work on the premium or piece work systems. All small tools should be provided for their use free of charge, these to be furnished new on completion of their trial period, and presented to them on the satisfactory completion of their term of apprenticeship. These tools should be inspected by an authorized official at stated intervals and the condition reported. These reports would be valuable in determining the interest and ability of the apprentices.

Technical graduates should be encouraged to indenture themselves to the trade by offering higher wages and shorter period of service. Influence should be brought to bear upon those in authority at the technical schools to impress upon them the demand in the machine tool business for men having a technical education and willing to learn the practical side of the business.

Indenture apprentices to the various branches of the machinist's trade, making the term of service short and wages relatively high. Offer bonus or reward for the satisfactory completion of apprenticeship.

Offer an opportunity for special apprentices to become regular apprentices, should they so desire on the completion of their special apprenticeship, the time so served applying on the regular apprenticeship course in proportion as may be thought advisable.

Finally, issue a diploma, bearing the seal of the National Machine Tool Builders' Association, to both regular and special apprentices, stating clearly the work accomplished during term of service.

STRENGTH OF GEARS.

JOHN S. MYERS.

The best solution of the gear problem is by use of the "gear slide rule," an instrument somewhat resembling Sexton's Omnimeter in appearance, which was developed by Mr. Carl G. Barth and placed upon the market in 1902. This device takes into account all the variable factors involved in a manner not practical for any table or chart. The writer does not offer the present article, with the accompanying diagrams, as affording so speedy or easily attained a solution of the problem, but more as an introduction to the special subject of bevel gears; the method of treatment of this phase of the subject here given being original with Mr. Barth and not heretofore published. The formula used for varying the stress according to the velocity was also developed by Mr. Barth, but upon submitting it to Mr. Lewis, he found it to be identical with one the latter had developed, but, to the best of the writer's knowledge, had never published.

The Lewis formula and the factors of strength for gears were presented to the public in 1893, and have been quite generally accepted as the standard for computations. The stresses for different speeds as first recommended by Mr. Lewis were only given tentatively in the absence of sufficient data upon which to base a definite formula expressing a mathematical relation. They have been found to agree fairly well with good practice, which indicates that, taken as a whole, they were approximately correct, notwithstanding some marked irregularities which are clearly evident by an inspection of the accompanying diagram, (see Plate III in the Supplement) where the dotted line represents Lewis's original table of stresses for different velocities. The formula devised to supplant this original table is as follows:

Let V = velocity in feet per minute at the pitch line of the gear;

S_s = allowable static stress in pounds per sq. in., *i. e.*, the allowable stress when the velocity equals zero.

S_v = allowable stress at the velocity V;

$$\text{Then } S_v = S_s \frac{600}{600 + V}. \qquad (1)$$

This formula gives a logical basis upon which to vary the stress according to the velocity, the value of S_s being chosen to suit the material used, class of workmanship and condition of service. In the diagram the three curves are plotted for S_s = 4,000, 6,000 and 8,000 respectively when reading on the bottom scale designated stress for cast iron, or, when read on the top scale for steel, the corresponding values of S_s are 10,000, 15,000 and 20,000. In the chart for strength of spur gears (see Plate II in Supplement) the column on the left gives the working load for gears of 1-inch pitch and 1-inch face, the stresses used being as given by the 8,000, 20,000 curve, and the column on the right working loads for stresses according to the 6,000, 15,000 curve, the former being approximately the values as originally given by Lewis, which are intended for first-class workmanship, the latter being ¾ of these values and applicable to a rougher class of machinery.

In order to give the scale of this chart representing the number of teeth a uniform appearance it was necessary to smooth out the inaccuracies of the Lewis strength factors by plotting them to scale and drawing a curve through the general direction. The explanation given in connection with this curve (see Plate I in Supplement) is sufficient to elucidate the method pursued.

To use the chart for strength of spur gears:

Case 1. To find the strength of a given gear; follow the vertical line representing the number of teeth to its intersection with the oblique line of the proper speed, and from this point follow the horizontal line to the left and read off the working load for 1-inch pitch and 1-inch face. Multiply this by the product of the face and the circular pitch and the result is the working load for the given gear, if the workmanship is good and the service not severe. If the contrary is the case use the working loads in the column on the right.

Case II. To find the proper pitch and face of a gear to carry a given load; proceed as before, going to left or right according to workmanship and service, and divide the given load by the working load for 1-inch pitch and 1-inch face. Make the product of the circular pitch and face of the required gear equal to this quotient. When using diametral pitch reduce it to circular pitch by aid of the table given with the chart, the first decimal place of these equivalents being sufficiently accurate for the purpose.

Example of case II: What should be the pitch and face of a 15-tooth, cast iron pinion running at a velocity of 1,000 feet per minute and transmitting a working load of 650 pounds at the pitch line?

By the chart, in the column on the left, the working load for 1-inch pitch, 1-inch face is 225 pounds, then 650/225 = 2.89 = product of pitch and face for the required gear. One-inch pitch and 3-inch face would fulfill the conditions with a margin of safety.

Going now to the subject of bevel gears, Mr. Lewis gives the formula

$$W = SPFY \frac{D^3 - d^3}{3\,D^2\,(D - d)}, \qquad (2)$$

in which

W = working load reduced to the pitch diameter at the large end,

S = allowable stress at the given speed,

P = pitch of teeth at large diameter,

F = face of gear,

D = pitch diameter at large end,

d = pitch diameter at small end,

Y = strength factor depending upon shape of teeth and formative number of teeth, this formative number of teeth being equal to $n \sec a = n\frac{L}{H}$, where n = actual number of teeth, a is the angle the pitch line makes with the center line; and L and H are the dimensions indicated in the sketch (see Plate IV in Supplement). He states that when d is not less than 2/3 D, as is the case in good practice, the formula

$$W = SPFY\frac{d}{D}, \qquad (3)$$

gives results almost identical.

If the above formulas be expressed in terms of the face F and the total possible length of face L they are then in a form which gives relative strengths for different face widths; and instead of expressing the limit of good practice in terms of the large and small diameters, which are only identical for both gears of the pair in the special case of miters, this limit is then stated by saying that the face width may be 1/3 L.

To express formula 2 in terms of F and L:

$D = 2\,L \sin a$ and $d = 2(L - F)\sin a$, then

$$\frac{D^3 - d^3}{3\,D^2\,(D - d)} = \frac{(2\,L \sin a)^3 - [2\,(L - F)\sin a]^3}{3\,(2\,L\sin a)^2\,[2\,L \sin a - 2\,(L - F)\sin a]}$$

$$= \frac{8\,(3\,L^2F - 3\,LF^2 + F^3)}{24\,L^2\,F} = \frac{L^2 - LF + \frac{1}{3}F^2}{L^2} = \frac{L - F}{L} + \frac{1}{3}\left(\frac{F}{L}\right)^2 \qquad (4)$$

We may then write formula 2 thus:

$$W = SPFY\left[\frac{L - F}{L} + \frac{1}{3}\left(\frac{F}{L}\right)^2\right] \qquad (5)$$

The quantity in brackets is the ratio of the strength of a bevel gear to the strength of a spur gear of the same pitch and face. This quantity may also be written

$$1 - \frac{F}{L} + \frac{1}{3}\left(\frac{F}{L}\right)^2$$

Since $1/3(F/L)^2$ is small compared to $1 - F/L$ when F/L does not much exceed 1/3 it may be neglected and formula 5 then becomes

$$W = SPFY\frac{L - F}{L} \qquad (6)$$

which is accurate enough for all practical purposes. This is shown clearly in chart 1 (see Plate IV. in Supplement) where the full curved line, plotted from the calculated values given in the table just above the chart, represents the correct ratio of strength while the straight dotted line gives the approxi-

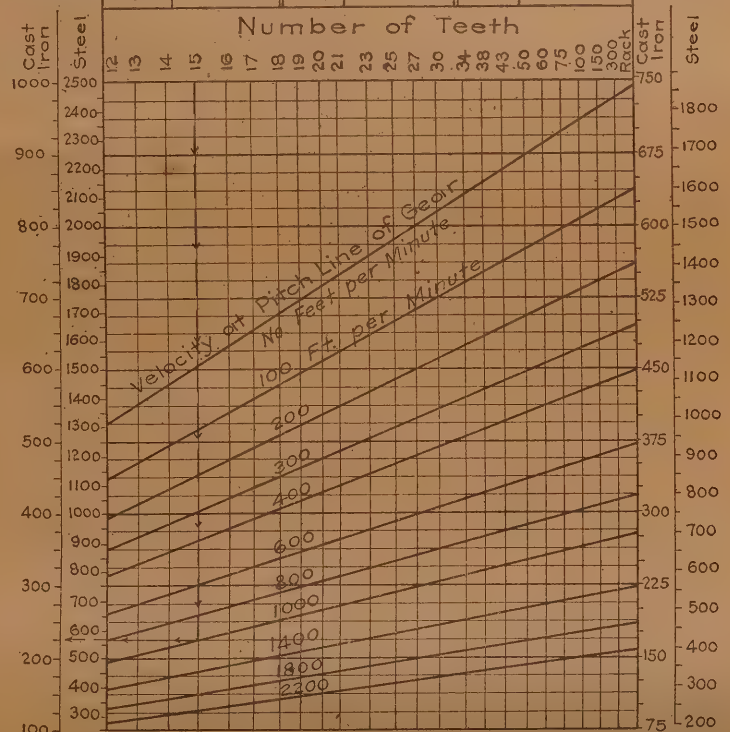
STRENGTH OF GEARS.—II.

15° Involute and Cycloidal Spur Gears

Based on Lewis's formula with strength factors slightly modified

To find the strength of a spur gear multiply the working load given in the diagram by the product of the pitch and face. Reduce diametral to circular pitch by table in which D = diametral and C = circular pitch.

D	C	D	C	D	C
1	3.142	2¼	1.396	4	.785
1¼	2.513	2½	1.257	5	.628
1½	2.094	2¾	1.142	6	.524
1¾	1.795	3	1.047	8	.393
2	1.571	3½	.898	10	.314



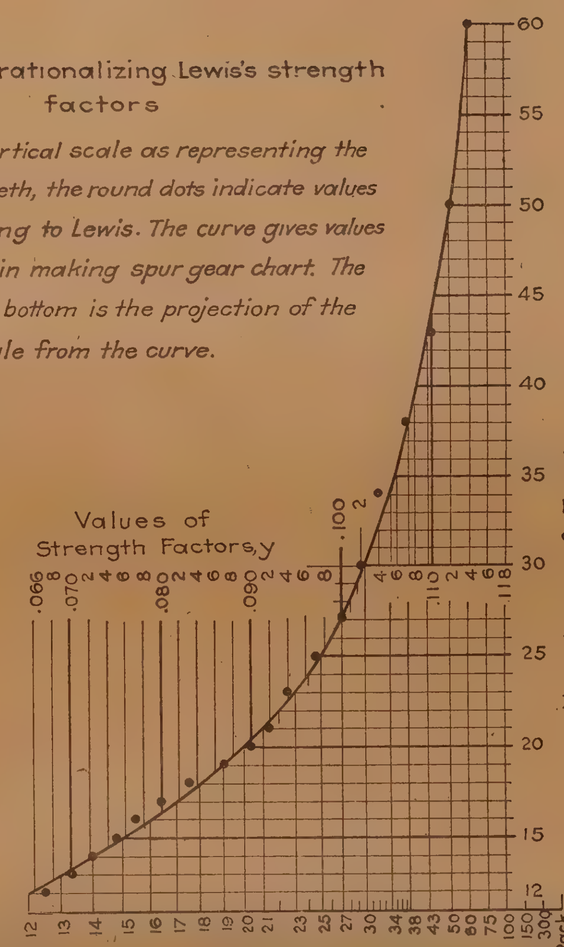
Example, 15 teeth at 1000 ft. per minute, working load = 225 # in cast-iron, for 1" pitch, 1" face

MACHINERY, N.Y.

STRENGTH OF GEARS.—I.

Method of rationalizing Lewis's strength factors

Taking the vertical scale as representing the number of teeth, the round dots indicate values of y according to Lewis. The curve gives values of y as used in making spur gear chart. The scale at the bottom is the projection of the vertical scale from the curve.



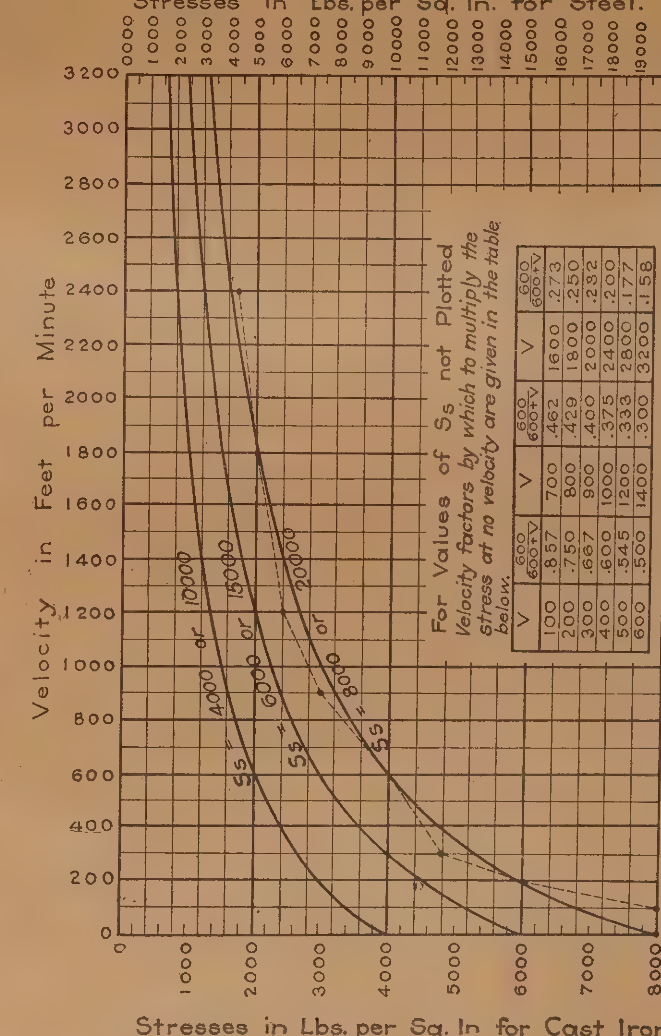
Scale used for number of teeth, in making spur gear chart, for 15° involute and cycloidal teeth.

MACHINERY, N.Y.

…number entitled, "Strength of Gears."

STRENGTH OF GEARS.—III.

Stresses for different Speeds



For Values of S_s not Plotted
Velocity factors by which to multiply the stress at no velocity are given in the table below.

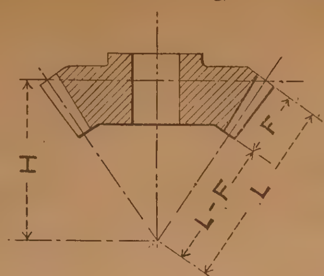
V	$\frac{600}{600+V}$	V	$\frac{600}{600+V}$	V	$\frac{600}{600+V}$
100	.857	700	.462	1600	.273
200	.750	800	.429	1800	.250
300	.667	900	.400	2000	.232
400	.600	1000	.375	2400	.200
500	.545	1200	.333	2800	.177
600	.500	1400	.300	3200	.158

The dotted line represents stresses as originally given by Lewis.
The curves give stresses according to the formula $S_v = S_s \frac{600}{600+V}$
where S_v = stress · for velocity V and S_s = stress when V=zero

MACHINERY, N.Y.

STRENGTH OF GEARS.—IV.

Strength of Bevel Gears.
According to Lewis and Carl G. Barth.



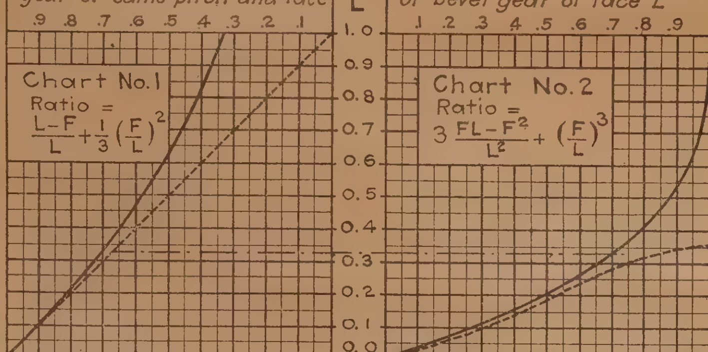
To find the strength of a bevel gear ; multiply its number of teeth by L/H and find the strength of a spur gear of this number of teeth and of the same pitch and face as the bevel gear; multiply the strength of this spur gear by the ratio given in chart No.1 below.

For face widths within the limits of good practice this ratio may be taken as equal to $\frac{L-F}{L}$

$\frac{F}{L}$	Ratio in Chart No.1	$\frac{F}{L}$	Ratio in Chart No.1	$\frac{F}{L}$	Ratio in Chart No.2	$\frac{F}{L}$	Ratio in Chart No.2
0.1	.9033	0.6	.5200	0.1	.2710	0.6	.9360
0.2	.8133	0.7	.4633	0.2	.4880	0.7	.9730
0.3	.7300	0.8	.4133	0.3	.6570	0.8	.9920
0.4	.6533	0.9	.3700	0.4	.7840	0.9	.9990
0.5	.5833	1.0	.3333	0.5	.8750	1.0	1.000

Ratio of strength of bevel gear to strength of spur gear of same pitch and face

Ratio of strength of bevel gear of face "F" to strength of bevel gear of face "L"



The dotted line indicates the ratio $\frac{L-F}{L}$ showing that for general use this is near enough to the true ratio for values of F/L not exceeding 1/3, which may be considered the limit of good practice

This diagram shows that when F/L = 1/3 there has then been developed .7 of the theoretical strength of the total cone.
The dotted line indicates the probable practical results, showing folly of making F more than $\frac{1}{3}$ L

MACHINERY, N.Y.

mate ratio $\frac{L-F}{L}$.

For $\frac{F}{L}=\frac{1}{3}$, the correct ratio $1-\frac{F}{L}+\frac{1}{3}\left(\frac{F}{L}\right)^2=1-\frac{1}{3}+\frac{1}{3}\times\frac{1}{6}$ $=\frac{19}{27}=0.7037$ and the approximate ratio $\frac{L-F}{L}=1-\frac{F}{L}=1-\frac{1}{3}=\frac{2}{3}=0.6667$, which is a difference of only $\frac{1}{27}=0.037$, or less than 4 per cent error for the greatest face widths used in good practice and this error is on the side of safety.

Chart 2 shows the ratio of strength of a bevel gear of face F to the strength of a bevel gear of face L. It thus indicates the proportion of the total possible theoretical strength of the entire cone developed by any given face. The formula may be developed as follows:

$$\text{Ratio}=\frac{\text{strength of bevel gear of face } F}{\text{strength of bevel gear when } F=L}$$

$$=\frac{SPFY\left(\frac{L-F}{L}+\frac{1}{3}\frac{F^2}{L^2}\right)}{SPLY\left(\frac{L-L}{L}+\frac{1}{3}\frac{L^2}{L^2}\right)}=\frac{\frac{FL-F^2}{L}+\frac{1}{3}\frac{F^3}{L^2}}{\frac{1}{3}L}=3\,\frac{FL-F^2}{L^2}$$

$$+\frac{F^3}{L^3}=3\frac{F}{L}-3\left(\frac{F}{L}\right)^2+\left(\frac{F}{L}\right)^3 \qquad (7)$$

Values of this ratio, as given in the table above the chart, were calculated and used in plotting the curve. It is to be noticed that this curve commences to change direction rapidly from $F/L=0.3$ and over. When $F/L=1/3$ this theoretical ratio $=0.7037$ and in practice there has probably been developed 0.9 or even 0.95 of the possible strength to be attained. This is indicated by the dotted curve which shows clearly that there is nothing gained by making the face over about $1/3\,L$.

It is believed by the writer that this method of treating the bevel gear problem has much to recommend it and he therefore takes pleasure in presenting it to the readers of MACHINERY.

* * *

"WILL THE AUTOMOBILE FOLLOW THE BICYCLE?"

The following letters are replies received in answer to an editorial on the above subject which appeared in the October issue. They will be found of interest as indicating a conservative attitude of the leading automobile manufacturers to their business and their ideas as to its permanency. The future of the automobile and its economic effect are matters of importance to us all, whether we are users or non-users. Mechanical engineers, in general, are heartily interested in its ultimate triumph, for it is in direct line with general mechanical development, but many have become disgusted with the uses to which the automobile has been put by wealthy users. The influence of road races, cross-country runs and other manifestations of the sporting class have been of little good. It is probably safe to say that few, if any, of the automobile manufacturers are satisfied with the present trend of affairs. They build automobiles for pleasure and racing purposes because this at present represents the best market, but they all recognize the fact that the future of the automobile largely depends upon its value for strictly utilitarian purposes. As to the present status of the bicycle, it will be apparent that some of the writers do not agree with the common impression that the bicycle is out of date, but they rather imply that the number in use at the present time is more than ever before.

From E. R. Thomas Motor Co., Buffalo, N. Y.

"The rise and decline of the bicycle was a phenomenon well within the memory of most readers. Will the automobile follow the bicycle?"

As a manufacturer of bicycles, I confess that the sudden decline of the use of bicycles was a severe and unexpected shock, and its quickly waning popularity was without a parallel, except roller skating.

It was patent to every bicycle manufacturer that the abnormal demand for bicycles created by intense competition and the most strenuous advertising could not continue forever. As long as radical improvements were made each year, that contributed to ease of running, light weight and beauty, it was an incentive sufficient to induce a large majority of riders to change their mounts annually.

The decline was further accelerated by an overproduction of cheap—almost worthless—wheels, riders continuing the use of their bicycles for two or more years, instead of only one when great annual improvements were the rule; the increase of gear which made harder work, and strange to say, prices becoming too cheap, etc. But after all the so-called decline was the temporary lull from an abnormal to a normal demand. There are more bicycles manufactured in France, and possibly England, than ever before, and American bicycle manufacturers tell me that notwithstanding the wealthier classes have retired from the field in favor of automobiles, the demand is steadily increasing and the business is again on a profitable basis.

From another point of view, there is no parallel between the uses of bicycles and automobiles, and there is no reason why the decline or fall of one should influence the other.

The bicycle is primarily more an article of pleasure and relaxation than a necessity. It was never supposed to usurp the functions of a horse—its radius to the average rider was much more limited, it was rather dirty and required too much exertion to remain permanently popular with the wealthier classes, most of whom owned horses, carriages, etc. I never heard of anyone discarding horses and relying principally upon bicycles for their method of transportation, while most automobilists are discarding horses.

In my opinion, the question should properly be: Will the demand for automobiles have a decided lull and a slow reaction the same as the bicycle?"

To a comparatively limited extent, I should say there will be within a few years a temporary and healthy lull in the demand for pleasure cars. At the present time, there are a large number of automobile manufacturers who have neither the capital, experience, facilities or volume of business to profitably succeed, and that element will necessarily and gradually withdraw. The beginning of the end of that kind of competition has already begun, for more than fifty small or prospective manufacturers. As a matter of fact the small manufacturer cannot now successfully compete in price and quality, for the large manufacturer now makes and ships the first two hundred or more cars without profit.

Since ancient times, the only method by which individuals were transported, was the horse, and the use of the horse, both for pleasure and business, had constantly increased for two thousand years up to within the past two or three years, when the decline of the horse for the transportation of individuals has noticeably decreased each year more and more.

Baron Rothschild predicted four years ago that within ten years the horse would not be seen on the streets of Paris. Even a better authority has predicted that within two years not a single horse-drawn cab will be seen on the streets of Paris. The streets of Paris to-day are full of automobile cabs that transport individuals cheaper and faster than horse cabs, and the most skeptical observer must admit, upon investigation, that the automobile within five years will entirely succeed the horse in everything except freight handling, and even that day seems not to be far off.

If it is a fact that for two thousand years the horse was practically the only method by which individuals were transported with scarcely, if any, improvement, since the days of the Roman chariot, the automobile, being the only successor, must be the only method until some better way is devised. This, at the present time, is not even dreamed of or predicted, and hence, I believe that for a thousand years, the automobile, especially when changed, perfected and improved to suit the growing needs, will be practically the only method by which individuals are transported beyond a walking radius, and the demand will increase and increase until the man afoot, beyond a short walking radius, will be a rarity. In fact, it may not be an idle dream to predict that within a century the practice of walking long distances will be discontinued and people will be unable to take long walks, but will use roller skates, bicycles, motor bicycles and automobiles. E. R. THOMAS.

Buffalo, N. Y.

From Ford Motor Co., Detroit, Mich.

You make the erroneous statement that there are less bicycles in use to-day than in the days when they were the craze. I think if you will take the trouble to look it up you will find that there were more bicycles manufactured last year than there were manufactured in any one year previously. The Geo. N. Pierce Company, of Buffalo, who rank as one of the most successful automobile concerns, will tell you that their bicycle business is still the more profitable industry, employs more men, and is altogether of greater magnitude than their automobile business.

True, there are not so many concerns manufacturing bicycles as there were; but this is due to the fact that the bicycle has to-day been reduced to absolutely standard form and is

manufactured in enormous quantities by automatic machinery. It was only when this state of perfection had been reached that there was over-production of bicycles.

You say, "In many towns the bicycle is rarely seen on the streets." If you take another look, you will see them in plenty. The difference is that we do not *notice* them now days. It is true that as a pleasure conveyance the bicycle has out-run the craze period, but only a few days ago we had to build a large addition to our bicycle shed to take care of the new machines of our employees. In other words, it is a utility vehicle.

You will remember that you saw more automobiles on the streets when there were only a score or so of them than you do to-day when there are thousands. They were a curiosity then, now they are as common as horses.

We agree with you that the "cross-country runs," to express in your own very admirable terms, "tearing through the country at railroad speed, going nowhere in particular, and seeing nothing as he goes," will soon come to an end. I think the majority of automobilists, while demanding high speed possibilities in their machines, really prefer to drive at a rational pace and enjoy the fresh air and scenery, rather than gulp down dust and leave dust behind them for others to swallow; and for genuine pleasure riding the touring car will stay, while for business purposes the runabout will take the place of the horse-drawn runabout almost exclusively. Then in the commercial field the possibilities are simply unlimited.

Concluding, the bicycle is not past but still remains the most useful mode of transportation for the individual that man's ingenuity ever devised. There is no relation between the automobile and the bicycle, except the pneumatic tires, any more than there is between the horse and the bicycle; and there is no more reason why the motor-propelled vehicle should ever become obsolete than there is that we should substitute ox teams for locomotives for cross-country transportation. E. LE ROY PELLETIER.

Detroit, Mich.

From Olds Motor Works, Lansing, Mich.

Notwithstanding the fact that people are constantly predicting that the automobile is a fad, and will soon go the way of the bicycle, yet such is not the case. One might almost as well say that steam cars or electric cars will be relegated to museums in the course of a few years.

Any one who has studied the subject of transportation knows that anything which is done to decrease the time required for conveying people or freight from one place to another is bound to succeed and should realize that the automobile will fill its niche and remain an important factor in the business world. Whether or not the strictly pleasure vehicle will survive is a question.

Many of the men who are now driving machines are well-known horse fanciers, and it will not be at all strange if they take up this sport again after they are tired of motoring. A large number of automobile enthusiasts are in a like position, and may lose interest, but it is hardly possible that they will give up their machines entirely, owing to the fact that the new form of transportation has already become a necessity of their daily lives.

From a business standpoint, however, the situation looks entirely different. The various produce men of the country have already installed a large number of trucks and other style of motor cars; telephone, telegraph and railroad companies are using them in connection with their traffic department, and nearly all of the large wholesale and retail dealers in the cities have, or are contemplating the purchase of some sort of horseless vehicle. With the coming of good roads and good pavements the cost of transportation by means of the motor car will decrease proportionately, and the time will soon come when automobiles will no longer be a luxury but an absolute necessity—one of the most valuable adjuncts of the commercial world. Nor is this true alone of the larger companies. Individual salesmen, real estate agents, and in fact every business man who is called upon to make frequent and sometimes lengthy trips about the city, find a machine such an easy means of getting from place to place, that they would as soon think of giving it up as of throwing their telephone out of the window.

No; there is no question but what the automobile has come to stay and we, as manufacturers, are putting forth every effort to put this business on a strictly standard basis, and produce a car which will not be in style one year and out of style the next, but a machine which will be practically comfortable and serviceable for years to come.

Lansing, Mich. FAY L. FAUROTE.

From Stevens-Duryea Co., Chicopee Falls, Mass.

This is a subject in which we have been very much interested for a number of years, and, consequently, have looked it up much more carefully than people who are not directly interested in a heavy, financial way. Studying the situation of recreation and sports for many years past, we cannot help but notice that those sports which require a large expenditure of work by the participants, sooner or later lose some of their stronghold and, in that way, become "back-numbers."

Now every sane person knows that the recreation which one gets from a limited amount of bicycle-riding, golf or tennis playing, is a grand good thing for the human system; but in all of these sports a large amount of personal effort must be expended by the player, and many times in the year when the weather is very warm and uncomfortable, one prefers to sit on the piazza or in the shade of a good tree, rather than to go out in the open and exercise, which, if used in a limited quantity, would certainly do more good than inaction.

We consider that the human race is naturally lazy and one wants to get through life as easily as possible and with as little expenditure of energy as he can; consequently, the sports which give the most recreation with the least exertion would be the ones to stay with the public.

We consider that the automobile and the motor boat (and possibly in the near future, the balloon) will cover that requisite. Now take the motor boat business as an illustration: We consider that to the water what the automobile is to the land; but as the motor boat business has been developed many more years than the automobile industry, we have some data to work on in connection with the latter.

One cannot travel anywhere on the water nowadays without being surprised at the large number of motor boats of all sorts, shapes and sizes which are found throughout the country. The motor boat business has increased by leaps and bounds for a number of years past, and no man would think, in these days, of taking a twenty-mile pleasure row to call on a friend in an evening, when he could sit in his motor boat and be landed there with no energy on his part and a very pleasant recreation for both himself and his friends.

What applies to the motor boat business we think will equally apply to the automobile business, and, while the present prices of automobiles are prohibitory to a large class of people, yet in the future development, simplification of parts and stability of styles, makers not being obliged to change their entire output from year to year, will naturally bring about changes in prices, the same as it has in the motor boat business. The motor cycle is another illustration of an article which is becoming very popular from the fact that a person is able to cover a very large amount of ground without very much effort on his part.

When the "denaturized alcohol" bill goes into effect, it may reduce the cost of running both of automobiles and motor boats considerably, and, as time goes on, other materials may be adopted to be used for fuel, and, in that way, reduce the cost.

But turning to the automobile truck situation: We feel absolutely positive that both the small and the large trucks will very largely supersede horse-power for moving the traffic of our towns and cities. It may take quite a little while to bring this about, but it is surely coming as certain as the sun rises every morning. We do not consider that it is more than a few years away when every small tradesman who makes delivery of goods or parcels will have his automobile carriage or truck for delivering the same, taking the place of his horse-drawn vehicle. J. H. PAGE.

Chicopee Falls, Mass.

* * *

One of the petty abuses to which the various express companies seem to be given is the deliberate losing of empty return packages for butter, eggs and other farm products. Finding that the return privilege means the annual handling of thousands of empty packages for which no direct return is obtained, the companies are apparently following the policy of side tracking such packages indefinitely and making the shippers stand the loss. It seems to be another example of the deliberate trampling on the rights of people who have to make use of the common carriers, and is one of the examples which tend to make people in general regard all transportation companies sourly and with suspicion. The abuse is one of considerable importance when we consider the enormous number of packages used annually for handling such products. With the present high price of lumber and the growing scarcity and consequent increase in price it becomes more and more imperative that economy in packages should be the rule. Years ago express companies made the concession of returning empty packages free in order to stimulate this class of shipments. The matter of negligence on the part of common carriers is held as not coming within the purview of the Interstate Commerce Committee, but seemingly it is an abuse which must be handled by a body more powerful than the private individual.

* * *

The coming exposition of safety devices mentioned in the October issue will be held at the American Museum of Natural History, New York, January 28 to February 9, 1907. The exposition will show safety devices for protecting the lives of workmen and of the general public; it will also have exhibits pertaining to industrial hygiene, care of the health, etc.

A EUROPEAN MACHINERY HOUSE.

In the attractive city of Cologne, founded more than a thousand years ago on the banks of the Rhine, the writer found the most complete establishment for selling machine tools in Europe or America; the center of a wonderful selling organization which covers a great part of Europe and is now reaching out for trade in the Orient. The foundation of the business of Alfred H. Schütte was laid twenty-six years ago, and with its branches now employs a staff of commercial men and engineers numbering about three hundred. The main offices and salesrooms at Cologne cover a floor space of 40,000 square feet, and including the branches at Brussels, Liege, Paris, Milan, Turin, Barcelona and Bilboa, the firm will have

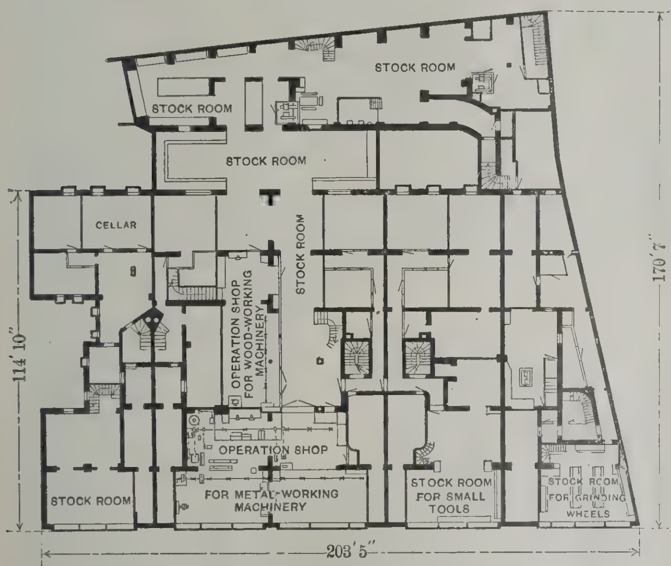


Fig. 1. Plan of Basement, Alfred H. Schutte's Machinery Store at Cologne, Germany.

a floor space of nearly 120,000 square feet after January 1st next, when the new stores under construction at Paris and Milan will be occupied.

The salesrooms at Cologne face one of the large squares in the center of the city, and have a row of show windows 205 feet in length in the handsome building which we illustrate, and which has been especially designed for the use of this firm. These windows permit not only a view of the salesrooms, but of a considerable part of the basement near the street, where metal and woodworking machines of the latest type are being operated under power, and where a plant of pneumatic tools is also shown in operation. The demonstration of machines in operation is found in nearly all of Mr. Schütte's stores and contributes largely to the success of the firm, because European engineers are more likely than our own to insist on seeing a machine in operation before purchasing. These facilities enable the firm to educate their staff of salesmen in the systematic manner characteristic of German methods, and they also contribute to the education of the young mechanical students of Cologne and vicinity.

The arrangement of the small tool department shown in one of the views is both attractive and convenient. Heavy oak is used for the wood work, and all the small tools, such as twist drills, reamers, etc., of which they carry a large stock, are placed behind sliding plate glass windows. One of the salesrooms is used exclusively for the exhibition of grinding wheels, and the writer saw there the largest stock that he had seen anywhere. The showrooms are situated on the ground floor and the operating rooms in the basement, which not only affords excellent light on the machines, but adds a touch of life to the building as the machines are seen in operation through the basement windows, a feature which is seldom found in a machinery salesroom. Facing the square are the private offices with bookkeeping and statistical departments. In the latter department each customer has an account showing the inquiries he made with the results of the offers submitted to him and his purchases, which affords an opportunity for calling the salesmen's attention to customers whose purchases have dropped off in any particular line.

An interesting feature is what might be termed the daily inventory. Every day a list is prepared showing a summarized statement of all the machines in stock in each of the stores of Alfred H. Schütte throughout Europe. At night all the machines sold during the day are checked off from this list and a new one prepared, a copy of which is furnished the next morning to every man who has anything to do with inquiries for machinery or tools. This list enables him to find at a glance whether a certain machine is in stock or not, without going into the stock rooms and referring in each particular case to the keeper of the stock. This feature of the system actually amounts to a daily inventory, but on account of the precision with which the records are kept there is very little delay or unnecessary work connected with the making up of these lists.

The department for correspondence, etc., is located in the rear, and its organization is very thorough and carried out in great detail. There are four different departments having charge of the sale of different kinds of machines and tools, each of which has special engineers at its disposal to push the selling end from both the mechanical and engineering points of view. Statements of sales are made up by every department at the week's end, and naturally each one tries to outdo the other in this friendly competition. In the department which handles automatic machinery is an unusually complete collection of sample pieces that have been made on full and half automatics sold by the firm, with full information regarding the cost of output, material, time required, etc.

One feature which indicates the extent to which the details of organization are carried is worth noting: Each Monday Mr. Schütte has on his desk a brief summary of every letter of importance that has been received or written by all of his houses throughout Europe and the answer thereto, as well as a complete statement of all machines and tools sold and in stock in each branch house during the previous week. These are arranged in the form of a list, and if Mr. Schütte for any reason, desires to follow up the details further he simply marks with a blue pencil the specific letters

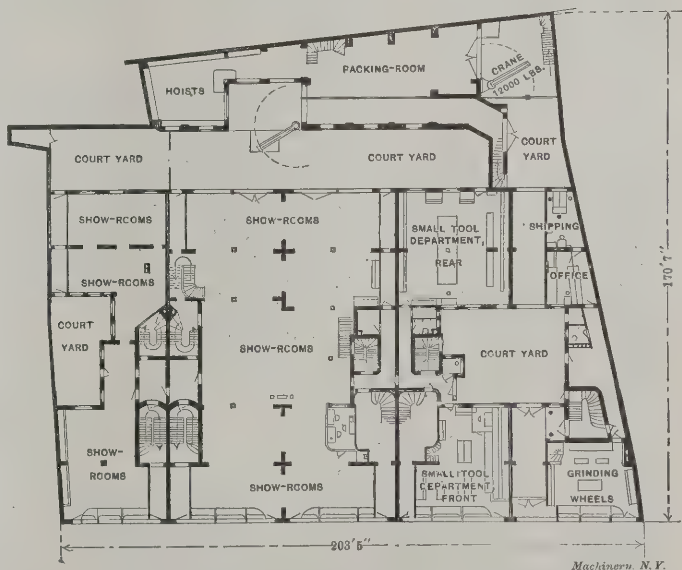

Fig. 2. Plan of Ground Floor, Alfred H. Schutte's Machinery Store at Cologne, Germany.

he desires, and complete copies are brought to him. All that portion of Europe covered by the Schütte organization is regularly visited by a large staff of salesmen reporting to the headquarters for each territory. In this way the entire territory is covered, not only by salesmen, but by specialists connected with important manufacturers whose product the firm sells. The catalogue and advertising work is in charge of engineers with practical experience in those lines.

Separated from the main office, but adjoining Mr. Schütte's private office are the offices of the newly established Asiatic and South American export department, in charge of Mr. T. H. Marburg, who until recently was manager of the New York office, and at the time of the writer's visit was preparing for a trip around the world to cover two years, for the

1. Special Tool Department for Automatic Screw Machines.

8. Grinding Machine Store.
9. Main Machinery Hall, Left Aisle.

purpose of forming new connections and cultivating existing ones.

The organization of the different branches is carried along on similar lines, and a short description of these will doubtless be of interest.

In the small but wealthy industrial country of Belgium the firm employs a staff of thirty-four men. In 1897 a branch was started at Brussels under the management of Mr. A. Ispert, who is a junior partner of the Belgium firm. The gradual increase of business soon made it necessary to abandon the original quarters for larger ones at 5 Vieux-Marche-aux-Grains. In 1903 a sub-branch was established at Liege, the center of the Belgium arms manufacture, and in this branch the firm is doing a good business in small tools. A demonstration room has recently been erected in the rear of the Brussels store in order to improve the existing facilities for showing tools in operation, and including this new addition the firm has now over 12,000 square feet of floor space in the busiest parts of Brussels and Liege at its disposal.

The French establishment of the firm was organized in August, 1903, under the management of Mr. Max Bühling, and although only entering its fourth year is one of the largest dealers in American machine tools in France. The present offices are located near the center of Paris, but owing to the development of business a new building specially adapted to machine tools is now under construction and will be finished by the end of the year. This store will be about four times the size of the present one, covering a floor space of about

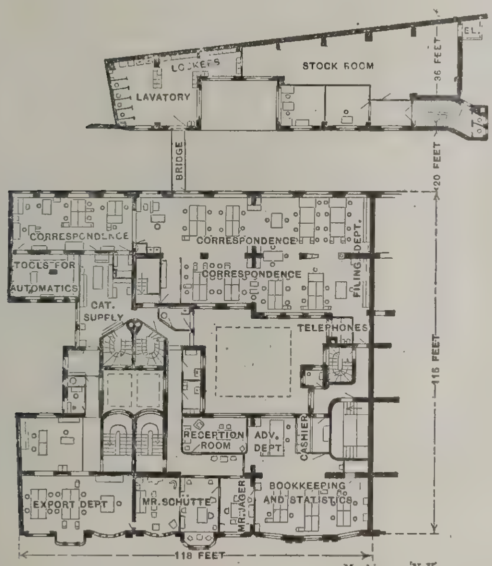

Fig. 3. Plan of Second Floor, Alfred H. Schutte's Machinery Store at Cologne, Germany.

25,000 square feet and will be provided with traveling cranes, etc. The demonstration rooms will be divided into two distinct parts, one for metal-working and the other for woodworking machines, electrically driven by two 30 horsepower motors. The general arrangement of the small tool department at the new store will be similar to the one in the Cologne establishment. The diversity of nationalities found in all of the Schütte houses is most pronounced in Paris, where a staff of forty, composed mainly of Frenchmen and Germans, with some Americans and Englishmen, seems to work in perfect harmony.

The Italian branch was established in Milan in April, 1903, under the management of Mr. H. Wingen, who had previously worked up a connection among the leading Italian manufacturers, notably those in the motor car industry, which has since then developed with great rapidity. The Milan branch was started with twelve employees, but during the past three and a half years the business has increased to such an extent that a force of about sixty is now employed, and a store established at Turin to further facilitate the distribution of goods, as well as a branch office at Genoa to handle machinery arriving from America. New quarters somewhat similar to those in Paris are under construction, which will give the Milan branch a floor space of about 25,000 square feet after January 1, 1907.

Business in Spain has been pushed by the firm for many years, but not until 1903 was a store opened at Bilboa and put in charge of Mr. Max Daunert, formerly manager of the New York office. The machinery industries are developing slowly in Spain, manufacturers there not taking as readily to the better class of tools as in other European countries. Notwithstanding these conditions and the general depression which has prevailed in Spain for the last two years, the firm has started a second store, also under Mr. Daunert's management at Barcelona, and the prospects are good for satisfactory business.

At New York the firm maintains an office in the Havemeyer Building, 26 Cortlandt Street, Mr. F. W. Jaeger, manager, which keeps in close touch with the machinery trade in this country and cares for the shipments to the different branches.

ANNUAL MEETING OF THE A. S. M. E.

The annual meeting of the American Society of Mechanical Engineers will be held in the auditorium of the New York Edison Co., 44 West 27th Street, beginning December 4, and continuing through December 7. Following are the papers:

President's address by Mr. Fred. W. Taylor, Philadelphia, Pa.: "The Art of Cutting Metals."

Report of the Committee on Standard Proportions for Machine Screws.

"The Evolution of Gas Power," by Mr. F. E. Junge, Berlin, Germany.

"Producer Gas Power Plant," by Mr. J. R. Bibbins, Pittsburg, Pa.

"Steam Turbine Characteristics," by Mr. Hans Holzwarth, Hamilton, Ohio.

"A High Duty Air Compressor," by Prof. O. P. Hood, Houghton, Mich.

"Design of an Improved Boiler Setting," by Mr. A. Bement, Chicago, Ill.

"The Steam Plant of the White Motor Car," by Prof. R. C. Carpenter, Ithaca, N. Y.

"Saw-Tooth Roof Construction," by Mr. F. S. Hinds, Boston, Mass.

"Ferroinclave Roof Construction" by Mr. A. E. Brown, Cleveland, Ohio.

"Saw-Tooth Roofs for Factories," by Mr. K. C. Richmond, Providence, R. I.

"Weights and Measures," by Mr. Henry R. Towne, New York.

"Mechanical Engineering Index," by Prof. W. W. Bird and Prof. A. L. Smith, Worcester, Mass.

"Ventilation of Boston Subway," by Mr. H. A. Carson, Boston, Mass.

"Flow of Fluids in Venturi Tubes," by Mr. E. P. Coleman, Buffalo, N. Y.

"Tests of an Elevator Plant," by Mr. A. J. Herschmann, New York.

* * *

The ease with which some inventors are able to induce people of sufficient capital to believe in the possibilities of their inventions has often been referred to. However, our English brethren seem in this respect to excel our own inventors. An English gentleman who lately attended the London Bankruptcy Court and whose liabilities amounted to $75,000, compared with $7,500 assets, stated that his financial difficulties were due to his connection with an inventor who invited him to join in a hydroscope scheme. The hydroscope, he informed the court, was an instrument for searching under the sea for sunken treasures and he was to be reimbursed either from the treasure when discovered, or out of the proceeds to be derived from the sale of the patent to an exploiting company. It is at least to the credit of our English contemporaries that the forming of such a company did not seem to be within the possibilities of the able inventor. We find occasion to recall the incident of the American company which a few years ago was to proceed to procure gold out of sea water.

WILLIAM KENT.

REPRESENTATIVE AMERICAN MECHANICS AND ENGINEERS.

William Kent was born in Philadelphia, March 5, 1851. He was educated in the public schools and graduated from the Central High School of Philadelphia in 1868 with the degree of A.B. The degree of A.M. was conferred in 1873. He was clerk and bookkeeper in a coal shipping house for nearly two years and then was bookkeeper in the Jersey City gas office two and a half years. While there he attended night school in Cooper Union, New York, and graduated with the class of 1872. After graduation he obtained the position of bookkeeper in the Ringwood Iron Works, at Hewitt, N. J., where he had an opportunity to get some practice in engineering and chemistry. The depression in the iron trade following the panic of 1873 caused the shutting down of the blast furnace, and he left at the end of 1874 to enter Stevens Institute of Technology as special student. In June, 1875, he was appointed assistant to Prof. R. H. Thurston in the work of the United States Iron and Steel Testing Board, and under his direction carried on for two years a research on the properties of the alloys of copper and tin, and copper and zinc. He also qualified as regular student in the senior class and graduated in 1876 with the degree of M.E.

In 1877, on the conclusion of the research, he went to Pittsburg to take a position as draftsman with a firm of blast furnace engineers. While in that position he made a trip through the new iron district in the Hocking Valley, Ohio, and wrote an account of the district for the *American Manufacturer* of Pittsburg. This led to his appointment as editor of that paper, which position he held for two years. In the next three years he was engaged in the iron and steel works of Shoenberger & Co., first as general assistant, and later as superintendent of the open hearth steel department. A severe attack of typhoid fever followed by a nervous breakdown led to his resigning his position in 1882 and going to Europe for three months for his health. On his return he opened an office in Pittsburg for the Babcock & Wilcox Co., and introduced that company's boilers in Western Pennsylvania and Eastern Ohio. He also formed a partnership with William F. Zimmerman in the organization of the Pittsburg Testing Laboratory, which was sold three years later to Messrs. Hunt and Clapp. In 1883 he was transferred to the New York office of the Babcock & Wilcox Co. as superintendent of the sales department and engineer of tests. He resigned in 1885 to become the general manager of the Springer Torsion Balance Co. He developed the invention of the balance (a weighing scale with torsional pivots instead of knife edges, used generally in the retail drug trade), and built and equipped a factory in Jersey City for its manufacture. This work occupied him until 1890, when he opened an office in New York as consulting engineer.

For the next thirteen years his work was of the most varied character, including engineering design and construction, engine and boiler testing, expert work in the courts, and literary work. In 1891 he began work on his "Mechanical Engineer's Pocket-Book," which took four years to complete. The book was published in 1895 and immediately was recognized as filling a long-felt want among engineers, draftsmen, machinists and others having to do with mechanical work and design. More than 45,000 copies have been sold at the present time and the sales are increasing from year to year. Prof. Kent is an ardent opponent of the metric system and in speaking against it before the House Coinage Committee of Congress in 1903 he used his experience in the compilation of the pocketbook against the adoption of the metric system in the following effective language (see MACHINERY, May, 1904):

"In 1895 I published a mechanical engineer's pocketbook, of which more than 30,000 copies have been sold. The collection of material for this pocketbook took more or less of my time for twenty years, and the making of the book not less than three years' full time. The things compiled in it involved reference to engineering works, papers and periodicals, some of them dating back at least sixty years. There are 1,100 pages in the book, and each page has about 900 words. The number of figures and formulas in the book, which are based on the English inch, run into more thousands than I would care to figure. The task of getting such a book free from errors is a tremendous one. Over a thousand typographical and other errors have been reported in the last eight years. Mr. John C. Trautwine, Jr., told me some twenty years after his father's civil engineers' pocketbook was first published that he was only then beginning to feel that the book was reasonably free from errors. If my book were translated into the metric system, it would be at least ten years before all the errors in the translation would be rectified. I doubt if the translation could be made without at least five years' hard labor of an expert mathematician."

In 1898 and 1901 he obtained patents on the "Wingwall" smokeless furnace for steam boilers, which is now being introduced in the West by his agents, Power Specialty Co., New York and Chicago. He also patented in 1903 a gas producer for use in connection with gas engines. It involves the principle of getting rid of the tar in the gas by burning all the hydrocarbons in the producer itself by means of air drawn in at the top of the producer. In 1901 he brought out his treatise on "Steam Boiler Economy." In 1895 he became one of the associate editors of *Engineering News*, holding the position until 1903, but in the last four years of that time did only occasional editorial work, on account of the pressure of other work. In 1903 he accepted the position of Dean and Professor of Mechanical Engineering in the L. C. Smith College of Applied Science in Syracuse University, which position he still holds. In 1905 the university conferred on him the degree of Doctor of Science.

Prof. Kent has been a member of the American Institute of Mining Engineers since 1876, and of the American Society of Mechanical Engineers since its organization in 1880. He has been vice-president of that society and last year he was president of the American Society of Heating and Ventilating Engineers and of the Technology Club of Syracuse, N. Y.

Two large chimneys of reinforced concrete are at present being built in England, one with a diameter of 20 feet and a height of 265 feet, and one with a diameter of only 8 feet 6 inches and a height of 245 feet. In this country there are also a few chimneys of similar proportions being built out of reinforced concrete. There are ample indications that concrete is going to replace brick in a large measure in the future, particularly with present high prices of brick. Certain kinds of brick have doubled in price during the last decade.

* * *

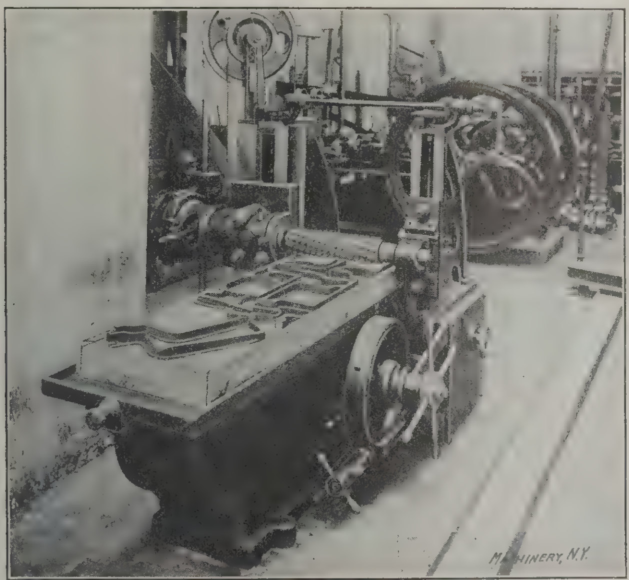
The possibilities which will present themselves in many fields where denatured alcohol can be used are fairly indicated by the low price at which it can be sold when produced on a sufficiently large scale. The present wholesale prices in Germany, where more than 25,000,000 gallons are consumed in a year, are at present 25 to 26 cents a gallon, and the retail prices vary from 27 to 30 cents a gallon.

LETTERS UPON PRACTICAL SUBJECTS.

HOLDING THIN IRREGULAR CASTINGS TO THE PLANER TABLE.

We have seen in your September issue an article "Planing a Small Machine Part." The examples given are very good indeed, but we think that we have something fully as interesting on the same line to put before your readers. The chucks and jigs shown in the article are very expensive; they take up considerable space and in our opinion they do not quite fill the purpose, especially when the castings are very thin. The accompanying halftone shows how we hold thin, irregular castings on the table of the planer or the milling machine. The idea has been carried out by our works manager, Monsieur Tête, and is a development in the manufacture of our pattern plates.

The illustration shows a number of irregular-shaped castings on the table of an Ingersoll milling machine, which we have in our works. When the castings are in place, four boards or planks are put on the four sides of the table and a few pieces of wood in the table holes. Then plaster-of-paris is poured around the castings and allowed to set for a few minutes. By this means the pieces are not only clamped but supported underneath the whole surface, and thus have no



Holding Thin Irregular Castings to the Planer Table.

tendency to spring under the pressure of the cutter. This method when first tried proved a success and since this time all work of a similar character is made in the same way in our works. The method saves a lot of time and is a real economy in the cost of production. We believe that the idea can be extended a great deal and that it will be of benefit to some of your readers. Plaster-of-paris is very cheap and sets in a few minutes. The only drawback to its use is that the table of the machine gets dirty after the plaster has been broken into pieces. PH. BONVILLAIN AND E. RONCERAY.

Paris, France.

FINISHING VALVE SEATS AND CYLINDERS.

There are probably more differences of opinion regarding the proper way to finish valve seats for slide valves in locomotives and boring cylinders than in regard to almost any other parts of the whole locomotive. In most cases the valve seats are planed and scraped and the valves treated in the same way. Scraping seats to a bearing means a lot of work, and unless it is done by a good man it is apt to be worse than when it came off the planer.

Wilson Eddy, whose genius presided over the old Worcester and Springfield road in the late fifties and sixties, and who was a wonderfully sensible railroad man in many ways, used a false valve seat of cast iron about as shown in Fig. 1, and held the whole thing down by the steam chest cover, which was bolted on the outside, as shown by the stud holes. The false seat was more necessary in the days before the portable planer than now, and it was not of this as much as of his way of finishing that I intended to speak. The valve was clamped to the planer with as little strain as possible, to avoid spring when released, and after the roughing cut (if a new valve), the finishing cut was made with a sharp pointed V tool with a fine feed, so as to make a series of fine grooves along the face of valve. The seat was planed in the same way, but with the grooves running the other way, and they

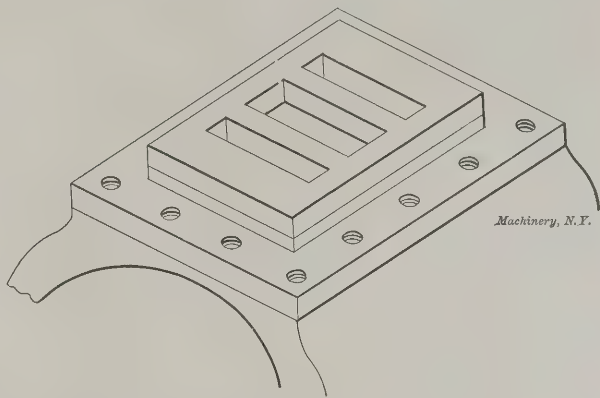


Fig. 1. False Valve Seat for Locomotive Slide Valves.

went into service without having a scraper touching the seat or valve. The grooves held the oil until the tool marks wore out, which happened in a comparatively few miles and the valves never cut. They wore down to a bearing, and made a first-class job in every way. Even with the seats planed by a rotary planer as at present, there should be no trouble about using valves planed in this way and it would at least be worth a trial. Fig. 2 gives an exaggerated idea of the tool marks left on the face of the valve; those in the seat run the other way.

Cylinder boring is another question that is open to discussion. It used to be considered a crime to stop a lathe or boring mill on a cylinder cut until it was through, and some places even go so far as to use emery in the cylinder to polish them and get out the tool marks. I believe the emery is bad in any case and I also question the advisability of trying to get such a smooth cylinder. One of the best engineers I know of, one who has charge of large steam plants and is responsible for their economical performance, never allows a finishing cut to be taken in the cylinders of his engines, either when making them new or when reboring. He prefers to have them just as they come from the roughing tool. They soon wear down to a good bearing, the piston travels too fast to have any leakage past the rings around the bore of the cylinder, and he can always depend on what a cylinder will do in the way of tending to business and not get to cutting. Last but not least, it saves the cost of the finishing cut as well as the time it keeps a locomotive out of service, and this time is quite an item when slowly-working portable boring bars are used so as to facilitate the work. Whether you try the plans or not they are worth thinking over.

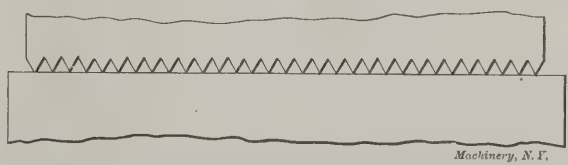

Fig. 2. Exaggerated Appearance of Valve Face.

I. B. RICH.

JACK MAKES A FORMULA.

We were making some rings at our shop, of a section shown in Fig. 1. The fillet was made up of two curves; one had a short radius s and was $\frac{3}{8}$ inch long, while the other radius R had its center $1\frac{1}{2}$ inch from the vertical side, but the length of R was figured out so that we should have a smooth curve

when the two arcs met. Of course the fillet was a tangent to the vertical and horizontal sides.

There were several sizes of rings and we were to make templets for them; so while I was making the first drawing our apprentice, who is just now having a show at drawing, took a sketch of the ring and fillet, and tried to hitch up his correspondence school mathematics to the job of pulling out a formula to give the exact length of R. Jack had to have a little help to get started and then it was just like other algebra examples in his book.

His sketch is shown in Fig. 2, and all the dimensions are letters instead of figures:

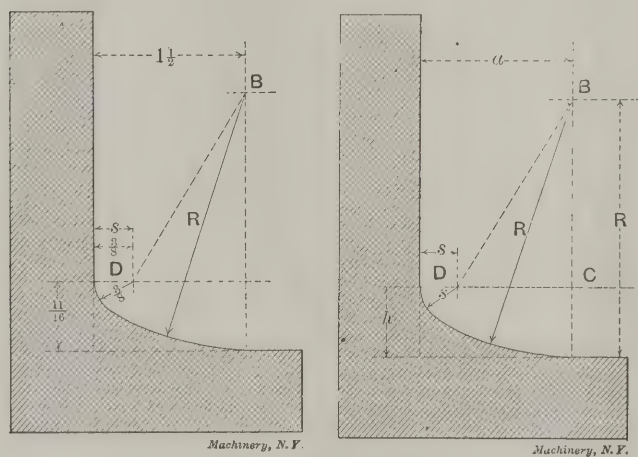
a = distance from vertical wall to center B.
s = distance from vertical wall to center D.
h = distance up from horizontal wall to center D.
R = distance up from horizontal wall to center B.

We know all of these distances except R (see Fig. 2), and if we can make up an equation using these distances we can solve the equation and find the length of R.

Suppose we let R swing up to the line $B\,D$ and at the same time let s swing down till its arc meets the arc made by R. These curves will meet and make a smooth curve for the fillet. Jack says he can prove that by geometry. There is a triangle, $B\,C\,D$ in Fig. 2, with a right angle at C, and we can make up an equation by the aid of this right-angled triangle.

The side $B\,C$ is equal to $R - h$;
The side $C\,D$ is equal to $a - s$;
The side $D\,B$ is equal to $R - s$,

because R and s make a straight line from B through D to the fillet. Now, in every triangle like $B\,C\,D$ the square of the side opposite the right angle is equal to the sum of the squares of the other two sides. Hence Jack wrote his equation as follows:



Figs. 1 and 2. Jack Makes a Formula.

$$(R - s)^2 = (a - s)^2 + (R - h)^2$$

and solved for R as below:

$$R^2 - 2\,R\,s + s^2 = a^2 - 2\,a\,s + s^2 + R^2 - 2\,R\,h + h^2$$
$$R^2 - R^2 + s^2 - s^2 - 2\,R\,s + 2\,R\,h = h^2 + a^2 - 2\,a\,s$$
$$R\,(2\,h - 2\,s) = h^2 + a^2 - 2\,a\,s$$
$$R = \frac{h^2 + a^2 - 2\,a\,s}{2\,h - 2\,s}$$
$$R = \frac{h^2 + (a - 2\,s)\,a}{2\,(h - s)}$$

Jack substituted the dimensions given in Fig. 1 ($a = 1\frac{1}{2}$, or 1.5 inch; h = 11-16, or 0.687 inch; $s = \frac{3}{8}$, or 0.375 inch) in the formula and multiplied, added, etc., as the signs in the formula direct.

$$R = \frac{0.687^2 + (1.5 - 0.75)\,1.5}{2\,(0.687 - 0.375)}$$
$$R = \frac{0.472 + 1.125}{0.624}$$
$$R = \frac{1.597}{0.624} = 2.559, \text{ or } 2\ 9\text{-}16 \text{ inches, very nearly.}$$

Then I set my compasses to Jack's figures and finished the fillet. It was all right. The templet maker has not yet found any trouble with the radius, and Jack is sure the radius R is all right.

If the boys in the shop would try to figure out some problems that come up there, they would get the knack of applying their mathematics to "cold iron." The above has been written to help young men like Jack to use some of the mathematics they have studied.

JACK'S FRIEND.

THE BORING BAR VS. THE FORGED BORING TOOL.

There is scarcely any machine shop operation more tedious and unsatisfactory than that of boring a *long* hole, which is required to be *quite parallel*, with a common forged boring tool. In the best manufacturing shops, suitable drills and reamers are provided for each job, and standard sizes are

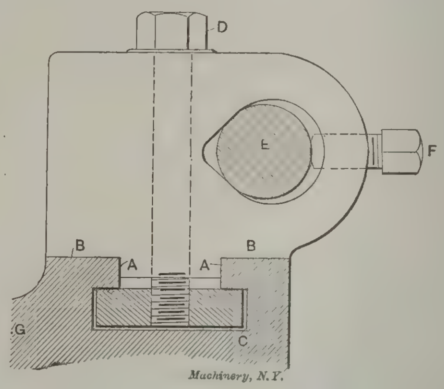


Fig. 1. Boring Tool Holder.

generally used. But in the repair shop and job shop the conditions are quite different. In the very nature of the case such shops cannot have tools exactly suited to every unexpected and nondescriptive job which may be presented. However, some job shops make very little effort to keep up with the times, and their equipment is too much of the scrap-heap order. The writer at this time has in mind one of these back-number institutions. A short time ago Mr. A. brought to the shop in question a job of boring which was wanted in a hurry. Well, he did not get it in a hurry; and when the bill was presented the charges were so much beyond what Mr. A. had expected that he consulted the writer as to how it was possible to put in so much time on the work. The latter consisted in enlarging the bore of a device which was sold on a very small margin. When the job shop got the work done there was no margin at all. Now, there had apparently been no dishonesty as to the time charged. It was difficult to true up the work in the "rickety" old chuck, and it took a long

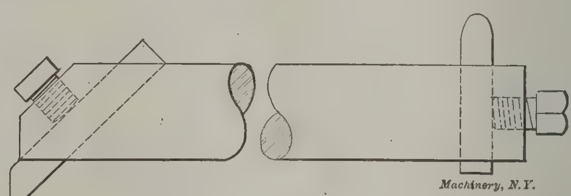

Fig. 2. Boring Bar with Cutters Inserted.

time to bore it, because the only long tool available was by far too slender and "springy." Mr. A paid the bill, but declared he would never take another job to that shop. The job shop man presumably means to be honest, but the writer fails to see how one can be strictly conscientious who *regularly* uses time-wasting tools and charges the full price for the time so wasted. However, the job shop proprietor did not see the matter in that light.

There have been various designs of boring tool holders described in the mechanical papers. The best of these require a different bushing for each size of bar; but such as have been made by the writer need no bushings. Fig. 1 shows an end view of a device which costs very little to make, and which works very well. This was designed for a young machinist who has a small shop with no other machine tools than a lathe

and a drill press; and he wanted to avoid the expense of having his casting planed, or of milling it at a disadvantage in his lathe. Under these circumstances the pattern, which was in one piece without core prints, was made so close to size that it required but a few minutes chipping and filing on the sides *A* of the tongue, and on the flats *B*, to make the casting fit the slot of the tool rest *G*. The part *C* in the sketch was simply a piece of flat bar stock equal in length to the slot, and tapped for two screws *D*. The bar, a section of which is shown at *E*, is held by two setscrews *F* as indicated. As to the construction of the bars, these were also made, or at least could have been made, with small expense. While a turned tool steel bar might be desirable, simple cold-rolled steel, or rough machine steel will answer fairly well. The cutters may be round bar steel (no turning is needed) held in a drilled hole by set screws. Fig. 2 shows such a bar with a cutter at each end. Three or four different sizes of these bars will answer for a wide range of work. Now, is there any excuse for the job shop being without such an outfit as this? In the long run, far more time is wasted in using inefficient boring tools, and in redressing old ones, than would be required to make the tools here described.

Having tools somewhat similar to the foregoing, the writer once wanted to bore a hole which was too long for any bar on hand. It was a simple matter to select from the stock of steel the shortest piece of the right diameter, and drill it for cutters and set screws. This was accomplished in less time than would have been required to forge a new tool. As the bar was only about three feet long it was retained for emergencies; but obviously it could have been cut up and used for any other purpose. This case suggests the expediency of making the bars amply long in the first place. A long bar does not need to project from the clamping fixture any further than necessary for the job on hand. Not so with the old-fashioned boring tool. If that be made extra long it cannot advantageously be used with shorter projection.

One of the strongest points in favor of the boring tools here advocated is yet to be discussed. This feature can best be described by referring again to the foregoing example in which the long bar was employed. In this case a long parallel hole of a size different from any available reamer was wanted. Having rough bored the hole to within about 1-64 inch of the final diameter, a double-pointed cutter was made from bar stock. With this, one cut was taken through the hole, when it was found to be entirely satisfactory. It will be understood that the advantage of the double-ended cutter lies in the support that one point furnishes for the opposite cutting point. This bracing effect tends toward parallelism of the cut, and such an arrangement may take the place of a reamer in emergencies. To get the best results with a double cutter, its ends should be turned in the lathe while the cutter is secured in its bar. For this purpose one end of the bar may be held in a chuck, the other end being supported in a steady-rest placed near the cutter. After being turned, the cutter is, of course, backed off and tempered. In this connection it should be remembered that a minimum of clearance should be filed on the heel of the cutter, otherwise chattering will result. The apparatus described (cutters excepted) may be used for polishing a bored hole, or for slightly enlarging it at any point where the gage may fit a little too snugly. For this work secure a short leather sleeve around the bar at one end, and glue emery cloth to the leather. The bar while clamped in the fixture may be fed through the hole by the regular carriage feed mechanism. Slightly revolving the bar will give new contact of the emery cloth.

The machinist for whom the fixture shown in Fig. 1 was designed requested the writer to show him how to make a rig for grinding in the lathe. For this purpose a cylindrical piece of cast iron was drilled lengthwise and babbitted to fit a small emery-wheel spindle. The cast iron was then turned on the outside to slip in the boring fixture; and thus the latter was used both for holding boring bars and for holding the bearing for the emery-wheel spindle. This rig, which was driven from an overhead drum, answered for grinding the 60-degree centers (the compound rest being swiveled for this) as well as for parallel shafts.

W. S. LEONARD.

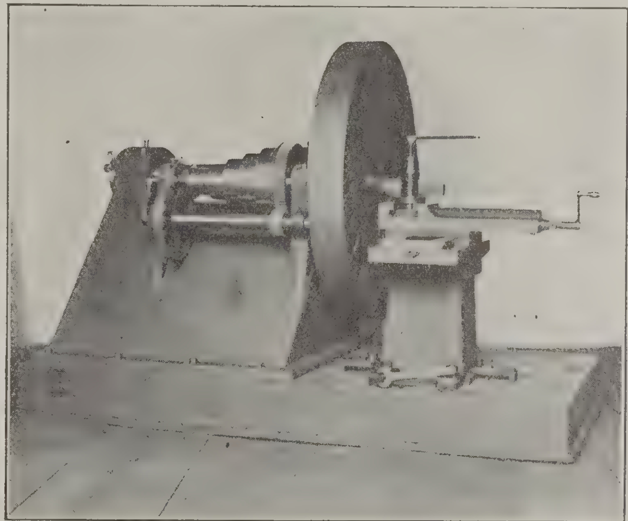
Lansing, Mich.

FACING LATHE OF UNUSUAL DESIGN.

The accompanying cut shows a machine, only one of which has ever been built so far as the writer knows, but the principle of which could be used for many special needs. It was built for work of from, say, 20 inches to 60 inches diameter to be fastened to the faceplate. It has feeds in all directions by means of an overhead rocking shaft, not shown. A hook will be noticed at the left-hand end of the spindle. This swivels on a bolt which can be moved across the spindle on a plate on the end of the spindle with a T-slot. To this hook is attached a chain which leads to one arm of the overhead rocking shaft and gives it a greater or less motion, according to the distance of the hook from the center line of the spindle. Near the other end of the rocking shaft is an adjustable arm which carries a chain which leads to a ratchet wrench which could be put either on the cross feed or the longitudinal feed-screw. With two holes in the ratchet lever, and the adjustment on the end of the spindle any feed from one tooth to five, or a range of from 0.02 inch to 0.1 inch could be obtained.

The way in which we happened to get the order for this machine was rather odd. One day an inquiry came from one of the numerous export agents in New York for a facing lathe to swing 50 inches, bid to be accompanied by drawings.

This inquiry came from a house which, so far as we knew, did not make a specialty of machine tools, and from such houses freak inquiries are common. I wrote and quoted on



Facing Lathe of Unusual Design.

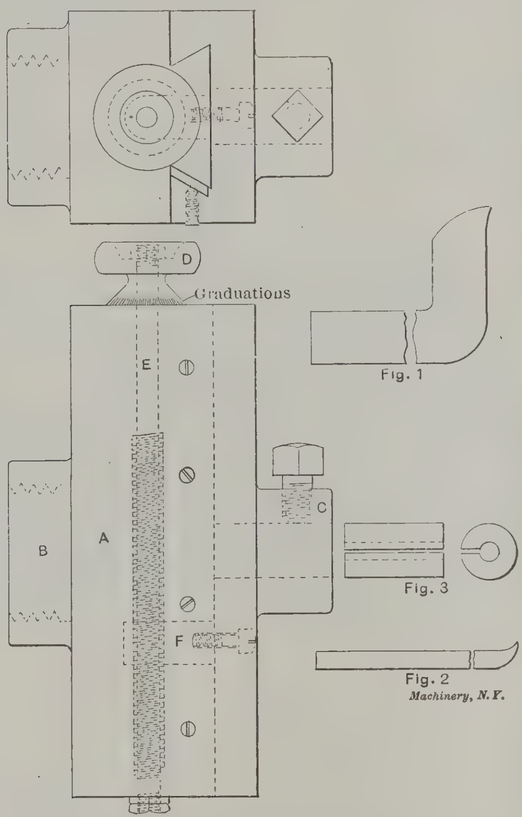
a full lathe with short bed. We received a letter back saying that price was what counted, and that only certain requirements were to be met, and asking for a revision of the bid. The idea came to me that we could build such a machine as shown in the cut. Consequently I made a bond-paper drawing fairly well to scale, but with only the principal dimensions of the bed and headstocks, and by that time I was tired of the job. I had not the slightest suspicion that an order would result, so I cut out a picture of a tool rest for a locomotive tire turning lathe from a catalogue and pinned it to a blueprint of the bed and head, added a hundred dollars to what I thought would be a fair price, and sent in the bid without a further thought. Three or four months later I was astounded to get an order as "per blueprint and specifications" for one of these machines to go to Vladivostock, Siberia. I chased up the drawing which I found I had used to scribble on, cleaned it up, put on a few more dimensions, and started in to see how we could get out of making a full set of patterns. We made a frame for the base with the molding around the bottom and let the foundry strike off the inside. Then we took core boxes that were used to take out the inside of a radial drill base and spliced up the sides two inches to fit. These cores hung over the edges of the drag and formed core and cope as well. The head itself was hastily framed up of ⅞-inch material to form its own core. The boxes for the main spindle were cast for babbitt. The bearings in front were set up for an 18-inch head cone and back gears. The spindle was of cast iron, 9 inches diameter front bearing. To

the spindle was keyed a 36-inch lathe faceplate with internal gear, but the faceplate was made 50 inches in diameter by casting on a false rim. This was swept up in the sand, and tightened by overhanging cores which framed both core and cope again. The spindle which ran through the cone pulley carried a driving pinion of steel to mesh with a cut internal gear on the faceplate. The tool rest demanded all new patterns except the top slide, which we took from a 36-inch lathe. The machine when ready proved to be just about what was wanted. It "growled" a good deal on high speeds, but on the size work called for it ran quiet enough. Except for the ratchet feed seeming a little crude, it was the equal, for work within its range, of the lathe on which we first quoted at a price three times as high, but with less than twice the profit in it for us. E. H. Fish.

Worcester, Mass.

BORING TOOL-HOLDER FOR MILLING MACHINE OR LATHE.

The sketch shows a fixture to be screwed onto the spindle of a milling machine or lathe for boring holes in work fastened to the milling machine table or to the carriage or cross-slide of a lathe. For boring holes in jigs and fixtures where the holes have to be exactly certain distances apart, either



Adjustable Boring Tool-holder.

in a vertical or horizontal plane, the fixture, if used on the milling machine, is a very serviceable tool. The fixture is screwed onto the machine spindle at *B* and when a tool is clamped in the tool-holder, *C*, the fixture is ready for use.

The knurled knob *D* turns the screw *E*, which works in the nut *F*, and causes the tool to move to bore a hole larger, or to be drawn back for a smaller hole.

In case of wanting to use the fixture on a machine which has a different thread on the spindle than the fixture, a taper plug can be made which fits the taper hole in the spindle and is threaded on the other end to fit the thread in the fixture. This particular fixture can be used for holes from ¼ inch diameter up to 6 or 8 inches diameter and 6 or 8 inches deep. For large holes, the tool is made of stock the size of the hole in *C*, and for small holes the tool can be made of smaller stock, and a split bushing made to fit the hole in *C* on the outside diameter, and the hole in the bushing to fit the tool. For large holes, the tool should be bent to a right angle, so that the tool-holder *C* will not have to be adjusted too far out. The adjusting knob *D* should be graduated in thousandths inch as shown in the sketch to provide for accurate adjustment of the tool. The fixture is fitted with gib and screws for the tool slide.

To get holes bored accurately certain distances apart in the milling machine, the holes are first drilled with a smaller sized drill than the finished size, and then the boring tool is used in the fixture, feeding the table along according to the graduated collar on the feed screw. The holes can then be bored very accurately. The roughing drill can be held in a split bushing, fitting the hole in the fixture. This fixture is used in the tool department of the Cadillac Motor Car Co.

Referring to the sketch, Fig. 1 is a heavy tool for large holes, Fig. 2 is a tool for small holes, and Fig. 3 is the bushing for the small tool. C. J. S.

TIME SAVING IN THE DRAFTING ROOM.

Under this heading in the August issue of Machinery Mr. F. R. Steuart recommends for quick duplicating of sketches a tracing in soft lead pencil. I believe my method is better than his, as it does away with any kind of tracing, pen or pencil, for sketches or for drawings. I have made short cuts and labor-saving dodges a close study for years, for the draftsman's work often comes in on the feast-or-famine plan, and there are times when a great volume of work must be rushed through quickly and accurately, though not necessarily with much neatness or finish. With the exception of drawings that must be repeatedly and frequently blueprinted, I make no tracings. Such as I make are made largely for the reason that they blueprint more rapidly and wear better. If the original drawing were used to blueprint from too often it would soon become worn out and unfit to make another copy from without much labor. So, for standard erecting plans, etc., I make tracings on cloth and keep the original carefully, though in the course of years it is likely to need alterations.

I use a smooth and semi-transparent drawing paper from which I can get a first-class blueprint in about two and one-fourth times the number of minutes required for tracing on cloth. The drawing is laid out in pencil, then the useless lines wiped off with a piece of "artgum," which is about halfway between stale bread and velvet rubber in its cleansing properties. It leaves the surface in good shape for inking, and when the drawing is inked it is done. There is no tracing to be made.

For sketching, I have two methods of duplicating, and which one is used depends generally upon the number of duplicates required. In case but one or two are needed, I make the sketch on fairly heavy cross-section paper with "Mephisto" colored copying pencils. The original sketch goes into the shop in this case, after being copied in an ordinary letter book with moistened pads. A second copy can be made on a loose sheet to send off in a letter if needed, but in case a second shop drawing is likely to be needed later I use the other method. This consists of a sketch made on thin cross-section paper with a stylographic pen loaded with Higgins' Eternal ink. This ink has sufficient body to yield a fair blueprint, though it is not thick enough to clog the stylo. If a more elaborate thing is required than a rough free-hand sketch, I lay it off in pencil and then go over the straight lines with the stylo, and the circles and arcs with the regular bow-pen or compass, which is much easier than trying to follow a true curved line with the stylo held in the hand.

From these stylo sketches a very good blueprint can be made, and working drawings put in shape for the shop in a very short time. The sketches are filed in indexed envelopes, and the copybook sketches in colored pencil are all indexed in the back of the book, so in either case it is not much of a job to locate an old sketch.

While I believe in making drawings and sketches fairly complete as to minor details, at the same time I think a liberal use of the English language legibly written on the same sheet with the sketch goes a long way to prevent misunderstandings. If draftsmen themselves cannot all agree as to what a certain view of a drawing really represents (and such cases have been spoken of more or less in the technical papers) is it any wonder the man in the shop sometimes has to scratch his head more than twice to see things as the

draftsman wants him to? Of course a written direction can sometimes be read differently by two men, each giving it a meaning of his own, but if the sentences are clear and concise, as all technical writing should be, there is not much chance for trouble here.

I believe in using just as many short cuts in the drafting room, and in the machine shop, too, as is consistent with good work and freedom from misunderstanding and mistakes. The drafting room is a mighty poor place to save time in when the saving is done at the expense of clearness and certainty, but as it is results that count, and not methods alone, any short cut that eliminates what is actually useless work should be given a fair trial. It may work in some cases and not in others, for the different classes of work, workmen, and shops must be taken into account. There are few good things that are of universal application, and drafting room practice must be, in a degree at least, adapted to the particular needs of the case in hand. In some shops it might be best to show each and every detail of a piece on the sketch and do away with all written explanations and additions, but I find written notes very helpful in most cases.

Drafting, like mathematics, is only a means to an end, and a man who makes his drawings as if they were the goal instead of a part of the course is likely to put a pile of work into them which is really useless. The sun may always shine from the upper left-hand corner at the Patent Office, and shade lines are well worth all the extra time they take on a good many jobs, but a fair amount of common sense is better than too many rules and regulations in a drafting room as well as outside of it. E. R. PLAISTED.

Montpelier, Vt.

OLD EUCLID IS ALL RIGHT.

In regard to the article "Old Euclid Disproved at Last" published in the November issue allow me to say that the drawing is distorted. With the angle ABD as nearly 90 degrees as it is shown, the perpendicular HG would be so nearly parallel with EF that the intersection of the two would be removed nearly at an infinite distance. Line BD if produced would then intersect EF long before HG reached it. Therefore the triangle DBK is impossible. Old Euclid is perfectly able to take care of himself even if he has been dead so many many years, but it is a good catch all the same.

Buffalo, N. Y. GEO. B. SNOW.

OLD EUCLID DEFENDED.

In the November issue of MACHINERY "R. S." gives a remarkable proof (?) that Euclid made a mistake. In a case of this kind I think it is as bad to make a misleading drawing as to make a misleading statement. R. S. proved (?) that although the sides of one triangle are each equal to each of the sides of another triangle the angles were not of neces-

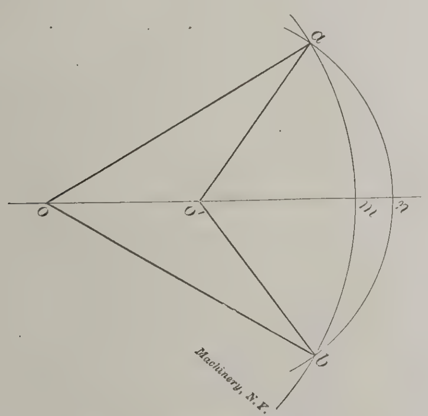


Fig. 1. Old Euclid Defended

sity equal. If his figure had been drawn correctly K would have been far enough away that DK would fall outside of point B. The above letters refer to his figure.

In Fig. 1 let amb and anb be the arcs of circles with centers at o and o'. From the definition of a circle o and o' must be equidistant from the points a and b. It is then easily proved that o and o' lie on the bisecting line of the angle $ao'b$ and aob, which statement must be true of any two arcs of circles intersecting in two points.

In Fig. 2 draw EE' (indefinite length) and AEB and $LE'C$ so that EE' is the perpendicular bisector of AEB and $LE'C$. Draw $BD = LB = AC$ so that angle DBA is larger than a right angle. Draw DC and erect a perpendicular at middle point H. EE' and HK intersect at K.

$CK = LK$, and $DK = CK$, as any point on a perpendicular bisector of a line is equidistant from the extremities; then

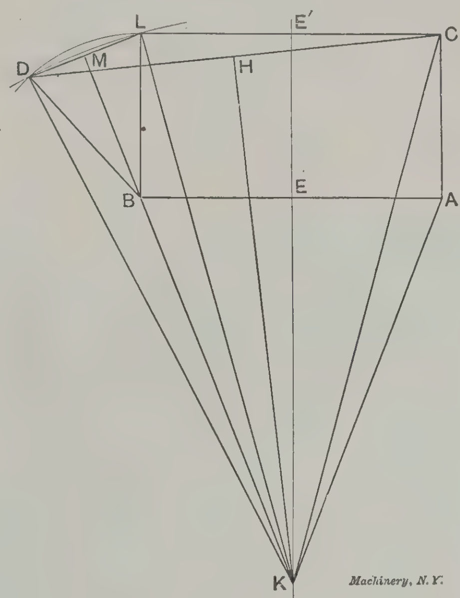

Fig. 2. Old Euclid Defended.

$DK = LK$ and an arc can be drawn through L and D with K as a center and also an arc through either L and D with B as a center. According to our proof in Fig. 1, B and K then lie on the line bisecting the angles DBL and DKL. It is then evident that the line combining D and K falls outside of the point B considered in relation to point A, and the whole proof in the "R. S." article becomes a nonentity. If this is not enough to convince "R. S.," who seems to be an extraordinary individual, the proof can be elaborated still further. The proposition reminds me of one I saw some time ago where a square 8 inches on a side was so cut and pieced together that it appeared to be 5 x 13 inches or one square inch larger than the square 8 x 8. Of course on close examination the fallacy of this was very apparent.

O. R. McB.

[Communications from readers upholding Old Euclid have also been received from E. A. Johnson, Hartford, Conn.; F. W. Barrows, Bridgeport, Conn.; C. J. Stuart, Montreal, Canada; W. L. Miller, Wellsville, Ohio; Arthur C. Garrecht, Easton, Pa.; Robert Cramer, St. Louis, Mo.; A. F. Sharp, Williamsport, Pa, and G. F. Key, Alpena, Mich. Their rigid stand on the question will undoubtedly convince "R. S." that there is no hope for the Nobel prize this year.—EDITOR.]

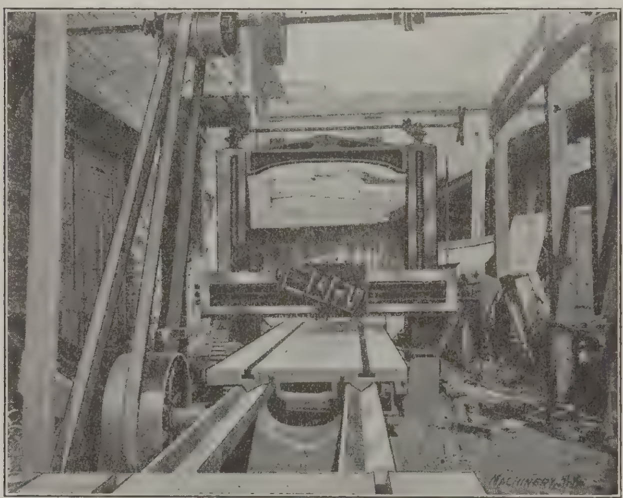
A MACHINIST'S CHRISTMAS PRESENT.

No matter whether we are running but a lathe or a whole shop, the question of Christmas presents presents itself to us with clock-like regularity. The great question of what to give *him* or *her* is before us. One might think that a machinist of all people concerned must buy his presents already made up, *i. e.*, that he cannot make anything worth while in the gift line. This is of course a great mistake, as any machinist who is good with the file can fashion watch charms galore, in different patterns from an anvil to a miniature locomotive. These would of course only apply to Harry and Fred, but if Eva is introduced, the patterns must be enlarged to the paper weight size. A very nice pin can be made by drilling and filing out the metal between the rim and head in a dime, leaving enough at top and bottom to hold it securely, then get some plating company to gold plate either the rim or the head (not both) for twenty-five cents, and add a safety pin to the back, completing as pretty a pin as any girl could wish for if the work has been carefully done. Of

course needle files are required to get into small corners. The operation might be reversed, and the head filed completely out, covering the back with a thin sheet of gold metal, which would make a very odd pin. Personally I prize a gift which has occupied the time and thought of the donor much above the "boughten" kind, and I feel sure that others share this feeling. W. L. McL.

AN OLD PLANER.

The accompanying halftone is made from a photograph of an old planer which is still capable of turning out a certain class of work, not requiring any great degree of accuracy. This latter statement is not to be wondered at when we consider that for over twenty years it has been in the great outdoor world beside the shop from which it receives its power. The bed of this planer is 45 feet long and it enjoys the dis-



An Old Planer.

tinction of having two tables, which can be used either singly or together, two in one as it were. The two bolts for coupling the tables can be seen in the picture projecting from the end of one table; the camera is on the other, the end of which is shown in the foreground. At one time the machine could boast of two heads, the connections for which can be seen at the right of the cross rail, but doubtless one of the operators wearied of thawing out any more parts than necessary to get the planer going after a snow storm and threw it off. The maker of this machine does not have to explain to a prospective purchaser that it is "full geared," a glance to the left between the pulleys and table will convince one of this fact.

The machine was built in England many years ago, and while being lowered into the vessel's hold for transportation had a foot knocked off. When it arrived here the buyer refused to take it, and told the steamship company to either get it fixed or give him the price of the machine. Not knowing what an easy matter the repair was, they quietly handed over the full price, and charged no freight upon delivering it to him, thus the lucky gentleman got it for the cost of the repair which would be dear at ten dollars. Should anyone coming around that shop inquire as to "what *it* is doing out there?" he will be at once enlightened by one of the boys, "Oh we keep that for planing up the weather." NEBALCM.

THE VALUE OF PROPER HARDENING.

The more I see of shop practice, the more I am convinced that few of us appreciate the value of properly hardened steel for tools and other purposes. My first recollections of early hardening operations show a small portable forge in which the fire pot was so small that air blasts must have hit the steel half the time and been responsible for many of the cracks that seemed mysterious at the time. Then too, I recall the warping of reamers and similar work, which had to be ground after hardening; taps that came out of the hardening water with numerous teeth missing, and milling cutters which looked as though a cyclone had struck them.

From what I now know, I believe most of these trials and tribulations could have been prevented if I had known of Mr. Markham's method of pack hardening. It is needless to say many dollars would have been saved my employer. Nor is this all; we are looking for steel that can cut 1,187 feet (more or less) a minute on rough work, but we lose sight of the fact that much of our work does not come under this head. This includes milling cutters both rotary and hollow, taps and dies and similar tools. They may come out of the bath whole and in good condition, but their cutting capacity is often below par. This may mean that a thousand-dollar milling machine is turning out a third less work than it should, and that it must be stopped entirely too often for grinding the cutters. This is by no means an exaggerated case, as there are numerous instances where a steel expert has greatly increased the amount of work by a proper hardening of the tools, and this with the same steel as before, or in some cases even a cheaper grade. Data on the subject of tool and cutting speed, that is, data which can be used as a guide in the average shop, is decidedly scarce.

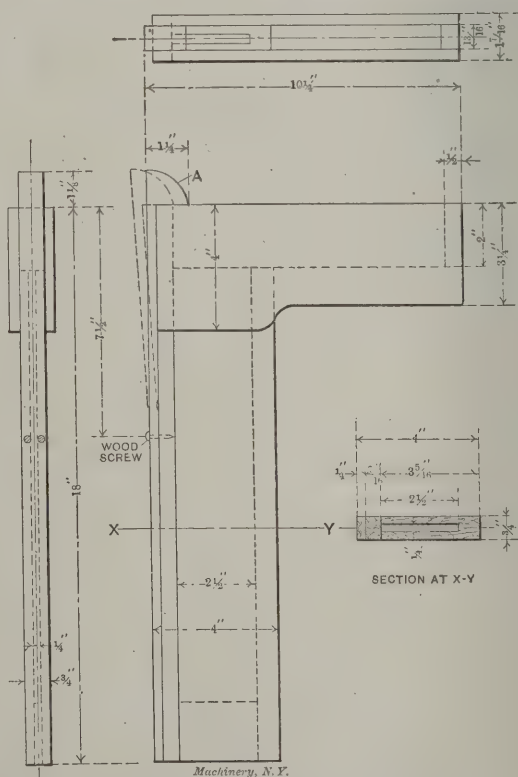
Some shops try to raise the speed themselves until the maximum is reached, which means that some cutters must be tested to destruction. In any large or even moderate-sized shop, it would probably pay to pick out a bright hardener and make it his duty to try to improve the working capacity of the tools. It does not pay to let a high-priced machine jog along all on account of a tool not worth over one per cent as much.

Then there is another side. It is the hardening, or perhaps, only casehardening of thin pieces which must be straight and true. If they warp, it's either a case of throwing away or spending time and money in straightening. Either way it is a loss which can be avoided if we just know how, and when we know that it is possible to prevent it, the sooner we do it the better. FRED H. COLVIN.

New York.

CASE FOR HOLDING AND PROTECTING LARGE SQUARES.

The accompanying cut shows a neat case for holding and protecting large squares when they are not in use in the machine shop. Machinists who have worked in various shops in the country claim it to be the best square case they have



Case for Holding and Protecting Large Squares.

seen. In the shop the case gets rough usage, but I have never heard of the latch permitting the square to fall out. The latch *A* is sprung back with the fingers when placing the square in or removing it from the case. The dotted lines

show the latch sprung back. All parts are firmly glued and the latch is fastened at a point about 7½ inches from the top with two small wood screws, preventing the same from being pulled off when it is sprung back. E. C. F.

BALL AND ROLLER BEARINGS.

George Le Guern.

The accompanying chart shows the result of experiments made in recent years by different firms on ball and roller bearings, from which experiments I have worked out the formulas and drawn curves. These formulas and curves are made for "safe working loads" for one ball and roller, which I think is the simplest and most practical way for the use of engineers and draftsmen. The matter is self-explanatory except it may be in regard to "three points ball bearings" where I have drawn the line MN parallel to line CAB, which not only assures a perfect radial contact between the three points, but prevents the balls from running over the lower path and does away with sliding between the top of the ball and the path.

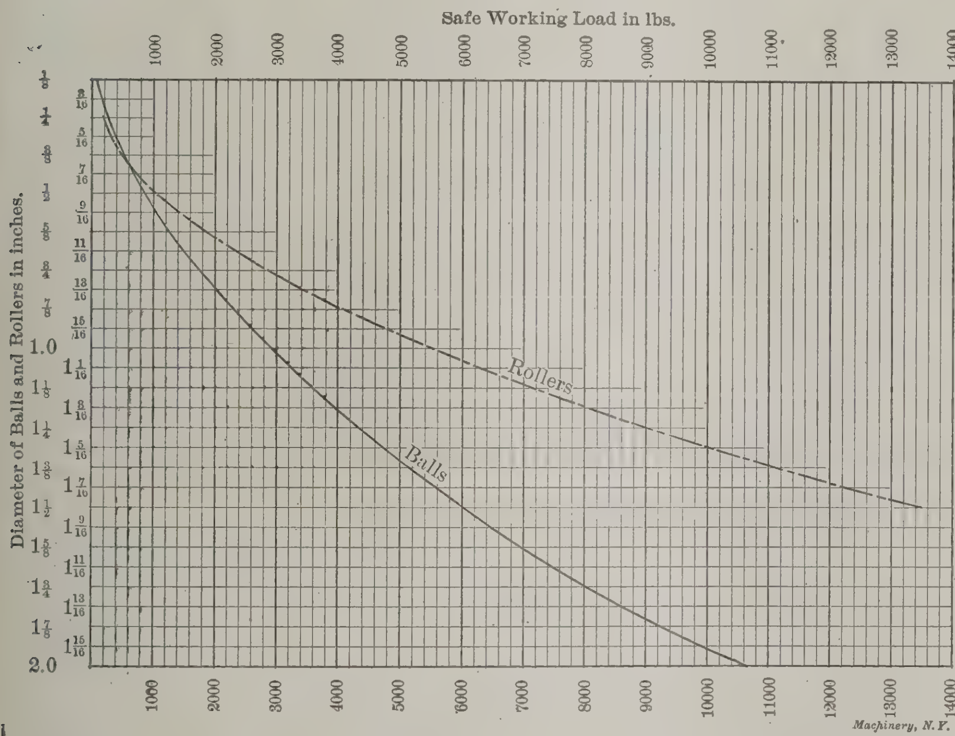


Fig 1. Chart giving Safe Working Load in Pounds for Single Ball and Roller.

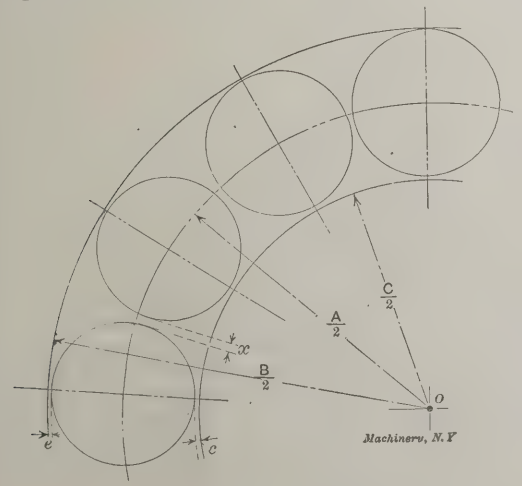

Fig. 2. Two-points Ball Bearing.

Formulas for ball bearing:

$D =$ diameter of ball

$N =$ number of balls.

Safe working load $= (D \times 10)^2 \times 31$

for balls up to 1 inch diameter, and

Safe working load $= (D \times 10)^2 \times 26.5$

for balls from 1 inch to 2 inches diameter.

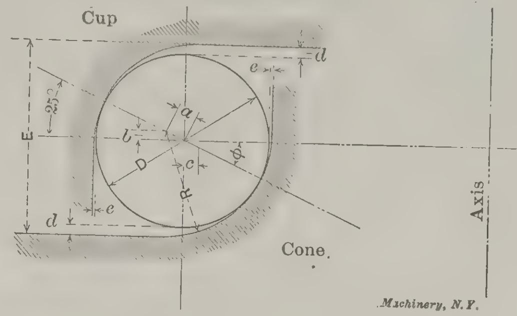

Fig 3. Two-points Ball Bearing.

Two points ball bearings: (Figs. 2 and 3.)

$x =$ clearance $= 0.003$

$a = 0.03125$

$b = a \sin 25° = 0.0132$

$c = a \cos 25° = 0.0283$

$$d = R - \frac{D}{2} - b = 0.018$$

$$e = R - \left(\frac{D}{2} + c\right) = 0.0029$$

$$A = \frac{D + x}{\sin \frac{180°}{N}}$$

$B = A + D + 2e$

$C = A - (D + 2e)$

$E = D + 2d$

$$R = \frac{D}{2} + 0.03125$$

Angle ϕ is figured at 25 degrees, which is good for general use. Where there is a great end thrust, angle ϕ is best made 30 to 45 degrees.

Three-points ball bearing: (Fig. 4.)

Make MN parallel to CAB.

Four-points roller bearing:

The upper part must be made same as the lower parts.

Formula for roller bearing:

Safe working load

$= [(D + k) \times 10]^2 \times 14$

where $D =$ diam. of roller in inches,

$k =$ term of an arithmetical progression, beginning at 0.1 for a roller ¼-inch diameter and having

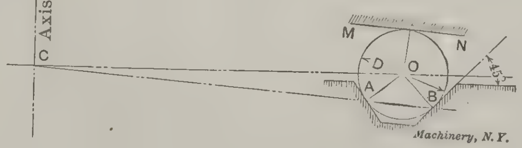

Fig. 4 Three-points Ball Bearing.

0.075 for a common difference, when the diameters of the rollers increase by 1-16 inch. Values of coefficient k for a number of diameters are as follows:

Diameter	Coefficient k	Diameter.	Coefficient k	Diameter.	Coefficient k
1/4	0.1	11/16	0.625	1 1/8	1.15
5/16	0.175	3/4	0.7	1 3/16	1.225
3/8	0.25	13/16	0.775	1 1/4	1.3
7/16	0.325	7/8	0.85	1 5/16	1.375
1/2	0.4	15/16	0.925	1 3/8	1.45
9/16	0.475	1	1.0	1 7/16	1.525
5/8	0.55	1 1/16	1.075	1 1/2	1.6

Washington, D. C. GEORGE LE GUERN.

A MARINE REPAIR JOB.

I wish to give some particulars of a marine repair job which may be interesting to a few of your readers. The high-pressure cylinder had broken at the top, a piece about 15 inches long and 5 inches deep being broken out and the cylinder wall fractured from one end of the break downward about 20 inches; the cover was also broken—leaving the flange on the studs.

The old liner, which extended up to the bottom of the steam port, was removed and a new one cast, being made the full length of the cylinder, with a flange at the top, as shown in

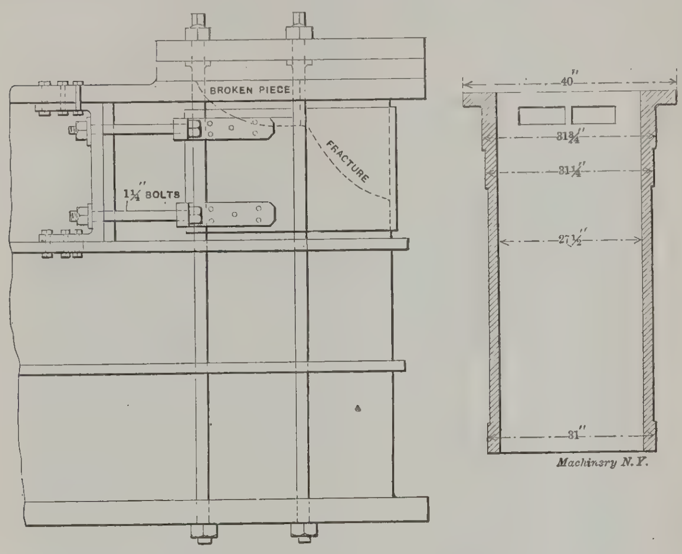

Fig. 1. General View of Repair Job and Section of Liner.

Fig. 1. New studs were made having a collar, as shown in Fig. 2, for which a corresponding counterbore was made in the stud holes in the liner. A square was left on the end of the studs, thus enabling them to be screwed tightly into the liner steam-tight, as the pressure carried was 200 pounds, liner and that of the cylinder. The liner was shrunk in, the cylinder being heated with steam. It was necessary to have the liner steam tight, as the pressure carried was 200 pounds, and if any leakage had occurred the broken wall of the cylinder would have had to bear the full pressure with obvious results. Above the top of the steam port the liner had only 2 inches of bearing surface, and as this was not considered sufficient to insure a good joint, two ¾ holes were drilled 2½ inches from each end of the port downward 1½ inch below the bottom of the port, a depth of 10 inches. Two copper dowels were then driven in tight and "staved up," so as to prevent any escaping steam from leaking round the fillet to the broken part.

In order to take the strain off the cover studs from the broken piece, two long bolts were used, one at each end of

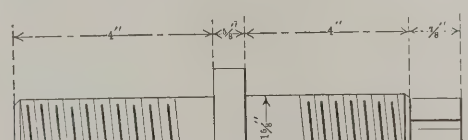

Fig. 2. Stud Provided with Collar for Fastening Liner

the break. They extended down through the bottom flange of the cylinder with nuts at each end and provided with a collar, the same as the studs. Two ⅞-inch studs were put through the broken piece and screwed into the liner, drawing the broken piece slightly up to the liner. A band made of 7/16 steel, 21½ inches wide, was placed round the top part of the cylinder and drawn tightly together by two 1¼ bolts, as shown in Fig. 1, the lugs on one side being bolted to the flange on the top and to a rib on the bottom. The job gave entire satisfaction and saved the large expense of making a new cylinder, which was first intended, not to speak of the delay to the steamer which that would have necessitated.

"PROPELLOR."

A FEW "WRINKLES."

It is a mistake to suppose that "wrinkles" and methods already known, perhaps, to "old hands" or specialists, are without interest or value to the readers of engineering journals. Recruits are constantly being enrolled both in the engineering and machinists' trade, and also in the company of those who believe such journals instrumental in broadening their outlook on their vocation. Therefore I do not apologize for presenting the following matter, each item mentioned in which has been personally tested, if not actually originated, by me.

Collars of wrought or gray iron or steel, the bore of which from any cause has worn too large, or which on new work has been bored a "shade" too large, may often be made serviceable again by heating to red heat and allowing to cool slowly, repeating this process several times. It is really surprising sometimes to what an extent the bore may be reduced by this means. This feature has often to be taken into account in the design of steam boiler and other furnace grates, as the firebars, etc., "grow" in length or bulk by repeated heating and cooling, especially when fires are regularly banked.

The profitable all-round utility of bright drawn, round machinery steel (cold-rolled steel) is somewhat limited by the fact that it is generally supplied in sizes suitable for *revolving* in standard-sized holes. If a gear, collar, cam, or analogous article is desired to fit tightly, it must be bored smaller than standard size, which is an unprofitable process. This drawback may be completely removed by knurling with, say, a Pratt & Whitney knurling tool the part of the shaft or spindle where the tight fit is required, any degree of tightness of fit being easily obtainable. Oil should be used when pressing the article on the shaft or spindle. The appearance of the knurled part is not at all unpleasing. Another advantage of this method is that collars, gears, etc., which require fastening by taper pins at definite distances from each other—and still must be easily removable—may be tightly held while being drilled and reamed, and afterward the knurled portion of the shaft may be eased to give the exact push fit required. This is no "botch" job, as it fulfills any requirements for a good job, viz.: it looks well, acts well, and is cheaply produced. It has been used in hundreds of cases within my own knowledge, without a single failure or complaint being heard of.

The reaming of taper holes in mild or machine steel, tough bronze, etc., is, in the ordinary way, a somewhat tiresome and costly process, as the ordinary fluted reamer is liable to attempt to "bite off more than it can chew," thus coming to grief by breaking completely or losing its teeth by chipping. A certain amount of special pleading or tenderness in manipulation of the reamer is therefore called for. If, however, the taper reamer is made with two flutes only, after the manner of a twist drill, the flutes having a left-hand spiral, and backed off so as to cut right-handed, if a hole the size of the smallest end of the pin is first drilled through the work, a reamer of the style described may follow at the same setting of the job, and be used at drilling speed. In a particular case I can mention, since the employment of this type of reamer, the piece-work price has been reduced 50 per cent and the men can earn more money than previously.

JAMES VOSE.

* * *

While high-speed steel has proven itself to be of great usefulness for cutting tools of general description such as lathe and planer tools, milling cutters, reamers, etc., it has not as yet proven practicable to make such tools as taps, threading dies and chasers, which cannot be ground after hardening, of this material. The reason for this is that most grades of high-speed steel have to be heated to such a high temperature when hardening that the sharp edges of the tools to be hardened are practically melted away, and as a rule, unless the tool is of such a construction that it can be ground after hardening, it is almost useless for cutting purposes. It is not to be inferred from this that taps and threading dies are impossible to make from high-speed steel, but the difficulties encountered in trying to successfully harden these tools are such that prominent manufacturers hesitate to undertake the making of tools not possible to be ground after hardening from this material.

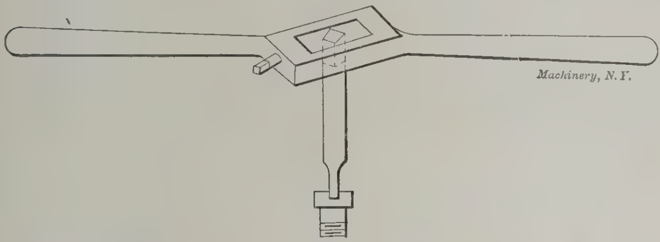
SHOP KINKS.

A DEPARTMENT OF PRACTICAL IDEAS FOR THE SHOP.

Contributions of kinks, devices and methods of doing work are solicited for this column. Write on one side of the paper only and send sketches when necessary.

A HANDY SCREWDRIVER.

The accompanying cut shows a cheap, handy and very powerful screwdriver made out of a piece of tool steel. Flatten one end for the screw slot, either by forging, grinding, filing, or milling, and square the other end; harden and temper.

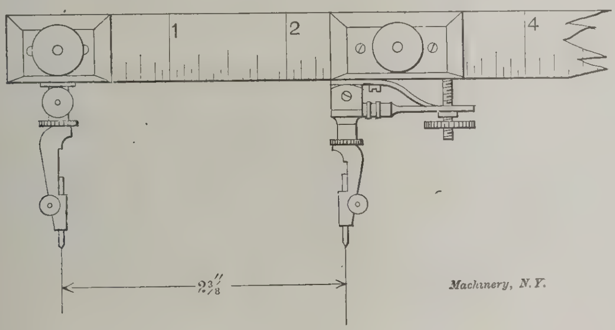


Use an ordinary tap wrench as a handle. Run the screw in with an ordinary screwdriver, and then tighten it with this tool, if the screw is large enough to require it. One can also use a monkey wrench or a dog on it, in an awkward place.

Beverly, Mass. CHARLES E. BURNS.

SCALE FOR BEAM COMPASS BAR.

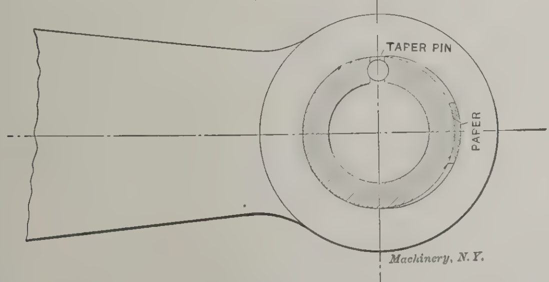
Beam compasses can be improved by placing a scale on the beam as shown. I had intended to purchase a paper scale engine divided in sixteenths and paste it on the beam, but finally decided that a linen tape measure would answer the purpose. There was no cost for this, as it was one furnished



by an advertiser, and on account of it being thin was better than could be bought. A coat of shellac keeps it clean and the divisions distinct. The object of the graduations is simply to get the pencil point approximately set, the finer adjustment then being made. WINAMAC.

TAKING UP WEAR IN A SOLID BUSHING.

After forcing the bushing out, I split it lengthwise with a hacksaw, cutting a slot about ⅛ inch wide; then I put two thicknesses of writing paper in the connecting-rod hole, on the side opposite to the pressure, clamped the bushing together, and slid it into the hole. Then I ran a taper reamer down into the slot, and drove a taper pin into it, very solidly; I

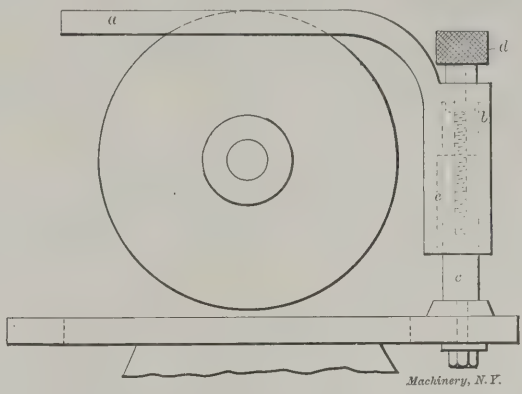


tried it in the arbor press and the bushing was a good pressing fit. The hole had been closed up just enough to be a good fit on the wristpin, and it also left a way open for future adjustments. The job has been in running condition five months already. CHARLES E. BURNS.

Beverly, Mass.

SURFACE GRINDING ATTACHMENT.

The cut shows a surface grinding attachment which can be used on any ordinary grinder and which I think is more handy than the one described in an article in the September issue of MACHINERY. Not every shop has a spare set of lathe legs as mentioned in that article. A stud with a nut and washer



holds this attachment to the slot provided on most grinders for holding the rest. The table *a* has a sleeve *b* on the lower side which slides on the post *c*. It is raised and lowered by the knurled head *d* of the adjusting screw. The key *e* prevents the table from turning on the post. H. K. G.

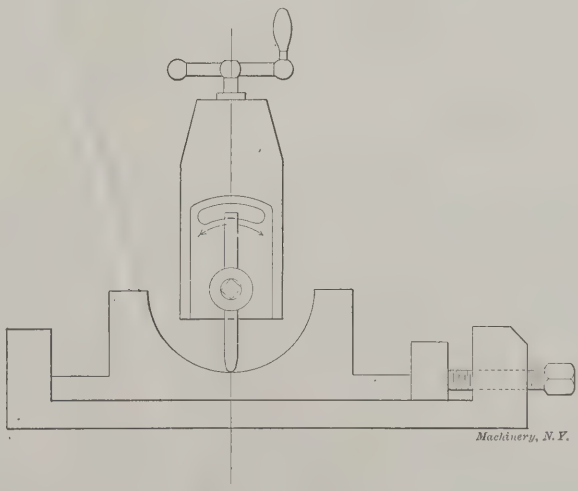
A SIMPLE SAFEGUARD FOR INK BOTTLES.

A very cheap and effective way of preventing ink bottles from being upset on the drawing table came to my notice recently. Simply cut a piece of card-board about 3 or 4 inches round or square, spread a thin coat of any good mucilage or liquid glue on the bottom of the bottle and set it in the center of the card-board. That's all. For the want of something more substantial, which is sometimes not to be had, this method does the trick very nicely.

Chicago, Ill. ROBT. A. LACHMANN.

PLANING AN ARC WITHOUT A RADIUS BAR.

There were some gray iron boxes and caps, which were too small in the bore to allow of sufficient babbitt metal between the shaft and the casting. To chuck them up in a lathe would have been expensive, so I placed them in the vise of a heavy shaper, and set a round-nosed tool with a long shank so that from the cutting edge to the center of the holder was the radius of the required boxes. Starting at the bottom, I fed from left to right by successive blows of a hammer on the shank, giving it all the cut the machine would pull, as



smoothness was no object. After finishing one half I loosened the tool and returned to the bottom, doing the rest by hammering the other side of the shank. This was much better than trying to start at one side and go the whole half circle, not only because the feeding would be more difficult, but greater inaccuracy would result if the tool shifted. This can be worked, when necessary, on a lathe without a compound rest. The trick is not new to many, but doubtless to the younger generation it will be. W. M.

SHOP RECEIPTS AND FORMULAS.

A DEPARTMENT FOR USEFUL MIXTURES.

This page will be used for the publication of shop receipts which the contributors know from experience to be practicable. Nearly all readers of MACHINERY can add something, and it is desired that they use this page as a medium for exchanging useful formulas. It makes no difference if they are old and supposedly well-known, provided they have not already appeared in this department.

268. SOLDERING GALVANIZED IRON.

For soldering galvanized iron without scraping use raw muriatic acid. WM. DAVIS.

Philadelphia, Pa.

269. CEMENT FOR LEATHER.

One ounce shellac, 2 ounces pitch, 2 ounces linseed oil, 4 ounces caoutchouc, 1 pound gutta percha. Melt together and apply hot. E. H. McCLINTOCK.

West Somerville, Mass.

270. NON-RUST SOLDERING SOLUTION.

A good anti-rust solution for soldering metals where acids must not be used, is made by dissolving rosin in acetone, making a solution about as thick as molasses; it is applied in the usual manner. W. R. BOWERS.

Birmingham, Eng.

271. TINNING WASH FOR BRASS WORK.

To prepare a tinning wash for brass work, use 6 pounds of white argil (potter's clay), 4 gallons of soft water, and 8 pounds tin shavings. Boil the brass work in this solution for 15 or 20 minutes. W. R. BOWERS.

Birmingham, Eng.

272. BLUING IRON OR STEEL.

Mix one part clean sand with one part powdered charcoal, heat the whole evenly in a pan or convenient receptacle until the piece, which has first received its finishing polish and been covered by the mixture, comes to the desired color. When cool, wipe dry with cloth. NERALCM.

273. ENAMEL GLAZE FOR COATING IRON PANS.

To prepare an enamel glaze for coating iron pans use flint glass, 130 parts; carbonate of soda, 20.5 parts; boracic acid, 12 parts. Dry at a temperature of 212 degrees and then heat to redness and anneal, that is, cool down very slowly.

Birmingham, Eng. W. R. BOWERS.

274. CEMENT FOR CAST IRON.

Mix 1 pound cast-iron filings, 1 ounce sulphur, and 2 ounces sal-ammoniac. Mix thoroughly and keep dry. When using, mix one part of this composition with twenty parts clear filings and some very fine sand. Make into a stiff paste with water. E. H. McCLINTOCK.

West Somerville, Mass.

275. PRESERVATIVE OIL.

To make a preservative oil use high test grain alcohol and best grade of sperm oil, equal parts. Keep in a tightly-corked bottle, and shake well before using as the alcohol and oil separate after standing. Any moisture on a tool or gun at the time of application is quickly absorbed by the alcohol which in a short time evaporates, leaving a good coat of sperm oil to protect the surface from rust.

E. W. NORTON.

276. CEMENT FOR STEAM-PIPE JOINT.

A good cement for use in making steam-pipe joints is made in the following manner. Grind and wash in clean cold water 15 parts of chalk and 50 parts of graphite. Mix the two together thoroughly and allow to dry. When dry regrind to a fine powder, to which add 20 parts of ground litharge and mix to a stiff paste with 15 parts of boiled linseed oil. The preparation may be set aside for future use, as it will remain plastic for a long time if placed in a cool place. It is applied to the joint packing as any ordinary cement and will be found to last a very long time.

Olney, Ill. T. E. O'DONNELL.

277. ANNEALING STEEL.

Heat slowly or rather evenly to a dull red heat. Put it in a dark place or corner, box or barrel, until all signs of red have just disappeared, then quench in water, taking care to hold it still. When annealing flat stock, heat evenly and thoroughly, place between two planed pine boards on an ash heap and cover with ashes. By this method the charcoal is produced, so to say, automatically. WM. B. BROOKS.

New Kensington, Pa.

278. TO ANNEAL ZINC.

In working zinc the greatest loss is on account of the zinc cracking and being too brittle to handle to advantage. It is surprising to find how very few mechanics understand the annealing or malleablizing of same. The following will be found unfailing: Heat in oil to about 500 degrees F. and plunge in hot soda water, which works the double operation of drawing the zinc to the proper degree and at the same time cleanses the surface from the oil. HARDENER.

279. COLD SOLDER.

For flux use 1 part metallic sodium to 50 or 60 parts of mercury. These combine if well shaken in a bottle. For solder use a weak solution of copper sulphate, about 1 ounce sulphate to 1 quart of water; precipitate the copper by rods of zinc, wash the precipitate two or three times with hot water, drain off the water and add 6 or 7 ounces of mercury for every 3 ounces of precipitate. A trifle of sulphuric acid will assist in the combining of the matter. The combination will form a paste which sets very hard in a few hours.

New Haven, Conn. A. L. MONRAD.

280. TINNING CAST IRON.

To tin cast-iron articles, dissolve chloride of tin in water until the solution is fully saturated; this saturated solution is to be thinned down when needed for use, by ten times its volume of water. The articles which are to be tinned are to be wrapped around lightly with zinc sheet or wire and left in the solution ten to fifteen minutes. On removing the articles they are to be dried in sawdust, after washing well with clean water and brushing them with a wire brush, and then polished with prepared chalk. ROBERT GRIMSHAW.

Hannover, Germany.

281. RETOUCHING BLUEPRINTS.

An excellent solution for retouching or marking in details on blueprints can be prepared according to the following receipt. The solution consists of 75 grains of potassium oxalate dissolved in 1 ounce of water. If the solution is too thin and watery, it may be thickened by adding some kind of a gum preparation. It can be applied with a pen, as ordinary ink. The blue background is removed very rapidly by the solution, but it is important that the print is immediately washed, as the solution has a tendency to soak into the pores of the paper and blur the lines. T. E. O'DONNELL.

Olney, Ill.

282. TO PREPARE FINE ABRASIVE QUICKLY.

To quickly prepare fine abrasive use FFF emery or "15-minute" carborundum with benzine or naphtha for a liquid, mixing them in a square bottle. Use about two ounces of the abrasive to one quart of liquid; shake well and then lay the bottle flat on its side for the number of minutes wanted to settle; then pull the cork and let the liquid flow out until level with the cork hole bottom. The liquid just drawn off can be used at once with a brush, but by allowing it to stand for a time, the top portion can be poured off leaving the abrasive with a little benzine which will evaporate quickly, and leave the clear powder.

In explanation of the term 15-minute carborundum, would say that this is a term applied to fine abrasive obtained by the process just explained (manufacturers, of course, using watertanks instead of bottles), the time the liquid is allowed to stand, in minutes, being used to distinguish it. Thus, if it stands 15 minutes it will be known as 15-minute abrasive, etc.

SCOTTY.

HOW AND WHY.

A DEPARTMENT INTENDED TO CONTAIN CORRECT ANSWERS TO PRACTICAL QUESTIONS OF GENERAL INTEREST.

Give all details and name and address. The latter are for our own convenience and will not be published.

29. G. E. R.—Why is it that a stud and nut can be screwed up tighter than a tap-screw?

A.—We know of no good reason for such a condition existing; the effect of friction and torsional elasticity should be exactly the same in both cases. But lack of exact alignment, of course, affects a tap-screw more unfavorably than a stud and nut. It is true that a tap-screw will loosen quicker when subjected to vibration but this comes from the stud being screwed in until it shoulders on the tapered part of the thread while the tap-screw cannot be screwed to this point, hence is more easily jarred loose.

---

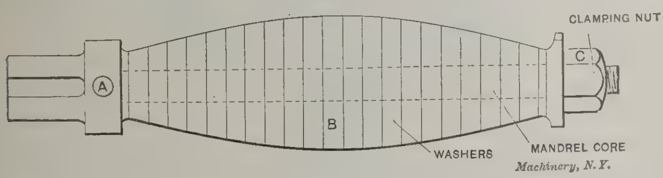
30. R. O. F.—What is the essential difference between the Willis and Walker system of cycloidal gearing?

A.—The Willis system is based on a single generating circle, the diameter of which is equal to the radius of the smallest gear in the interchangeable set. For example, suppose the Willis system is applied to a set of 3-inch circular-pitch gears, and it is desired that the smallest gear in the set shall have 15 teeth. Then the diameter of the generating circle will be 7.16 inches, which simply means that the faces and flanks of the teeth of the various gears will be shaped to conform with the curves generated by a point on a circle 7.16 inches diameter, rolling on the pitch circle of all the gears of the set. The Walker system is based on the same general principle as to using a rolling circle to generate the tooth shapes, but a single generating circle is discarded. Say the limits of an interchangeable set of Walker's gears are 10 and 200 teeth. Then the tooth shape is determined both with a 10-tooth and a 200-tooth generating circle, the tooth shape selected being a mean between the two for the faces or tooth parts above the pitch line; below the pitch line the flanks are shaped to the mean down to a certain depth and then the mean shape is departed from in order to give the necessary clearance for the top of the teeth for all the gears of the set. This system to a considerable degree overcomes the defect of under-cutting unavoidable with the Willis system on low-numbered gears, and is claimed to make a material improvement in the action in general.

---

31. A. L. M.—I wish to coil a few wire handles large in the center, similar to those used on stove-lid lifters. What kind of a mandrel is used for this work?

A.—Wire coils of this shape are manufactured on special wire coiling machines which require no mandrel, the coil being formed in mid-air, so to speak, by exterior rollers which automatically change position during the operation so as to



vary the diameter of the coil and thus make it of the required shape, *i. e.*, large at the center and small at the ends. For making a few such coils, however, you may use the form of mandrel shown in the cut, using it in an engine lathe in the usual manner. It consists of a number of thin steel washers mounted on a mandrel and turned to the required shape; they should be consecutively numbered so as to be readily replaced in order. The end of the wire is caught in the hole *A* made in the solid part of the mandrel, and the coiling is done on top of the washers *B*, the nut *C* keeping them close together. When the coil has been completed the removal of the nut allows the mandrel core to be removed and loosens the washers, which with a little rapping will fall out between the coils, if they be not too closely wound. This design of mandrel cannot be used for close wound coils unless very thin washers are employed. It is only recommended for experimental purposes and not for manufacturing.

32. A. L. B.—What is the use of a table of logarithms?

A.—A table of logarithms is of the same order of importance to the operations of multiplication and division that the multiplication table is to addition and subtraction. It is a great time-saver, and is practically indispensable for computation in which fractional powers are to be expanded, or fractional roots are to be extracted. For example, suppose the expansion of $189^{1.41}$ is required. The expansion is readily done by the use of a table of logarithms, but is impracticable by any other method within the reach or time of the ordinary calculator. Again, take such a calculation as finding the amount of \$1.00 at compound interest for 50 years at 8 per cent semi-annually. This is an almost interminable operation, conducted in the primitive manner, but it is simple with logarithms. To illustrate we will work out the example. The primitive calculation requires that \$1.04 (the amount of \$1.00 at 8 per cent for 6 months) be multiplied by itself 100 times, but using logarithms makes only one multiplication necessary. The logarithm of 1.04 is 0.017033; multiplied by 100 it is 1.7033, or the logarithm of the amount of \$1.00 for the given time and rate. The table discloses this to be 50.50. Hence the amount of \$1.00 for the given time and rate is \$50.50. To expand $189^{1.41}$ we simply find the logarithm of 189, and multiply it by 1.41. The logarithm of 189 is 2.276462, which multiplied by $1.41 = 3.209811$. Turning to the table it is found that 3.209811 is the logarithm of 1621.1, and this is the required expansion of $189^{1.41}$. By dividing the logarithm of 189 by 1.41 the 1.41st root is extracted, and so on.

* * *

SHORT LIFE OF MODERN HEAVY ORDNANCE.

The annual report of General Crozier, chief of ordnance, gives a startling idea of the short life of our 12-inch guns now in place in most of the coast fortifications of the United States. The report states that a 12-inch gun firing a projectile with a muzzle velocity of 2,500 feet per second will last for only about sixty rounds, after which the accuracy of fire is seriously impaired by erosion, which wears away and destroys the rifling. It is pointed out that the guns in any of the important fortified works of this country would last less than two hours in an engagement requiring rapid firing. General Crozier suggests that the caliber be increased to 14 inches and the velocity decreased from 2,500 feet to 2,150 feet per second, stating that the life of the gun is then increased to 200 rounds, and the penetration or smashing effect would be about the same.

The suggestion to reduce velocities and use larger calibers is one which we think will not be favorably received by military authorities in general. If it be considered that the life of a modern 12-inch gun firing projectiles with a velocity of 2,500 feet per second is only sixty rounds the situation is indeed serious, but high velocities and smaller calibers are the tendencies in both heavy ordnance and small arms. The thing to do is to find some material for lining high-powered guns which will not be affected by the incandescent powder gases as much as the steel now used. The suggestion has several times been made that high-speed steel is a material well adapted for such a purpose, inasmuch as it gains in hardness with an increase of temperature up to a low red and this is exactly what is wanted for the liner of a heavy rifled gun using smokeless powder. High-speed steel was developed in the manufacture of arms and armor and it would not be strange if it, itself, should become a necessary part of modern guns.

* * *

The substitution of machine steel for purposes for which carbon steel was formerly employed is one of the improvements about which little is heard. Nevertheless, some large concerns use it almost exclusively for dies, taps and other cutting tools which require toughness as well as hardness. A machine steel tap when skillfully casehardened will cut as freely and is said to wear practically as well as one of carbon steel. Besides being cheaper to make, it will not snap off suddenly when subjected to undue stress. We understand that the Singer Manufacturing Co. use little carbon steel in their Elizabethport works, and that all punches, dies, taps, etc., are generally made from machine steel, casehardened.

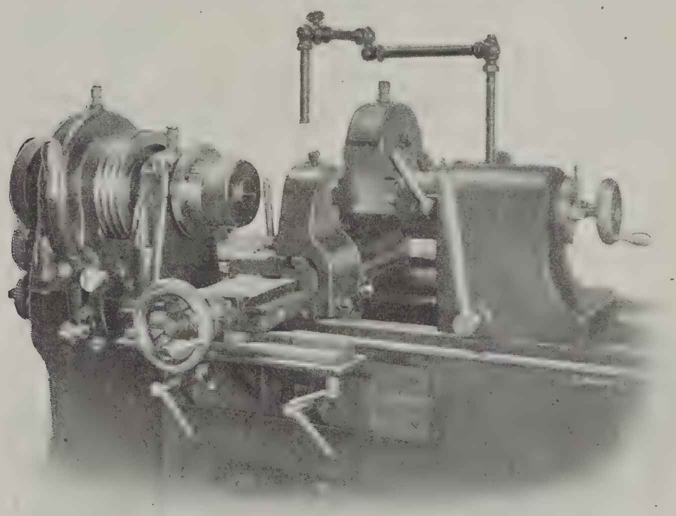
MACHINERY AND TOOLS.

A MONTHLY RECORD OF NEW APPLIANCES FOR THE SHOP.

TAPER ATTACHMENT FOR THREAD MILLER.

This attachment is designed, as shown in the cut, to be applied to the 6 x 48 Pratt & Whitney thread milling machine at the time the machine is built. In operation and general construction it is similar to the well-known Slate taper attachment for lathes. The taper bar is made in two parts, the one nearer the headstock being secured in a position parallel to the working centers, while the other is made adjustable to suit the required taper. This permits the threading of pieces which have both a taper and a straight portion. The bracket upon which the taper bar is mounted is attached to the front side of the bed in such a way that it may be shifted and clamped in any longitudinal position to agree with the location of the taper on the piece whose thread is being milled.

The cutter head is carried on a transverse slide to which is also attached the cross slide screw with its micrometer disk and positive stop, thus providing means for adjusting the position of the cutter for diameter of work and depth of cut in-



Taper Attachment for Thread Miller.

dependently of the mechanism of the taper attachment. The cross movement imparted by the tapered bar is communicated to the slide through the action of the positive shoe attached to it, held in contact with the front side of the taper bar, through the action of a roll under adjustable spring pressure on the rear side. The greatest angle to which the taper bar may be adjusted is 10 degrees, corresponding to about 4 inches taper per foot. All the required adjustments may be made without the use of a wrench. The Pratt & Whitney Co., Hartford, Conn., are the builders.

IMPROVED FOX TRIMMER.

The well-known universal trimmer made by the Fox Machine Co., 815-825 N. Front Street, Grand Rapids, Mich., has been redesigned and improved in a number of particulars. The rigidity and weight of the machine has been increased while its portability is still retained, it being mounted on three casters so that it may be easily shifted from place to place as required. A slight forward pull of the handle shown at the base of the machine in Fig. 1 raises it from its foundation onto the rollers, and the returning of the handle to the upright position settles it firmly on its base again. Other improvements relate to the means provided for taking up the wear of the cutter slide while still preserving the accuracy of the machine. Improved gages are also provided, both for angular cuts and straight work, while provisions are made for easily and accurately setting curved segments to bring the trimmed edge accurately radial and at the proper angle.

For plain angular work, the gages shown on the table in Fig. 1 are provided. A pivot block working through the curved slot in the table is fitted to the bottom of the gage by means of a carefully milled groove and tongue, and held by two heavy screws. The broad bottom of the gage rests flat on top of the bed of the machine while the pivot block underneath presents four carefully scraped and fitted bearings to the under side of the bed. This construction holds the gage rigidly. The pivot block has its center line directly on the

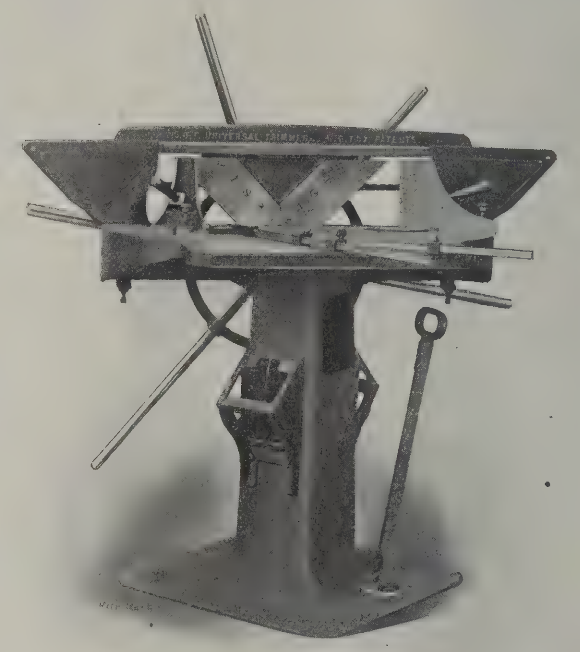


Fig. 1. Improved Fox Trimmer. Front View.

spot where the cutting edge of the knife and the point of the gage meet, so that in swinging the gage, it is constrained to move in a true arc of a circle with the gage point always at exactly the same spot. This design does away with the inaccuracies which come from wear with the usual construction and hold it so rigidly that it is possible to set it with spring taper stop pins without locking it by the clamping lever. Even under these conditions a heavy cut may be taken

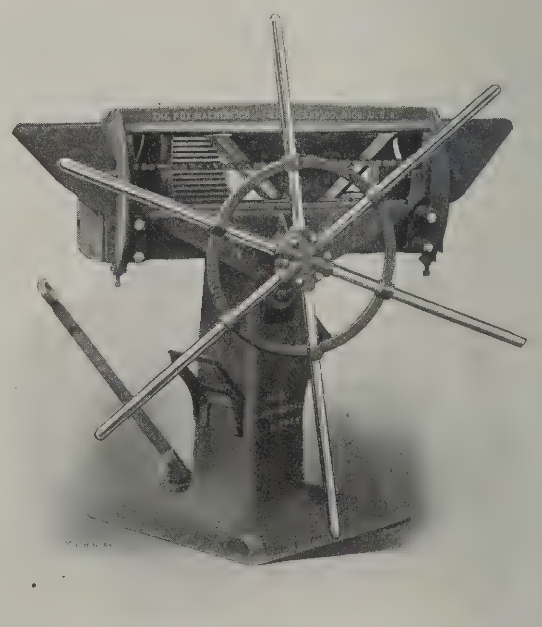

Fig. 2. Improved Fox Trimmer. Rear View.

without springing the gage perceptibly. Forty-five degree angle blocks are provided for tenoning and for work requiring double angle trimming. When not in use these rest in brackets provided for them on the column.

The line cut, Fig. 3, shows the design of the segmental gage supplied with this line of trimmers. The bed is laid

out for trimming segments of circles of 3, 4, 6, 8 and 12 segments to the circle, for diameters ranging from 6 to 95 inches. While universal trimmers have often been used on this work, hitherto close work has been impossible, the inaccuracy of the band sawing affecting the trimmed end. The new stop rod attachment shown limits this inaccuracy. The head which locates the outer end of the work can be pressed inward against the resistance of the spring mounted within it. In trimming the first end of the segment this head is pressed in. As the piece is reversed to finish the other end, the gage springs out again to the proper position for cutting the true angle on the other ends, the gaging being done from the already completed surface. The result of this is the elimination of the cut-and-try process in finishing the last piece.

Tabulated instruction plates are fastened to the knife guards at each side of the machine. That at the right hand contains a table giving the number of sides, center angles, angles between adjacent sides, radius of circumscribed circle, radius of inscribed circle and angle of setting for polygons of from 3 to 12 sides. Rules are also given for obtaining the length

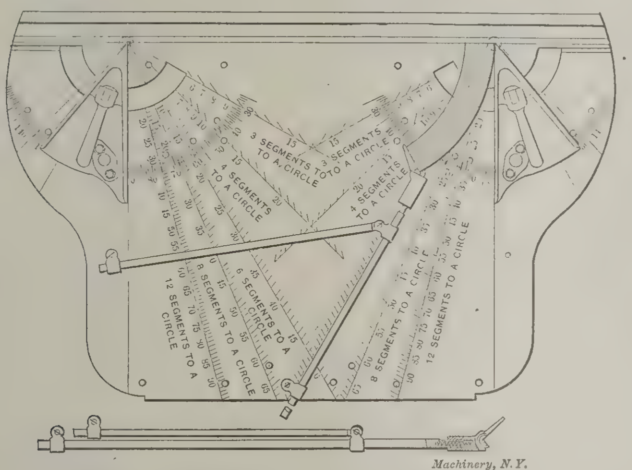

Fig. 3. Arrangement of Segment Gage Graduations on Surface of Table.

of a chord of a given segment. The other plate shows a graphic solution for finding the lengths of segments of a circle. This is intended to give the workman the number of degrees of a circle contained in a segment or triangle.

TWO NEW PRATT & WHITNEY PRODUCTS.

The Pratt & Whitney Co., Hartford, Conn., are now prepared to furnish their profiling machines in either the belt driven or spiral gear driven forms to suit the requirements or fancy of the purchaser. The use of belts is preferred to a spiral gear drive, as formerly provided, in cases where small cutters and excessive speeds are required. The No. 11 machine, for instance, when belt driven, may have as high a spindle speed as 2,500 to 3,000 revolutions per minute if the work requires it, thus adapting it to operations on the softer metals as well as iron and steel. The spindles are driven from a drum at the rear of the machine. The driving pulleys of the spindles are mounted on sleeves entirely independent of the spindle bearing. All the revolving parts including the drum and the pulleys are carefully balanced so that they may run at a high speed without vibration.

Another recent addition to the list of appliances made by this firm is a tool post grinder designed particularly for use with their bench lathe. The frame of this grinder is a steel casting with a shank of suitable form for holding in the regular tool post of the machine. The spindle is of tool steel, hardened and ground, with straight bearings running in bronze boxes, which are split, tapered on the outside and mounted in steel bushings with a nut at each end, by which the adjustment can be easily made to compensate for wear. The journals are thoroughly protected from grit and dust. The spindle has a tapered hole to receive the small arbors on which wheels for internal grinding are mounted, while the outside of the nose for the spindle is tapered to receive a wheel mount for external work. Oil for the spindle bearings is introduced at the rear end of the spindle, which is hollow and serves as a reservoir. When provided with small cutters on tapered sleeves this tool may also be used for light milling and drilling.

THE "JUST IT" LATHE TEST INDICATOR.

This little device is made by Mr. A. E. Babin, Waterbury, Conn., and is designed particularly for truing up work in the lathe, either from surfaces already finished or from prick

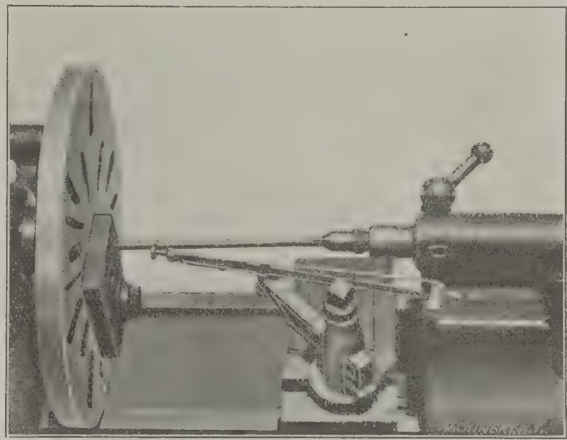

Fig. 1. The "Just It" Lathe Test Indicator Centering a Prick-punch Mark.

punch marks. Fig. 1 shows its use as a centering indicator. A bar is furnished having one pointed end and the other end centered. The pointed end is inserted in the prick punch mark of the work, while the centered extremity is held by the tailstock center, which is brought up to give it enough pressure to retain it firmly in place. The head of the indicator may then be brought against the end of the bar near the work and the error in setting found by noting the amplitude of the vibrations at the outer end of the needle. When used for truing a piece up from an exterior or interior surface, the end of the indicator is applied directly to the work.

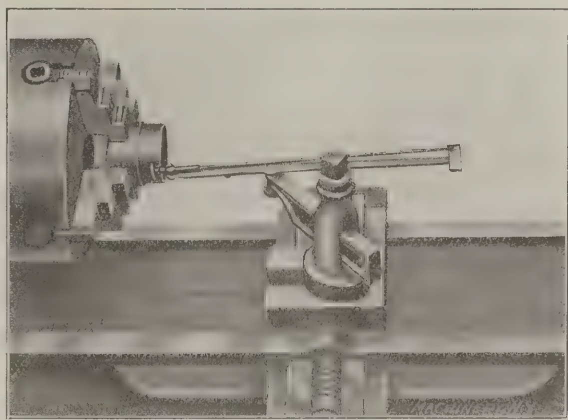

Fig. 2. The Indicator in use Truing the Outer Surface of Work Held in a Chuck.

The long distance from the head to the point where it is attached to the shank makes it very valuable for use with deep holes, as well as for work on the faceplate or planer where bolts and straps are used which would interfere with the ordinary indicating device.

HORIZONTAL BOILER RIVETER INSTALLATION.

The Chester B. Albree Iron Works Co., Allegheny, Pa., build a horizontal boiler riveter of a design different from the usual style in this country. The riveters employed in the boiler shops as a rule are vertically set machines, requiring a deep pit and high clearance for the crane overhead. In the design referred to above which is used to a great extent in Germany, the riveter is suspended horizontally from a trestle. The machine proper is supported by the trestle and is raised and lowered by means of a hand crane; a truck is provided for carrying the boiler back and forth during the riveting. On the top of this truck are placed six small rollers upon which the boiler rests during the riveting operation. These rollers are so arranged that the boiler may be rotated about its horizontal axis, thereby making it possible to bring any

part of its circumference under the riveting die. The manufacturers claim that this style of machine can be installed for half the price of a vertical stationary air compression riveter. The space saved by installing this style of apparatus may also, in many cases, be of importance.

THE FORTIN UNIVERSAL JIG.

The constant improvement taking place in the product of all manufacturing establishments means a constant change in the design and dimensions of the parts produced. Where these parts are made in such quantities as to warrant the use of jigs for the drilling, tapping, and reaming operations, this change in shape and dimensions involve a serious expense in the alterations thus made necessary in these tools. The B. P. Fortin Tool Co., Woonsocket, R. I., have designed and placed on the market a "universal jig," illustrated in the photographs and line cuts, Figs. 1 to 4. This tool is intended to be adapted to all ordinary work within its range, thus avoiding the necessity for a great number of jigs and the expense

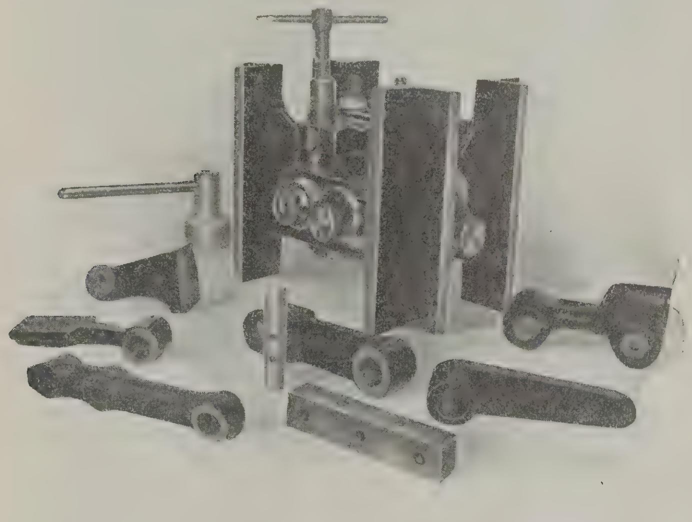

Fig. 1. The Fortin Universal Jig and Samples of Work.

of alterations and rebuilding consequent on changes in design, as described above. The main idea of the device is that of a rectangular box with a hinged cover. In each of the five sides, and the cover as well, slots are formed in which the required stops, clamping screws, locating surfaces, and drill bushings are fastened. In Fig. 1 the device is shown with its cover closed, and grouped about it is a collection of parts giving some idea of the variety of work to which it is adapted. Fig. 2 shows the jig tipped up with the cover open and a piece of work in place.

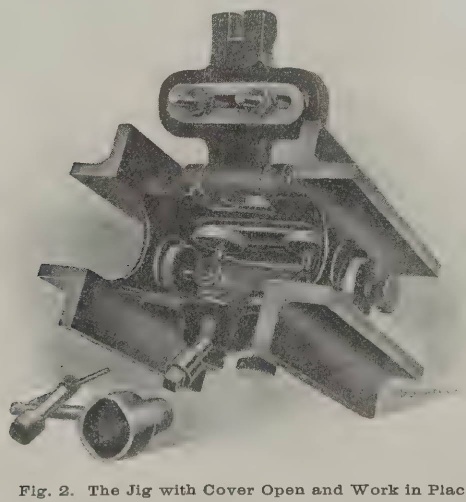

Fig. 2. The Jig with Cover Open and Work in Place.

The line cuts, Figs. 3 and 4, give a good idea of the design of the device. These cuts show two views of the jig as arranged in the halftone, Fig. 2. In Fig. 3, which is a horizontal section viewed from above, *A A A* are locating screws which form the abutment against which the work is clamped in a horizontal plane. These screws are provided with lock nuts and are threaded into bushings *B B B* which are clamped in slots in the side and end of the frame, as shown in the photograph. They are tightened by nuts *C C C*. As shown at *B* in Fig. 4, the holes in the bushings in which stop screws *A* are carried are eccentric, so that vertical and side adjustment for all of screws *A* is possible. Knurled clamped screw

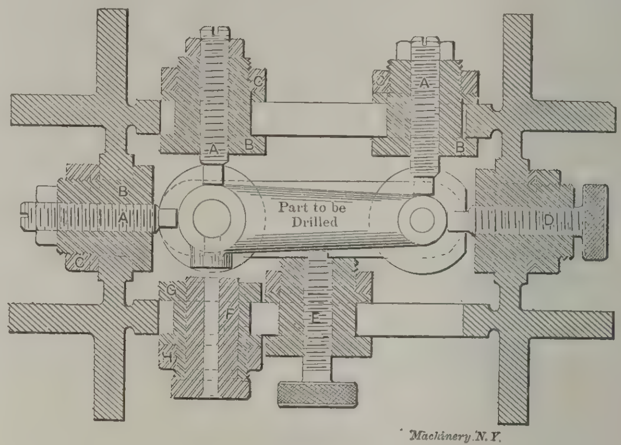

Fig. 3. Horizontal Section through Locating Screws.

D is carried in similar adjustable eccentric bushing in a slot at the other end of the frame. This screw holds the work against the left hand screw *A*, while a similar knurled head thumb screw *E* holds the casting against the back screws *A A*. Slip bushing *F* is carried by clamp bushings *G* and its nut *H* is carried by the front slot. This bushing may be removed to tap the hole after it has been drilled. So much for the holding devices and the jig bushings operating on the work in a horizontal plane. In a vertical plane, as shown in Fig. 4, the work rests on projections on the inner surface of drill bushings, *J J*, which are clamped by means before described in a slot in the body opposite the cover. Thumb screw *D* and stop screw *A* are those shown on the center line of Fig. 3. The cover *K*, which is mounted as shown in Fig. 2, carries in its slot two adjustable set screws *L L* held by lock nuts in the cover slot. The closing

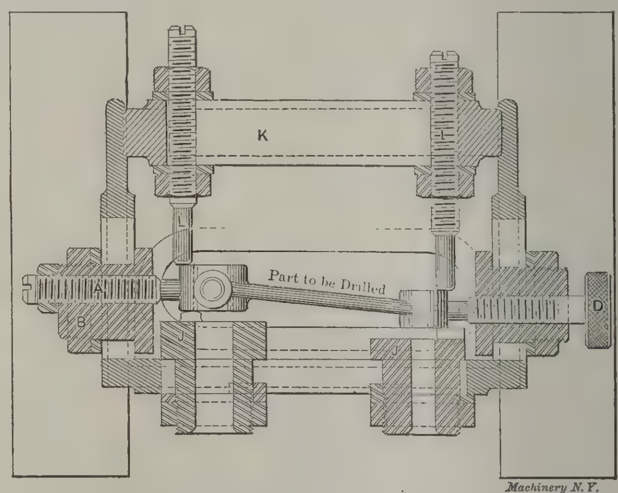

Fig. 4. Vertical Section through Cover Screws and Jig Bushings.

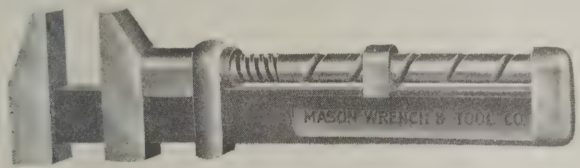
of the cover brings these down as shown on top of the work and the tightening of the cover nut with the key wrench shown in Fig. 1, in combination with the tightening of screws *D* and *E* in Fig. 3, fixes the position of the casting in relation to jig bushings *F* and *J J*. For holding round parts bushings *J J* with V-grooves formed in their inner faces are used.

In setting up the jig for a given piece, the location of the bushings is determined by inserting standard plugs in them, and taking measurements with micrometers or vernier calipers between the plugs themselves, and the surface plate on which the device rests, altering the adjustment until the correct location has been determined. After this has once been done a correctly made piece should be saved as a model; then, when the jig has to be set up again, the work may be placed within it and standard plugs used to bring the bushings in line with the holes in the model. The manufacturers state that this jig is the outgrowth of many years' experience on high grade jig and fixture designing. They call attention to

the ease with which it is adjusted and the accuracy of the work of which it is capable. The work may be placed in the jig and clamped in position as though it were specially designed for that particular piece. The bushings and gage points are all interchangeable. The device is made in eight sizes which will take in a complete range of work from 2 to 15 inches in length.

THE NOYES QUICK-ACTING WRENCH.

The most notable feature of the wrench shown below is the arrangement used for adjusting the jaws. A screw threaded in the jaw is used as usual. This screw, however, has a long body extending the full length of the handle and provided with a spiral groove of steep pitch. The sliding block or nut which engages this groove may be adjusted by hand to any position on the length of the handle. As it is moved its action on the spiral groove rotates the screw, which in turn

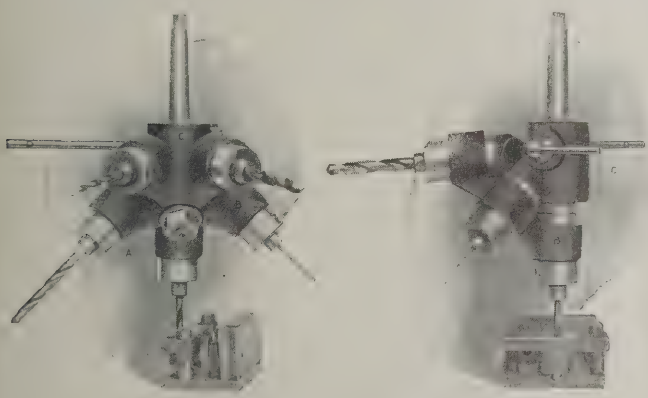


Noyes Quick-acting Wrench.

adjusts the movable jaw of the wrench. The pitches of the groove and the screw are so arranged that the mechanism is self-locking. This action is practically instantaneous since all that it is necessary to do to entirely close or entirely open the wrench is to slide the block from one extremity of its travel to the other. The makers, the Mason Wrench & Tool Co., First National Bank Building, Chicago, Ill., assert that special attention has been given to the strength of the tool, it having been designed to withstand any strain which may come upon it.

THE GEM TURRET HEAD FOR DRILL PRESS OR LATHE.

A five-tool turret head for the drill press or lathe in which only the tool in use revolves, is shown in the accompanying cut. To the inclined stud *A* is pivoted the revolving head *B*, carrying the five chucks for the tools. Handle *C* operates an eccentric which makes the connection between the revolving shank, driven from the spindle, and the tool chuck which is at the time in line with it. In the upper end of the chuck is milled a groove in which a hardened steel pin on the end of



Gem Turret Head for Drill Press or Lathe.

the shank is engaged. A tapered dowel in the center of the shank brings it and the chuck into perfect alignment. The bar *D* prevents the apparatus from turning as a whole.

The body of the turret is of gray iron, the spindle is of steel, the eccentric pin used in engaging the individual drills is of tool steel, suitably tempered. There are no springs or complicated clutch movements, and the drill working at the time is the only one that is in motion. Changes from one tool to another may be made almost instantaneously without stopping the drill press, regardless of the speed at which it is running. It may be applied to the spindle of a lathe for drilling work bolted to the carriage, or it may be held in the tailstock and take the place of a turret in finishing holes in work held in the chuck. This device is made by the Patterson Tool & Supply Co., Dayton, Ohio.

INDUSTRIAL NOTES FROM EUROPE.

Annealing and Hardening Furnace with Electrically Heated Liquid Bath, by L. M. Cohn, Berlin. The author gives a brief description of the processes in steel during annealing and hardening and deducts therefrom the conditions for a good annealing apparatus. Discussing the existing arrangements the author comes to the conclusion, that they by no means meet the requirements. Some afford the danger of changing the percentage of carbon in the steel; the obtaining of a uniform temperature depends to a great extent on the attendants; the temperature cannot be determined with sufficient accuracy; temperatures of up to 1,150 deg. C. (2,102 F.) as required for high-speed tools are only obtainable with one single type of furnace (electric hardening furnace by H. Craens, Hanau, Germany) and even there with difficulty; and temperatures of 1,300 degress C. (2,372 F.) as necessary for special steel tools for wholesale manufacture, and having to be of great strength, cannot be obtained at all.

The new furnace, designed and patented by Messrs. Gebr. Körting, Elektrizitäts G. m. b. H. Berlin, has a liquid bath heated by an electric current passing through it. The temperature of this bath is uniform throughout, except the uppermost layer, which may be considered as a sort of cover. The steel immersed in it is, therefore, heated uniformly in all parts. The temperature can be accurately measured and very easily adjusted to any temperature up to 1,300 degrees C. (2372 F.), and even higher still if required. The heating of the steel requires a comparatively shorter time than in other arrangements; waste or spoiled goods is exceptional; the percentage of carbon is not changed and the working is very economical.

The furnace consists mainly of a cast iron box, which is lined inside with fire-clay. Inside this lining is a second lining of fire-bricks, lined again with asbestos and inclosing the crucible made of one piece of fireproof material. The size of the crucible depends on the purpose the furnace is intended for. Two electrodes lead into the crucible, through which only alternating current has been sent, for avoiding electrolytical effects. The crucible is filled with metal salts, which in a cold state will not let electric current through, but are excellent conductors when molten. A special regulating transformer serves to regulate the current, and thus also the temperature. For temperatures above 1,000 degrees C. pure chloride of barium is used, the melting point of which is at about 950 degrees C. (1,742 F.); for lower temperatures a mixture of chloride of barium and chloride of potassium, 2 to 1 is used, melting at about 670 degrees C. (1238 F.). However, any other suitable salts may be used.

A test was made with a furnace, the bath of which was 6½ x 6½ x 7 inches. A 50-period alternating current of 190-volt primary tension was used. This tension had to be reduced to from 50 to 55 volts by the regulating transformer for starting the furnace, and lowered later on. The heating lasted about half an hour. For temperatures from 750 to 1,300 degrees C., the secondary tension amounted to from 13 to 18 volts. The consumption of energy was as follows:

Temperature in Deg. C.	Consumption of Energy, Kw.
880	5.4
1,140	8.5
1,300	12.25

A milling cutter 5 inches diameter, 1¼ inch bore, 1 inch thick, was heated in 62 seconds to 1,300 degrees C.

Another cutter 4½ inches diameter, 1¼ inch bore, ¾ inch thick, was heated in 55 seconds to 1,300 degrees C.

A bushing of ordinary tool steel 2¾ inches diameter, 2¾ inches long, ⅝ inch bore was heated in 243 seconds to 850 degrees C.

The two cutters had been previously heated in charcoal fire to a dark red heat, but the bushing had not.—*Elektrot. Z.* 1906, No. 31, Aug. 2, p. 721.

Some Grinding Machines exhibited by Naxos Union, Frankfort-on-Maine, at the Bavarian Jubilee and Lands Exhibition, Nuremberg, 1906:

No. 1. Grinder (German patent No. 247,711), with steel disks, covered with emery cloth or paper for accurately grinding small pieces of work.

No. 2. Grinder for edging heavy castings and forgings, plates, rolled iron, etc.; patent elastic, adjustable hinged guard (German patent No. 162,518).

No. 3. Direct electrically driven grinder for working heavy castings and forgings, edging plates, rolled iron, etc.

No. 4 Grinder (German patent No. 237,572) with revolving flexible shaft for grinding curved and molded round articles, which are stuck on the free end of the flexible shaft and thus rotated during work.

No. 5. Grinder with swiveling rest and direct electrical drive for wet grinding of profiled tools.

No. 6. Grinder with magnetic work table for smoothing thin articles, such as piston rings, etc.

No. 7. Grinder with planet-grinding spindle (circular motion of grinding spindle) (German patent No. 160,832), for grinding curved and straight links, grinding out sleeves and bores or large unwieldy parts or truing trunnions on the latter.

No. 8. Automatic twist drill grinder (German patent No. 166,460).

No. 9. Automatic saw grinder for circular and frame saws.

No. 10. Grinder with electrically driven grinding wheel for automatic grinding and polishing rolls.

Sewing Machine Industry.—This line has been very successful, the consequence being that several of the leading firms are contemplating extensions. Baer & Rempel, Bielefeld, have erected new large premises; Hengstenberg & Co., Bielefeld, are about to erect an annex; Dürkopp & Co., Bielefeld, are pushing the manufacture of sewing machines for special purposes; Siedel & Naumann, Dresden, are increasing their plant considerably, having put down a 1,000 horse power steam turbine, and are about to entirely reorganize their entire works; Clemens Müller, Dresden U., has erected a vast new building which he intends equipping next spring with new machine tools.

Electrical Engineering.—A new limited company has been founded as Elektrizitäts Gesellschaft Hochstrate & Böttcher Nachfolger, G. m. b. H., Witten, with the object of manufacturing and selling electrical machines and appliances. The capital invested amounts to $15,000.

Flexible Shafts for Cleaning Boiler Tubes.—Gustav Pickhard, Bonn, on Rhine, advertises his new flexible shafts for cleaning boiler tubes. These shafts consist merely of two or three closely wound wires, which thus form a very flexible, and yet strong spiral cable. These cables or shafts will not kink, and can be inserted to any depth into the boiler tubes. Tube cleaners, scrapers or brushes are attached to their end, and they allow of a great force being applied. They are supplied either in given lengths and then coupled together or they are supplied in one long piece. This causes no inconvenience whatever, as they are not heavy and are readily coiled up to a coil of comparatively small diameter. They vary from ¼ to ¾ inch outside diameter, the steel wires used being from 1-16 to ¼ inch thick. The prices vary from $1.75 to $12.50 per meter.

Suction Gas.—In a paper, "On the Development of Modern Suction Gas Plants," read before a special meeting of the Berlin branch of the Society of German Engineers, Chief Engineer Fritz Schleicher of the Gas Engine Works, Cologne-Deutz mentions a novel use of suction gas. The gas coming from the generator passes through the scrubber and purifier and through a fan producing the necessary action. Behind the fan the gas, which may be now termed pressure gas, is used to heat annealing furnaces, hardening furnaces and for soldering small parts. This novel use has been repeatedly and successfully employed in machine works for case-hardening parts of machines, in bicycles and motor car works, sewing machine works, etc., for hard soldering the various parts.

Iron Works Near Bremen.—A limited company has been formed by notable Bremen and Frankfort firms with a capital of $3,000,000, for preparing the establishment of large iron works. The chief products are to be pig-iron for export and foundry purposes, and steel for shipbuilding.

Grillo, Funko & Co., Gelsenkirchen, Westfalia, have leased a tract of land near the "Consolidation" pit, intending to erect there a plant for the manufacture of boiler tubes.

Berlin, Germany, November 15, 1906. D.

MISCELLANEOUS FOREIGN NOTES.

Craven Brothers, Ltd., Manchester, England, have lately redesigned their line of planers and have introduced two marked improvements in connection with this. On the smaller sizes there is a new cushioning device to prevent shock on reversal in high speed planing, and on the larger sizes there is a new system of main drive where the shifting belts are eliminated, although the drive still remains a belt drive.

A multiple drilling machine of a special design has recently been built by G. Swift, Halifax. It consists of five individual drill presses without tables mounted on a bed-plate 2 feet 6 inches high. The maximum distance between the spindles and the top of the table is 20 inches, the distance between the centers of the various spindles is 24 inches. The spindles are driven by direct gearing and will drill holes up to 1 inch in diameter. The driving arrangement is placed under the table or bed; this latter is 10 feet long by 3 feet wide.

D. Mitchell & Co., Ltd., Keighley, England, have placed on the market a new 4-foot radial drilling and tapping machine. The design is similar to that of ordinary radial drills, but there are some improvements in the driving and back gear arrangements. The drive may be either a 4-step cone driving the machine in the ordinary manner with or without back gears, or the machine may be supplied with a gear box and a single pulley drive. The arm is of pipe section and may be turned around to a complete circle; it is raised and lowered by means of worm gear and rack and pinion. The feeds obtained are 0.017, 0.011 and 0.006 inch per revolution of spindle. The bed of the machine is 2 feet 1 inch deep by 2 feet 3 inches wide and is provided with T-slots on the top and on the sides.

The firm of John Hetherington & Sons, Ltd., Manchester, England, has brought out a new high-speed radial drill. This machine is fitted either with self-contained motor drive or with countershaft drive, and is geared either directly to the spindle or by double or triple back gear arrangement. It is intended for use with high-speed steel drills. The radial arm has an adjustment through an arc of 180 degrees. The spindle has a diameter of 3 inches. The maximum distance from the base-plate to the spindle nose is 6 feet 2 inches, and the minimum distance is 4 feet 2 inches. The length of the radial arm from the center of the trunnion to the outer end is 7 feet 10 inches. The required floor space is 13 feet x 16 feet 3 inches. One smaller and two larger sizes of the same design are built by this firm.

In the first half of the year 1906 Scotland produced an amount of tonnage from her shipyards unprecedented in the history of shipbuilding. In these six months, according to a Glasgow dispatch, the shipyards put into the water no less than 207 vessels of all sizes, with an aggregate tonnage of 360,489. The nearest approach to that record was made in Scotland in 1902, when in six months 259,804 tons were produced. The large output from the Clyde yards was augmented by the launches of the *Lusitania*, a Cunard steamer of 32,500 tons, and the *Agamemnon*, a battleship of 16,500 tons, in the closing weeks of the half year.

The automobile and the motor omnibus have been considered in this country by many as more or less of a superfluous luxury. For this reason it is surprising to realize that the motor omnibus traffic in London reaches proportions far above what we generally conceive of. The motor omnibus in London carries in a year nearly 80,000,000 passengers which is considerably more than half the number of passengers carried by the New York subways. This fact is one of those which indicate the future of the automobile for other than recreation and racing purposes, and the automobile would fill its place and justify its existence far better if developed along such lines of general usefulness than along the lines of an expensive, and in many cases unnecessary, luxury.

SOCIETY FOR PROMOTION OF INDUSTRIAL EDUCATION.

In response to a call issued a month or two ago by a committee formed for the purpose, a party of manufacturers, educators, social workers and others interested in the project gathered at Cooper Union on the afternoon of the 16th of November, when the National Society for the Promotion of Industrial Education was organized and launched on what promises to be a thoroughly useful career. The objects of the society as expressed in the constitution adopted by that meeting are: "To bring to public attention the importance of industrial education as a factor in the industrial and educational development of the United States; to provide opportunities for the study and discussion of the various phases of the problem; to make available the results of experience in the field of industrial education both in this country and abroad; and to promote the establishment of institutions for industrial training."

The following officers were elected: President, Henry L. Pritchett, president of the Massachusetts Institute of Technology; vice-president, M. W. Alexander, General Electric Co., Lynn, Mass.; treasurer, V. Everit Macey, New York City. A board of managers consisting of twenty-seven members was also selected.

In an evening meeting of surprisingly large attendance, President Murray Butler of Columbia University presided, in the absence of President Pritchett, who was detained by ill health. This assemblage, in the crowded main hall of Cooper Union, was addressed by Dr. Butler, Frank G. Vanderlip, of the National City Bank, who spoke on the influence industrial education might play in our trade relations; Frederick P. Fish, president of the American Telephone & Telegraph Co., who discussed its effect upon citizenship; Alfred Moseley, whose speech related to American educational methods in general; Samuel B. Donnelly, secretary of the Building Trades Labor Association, who expressed the sympathy of organized labor with the aims of the new society; and, finally, Miss Jane Addams, of Hull House, Chicago. She dwelt upon the educational and moral side of the movement and expressed the hope that industrial education would lead to a greater satisfaction with life on the part of the workman, than was possible when he considered his work to be only a means of livelihood, without having for him any intrinsic interest.

According to the constitution adopted, all persons interested in industrial education are eligible to membership in any one of the four following classes: Members, paying annual dues of $2; sustaining members, paying annual dues of $25; life members, consisting of those who pay the sum of $250 or more; and honorary members, who are elected to that position by the unanimous vote of the board of directors, on account of having achieved "special distinction in promoting industrial education."

* * *

PERSONAL.

Corneil Ridderhof, treasurer and general manager of the Wilmarth & Morman Co., Grand Rapids, Mich., has sold out his interest in that company. He will remain with the concern for the remainder of the year.

* * *

FRESH FROM THE PRESS.

Annual Report of the State Geologist of New Jersey for the Year 1905. 338 pages, 6 x 9 inches. Illustrated. 3 maps. Copies can be obtained upon request. Address Mr. Henry B. Kummel, State Geologist, Trenton, N. J.

Car Interchange Manual. Booklet form 3½ x 5¾ inches. 223 pages. Published by the McConway & Torley Co., Pittsburg, Pa. Price 25 cents.

This book is a companion of the Catechism of M. C. B. Rules and is devoted to abstract decisions of the Arbitration Committee of the Master Car Builders' Association. It contains abstracts of cases 1 to 703 inclusive. Some miscellaneous matter is added, giving monetary values of wooden cars; tables of words often misspelled on car reports; limits of tire wear for various types of steel-tired wheels, principles of levers, first aid to the injured, etc.

The Mechanical World Pocket Diary and Year Book for 1907. 247 pages (exclusive of advertising). 4 x 6 inches. Published by Emmott & Company, Limited, Manchester, England.

This is a small mechanical handbook, issued annually, containing the useful tables and formulas found in handbooks of this kind. It is particularly complete in regard to steam engineering, nearly 100 pages being given up to this subject. At the end of the book is a calendar for 1907 with more than 50 pages for memoranda. For general use this is a very handy little book well worth its cheap price which is only 25 cents in England, but if ordered from the United States the postage to this country must, of course, be added.

Practical Alternating Currents. By Newton Harrison. 375 pages, 5 x 7½ inches. 172 cuts. Published by W. L. Hedenberg Publishing Co., New York. Price $2.50.

This book is a practical treatise on the principles and application of alternating currents and is written in a delightfully easy style. Mr. Harrison is an author of rare ability in presenting a complex subject in a simple and entertaining manner. We know of no treatment on alternating currents and power transmission so well adapted to the needs of young electricians and others desirous of understanding the principles of the alternating current as this. The book is gotten up in pleasing style, well printed and is altogether a creditable effort in the field of technical publication.

Catechism of the M. C. B. Rules, 1906. Pamphlet form 3¼ x 6 inches, 40 pages. Published by McConway & Torley Co., Pittsburg, Pa.

The booklet is what the title indicates, being a résumé in the form of questions and answers of the important Master Car Builders' rules. It contains a number of illustrations, formulas, etc., and is well worth having by those interested in car construction and maintenance. Copies are sent free on request to those interested.

Machine Design. By Charles L. Griffin. 184 pages, 6 x 8 inches. 82 cuts. Published by the American School of Correspondence, Chicago, Ill. Price $2.00.

This book forms part of the course of instruction in mechanical engineering of the American School of Correspondence and doubtless is one of the best treatises on practical machine design. It was warmly commended in these columns in the first review some years ago. It is strictly in sympathy with actual conditions which the machine designers have to meet, being written by a man well known for his sound mechanical judgment and practical common sense, who was, and is, closely in touch with the conditions surrounding the design and construction of machines. The work is well worth the attention of all machine designers.

Turning and Boring Tapers. By Fred H. Colvin. Pamphlet form, 5½ x 8 inches. 25 pages. 22 cuts. Published by the Derry Collard Co., New York. Price 25 cents.

This booklet is No. 1 of a series of practical papers, and is a copy of the second edition. The determination of tapers and the setting of machines to produce them is a matter of practical importance to shopmen. It perhaps would not be far from the fact to say that there is no one other technical subject that interests a lathesman more than this, and a book which will tell him just how to measure or determine the proper setting for tapers and give him a comprehensive and correct idea of the subject as a whole, is of much intrinsic value. This little work undoubtedly fills the bill.

The Machinist and Toolmaker's Instructor. By Edward Genung. 264 pages, 4 x 6¾ inches, illustrated. Bound in "pocketbook" style with flap Sold by N. H. Covert, Beaver Falls, Pa. Price $3.00.

This book was published by Edward Genung in 1896 and, of course, is not a new book containing all the latest features of toolmaking and mechanical work which have been developed since that time. A great deal of the matter, however, is of a character that is always good and instructive for apprentices, mechanics and others requiring the information contained. The book treats of arithmetic; geometry; screw threads; trigonometrical tables; gearing, including spur, spiral, bevel and worm gearing; milling machines; principles of mechanics; screw-cutting, steel working, etc. Many will doubtless find it of much practical value in their everyday work.

Air Compressors and Blowing Engines. By Chas. H. Innes. 290 pages, 4¾ x 7 inches, 285 cuts. Published in the United States by the D. Van Nostrand Co., New York. Price $2.00.

This book is specially intended for mechanical engineers taking up the theoretical as well as the practical sides of the subject. The first chapter treats of the physical properties of air, following which are chapters on experiments with compressors; valves for producing equalization of pressure; blowing engines; and air compressors. The theoretical chapter on the physical properties of air is of considerable extent, but without use of the higher mathematics. The general descriptive part has reference, of course, to British types of machinery. The illustrations are mostly line cuts and reproductions of wood engravings. These are not very well executed, but the book as a whole is of considerable value to those interested.

Text-Book on the Strength of Materials. By S. E. Slocum and E. L. Hancock. 236 pages, 6 x 9 inches. 170 illustrations. Published by Ginn & Co., Boston, New York and Chicago. Price, $2.00; by mail, $2.15.

The subject matter of this book has been divided into two parts: the first presenting the theoretical side of the strength of materials and the second the experimental side. This was done to provide for the needs of both the classroom and the laboratory. As might be expected, the theoretical side of the subject is rigidly mathematical, using the calculus for the deductions. Part 2, or the experimental part of the book, treats of the properties of iron and steel, lime, cement and concrete, reinforced concrete, brick and building stone, timber, rope, wire and belting. An excellent feature of the mathematical part of the book is the insertion of numerous problems to be worked out by the student. The answers are given in the back of the book.

Marine Engineers; Their Qualifications and Duties. By E. G. Constantine. 332 pages, 4¾ x 7 inches. 84 cuts. Published in the United States by D. Van Nostrand Co., New York. Price $2.00.

As indicated by the title this work is of the practical duties of marine engineers, giving an idea of what the nature of a marine engineer's duties are; what the requirements are as to education and training, term of apprenticeship, etc. The work takes up the history of the marine engine and its development; it treats of boilers and boiler management; and in addition gives copious notes on the Board of Trade examinations which must be passed in Great Britain in order to get an engineer's certificate. The book is interestingly written and presumably reliable in its statements. The work, of course, is strictly British in tone and the technical requirements laid down are those affecting British commerce and do not necessarily apply to the requirements for American marine engineers.

Metallurgy of Cast Iron. By Thomas D. West. 627 pages 4¾ x 7¼. 153 cuts. Published by the Cleveland Printing Co., Cleveland, Ohio, and sold by the David Williams Co., New York City. Price $3.00.

This well-known work now appears in the eleventh edition. The wide sale it has had is an indication of its worth to foundrymen and foundry chemists. The conditions of foundry practice have undergone a great change within the past twenty years; the old-time method of mixing depending on the judgment of the cupola charger has been largely superseded by the more intelligent and reliable practice of charging according to analyses. It is a consummation for which Mr. West has worked diligently, and to his efforts in a large measure, no doubt, is the improvement in present American foundry practice due. The book is a standard treatise on the metallurgy of cast iron and should be in the hands of every practical foundryman who expects to make a success of his business.

CONTENTS FOR DECEMBER.

American Stationary Engineering. By W. E. Crane. 285 pages, 5½ x 7½ inches. 107 cuts and diagrams. Published by the Derry Collard Co., New York. Price $2.00.

This book is intended for the engineer and fireman of power plants and the mechanical engineer as well. It is strictly practical in every respect, containing just such information as many are looking for but which is contained in few available works. The book treats of the boiler room; boiler feeding, pumps for boiler feeding; scale in boilers; boiler cleaning; strainers; strength of boilers; boiler settings and fittings; boiler explosions; taking care of expansion; main steam pipes; steam heating; mason work; making cements; pile driving; brick and steel chimneys; the engine room; balancing engines; lining engines; bushing cylinders. piston rods; hot boxes; Corliss engines; air pumps and condensers; tools for the engine room; belting, horse-power, belts; oils; cleaning; compression lap and lead; steam pumps; safety valve calculations; pop valves; estimating water power; examination questions, etc. It is one of the few books that can be conscientiously recommended to engineers, firemen and others requiring sound instruction on the essential principles and practices of stationary engineering.

NEW TRADE LITERATURE.

Rockford Machine Tool Co., Rockford, Ill. Circular describing and illustrating the 20-inch Rockford shaper.

The Graham Mfg. Co., Providence, R. I. Leaflet describing the Graham drill speeder, telling some things it will do and giving dimensions.

W. F. & John Barnes Co., 231 Ruby St., Rockford, Ill. Catalogue No. 61 treating of upright drills and other machine tools. These machines are illustrated and such description as is necessary is given.

Gisholt Machine Co., 1316 Washington Avenue, Madison, Wis. Leaflet illustrating a method employed by this company for finishing an automobile flywheel.

Joseph Dixon Crucible Co., Jersey City, N. J. Pamphlet of Dixon's motor lubricants. Lists and describes the various graphite lubricants and points out advantages of same.

The Pittsburg Automatic Vise & Tool Co., Pittsburg, Pa. Illustrated catalogue descriptive of the Pittsburg automatic two-way vises, a departure from former vise construction.

The Fairbanks Co., Springfield, Ohio. Catalogue No. 6 of "United States" tool-holders describing new lathe, planer and shaper tools including turning, threading, side, boring and cutting-off tools.

Franklin Mfg. Co., 203 South Geddes St., Syracuse, N. Y. Booklet showing the possibilities of the Franklin die cast process. Illustrations of the different styles of finished castings produced by this die cast method are shown.

The John M. Rogers Works, Gloucester City, N. J. Pamphlet of high-speed reamers containing illustrations and specifications of various types of reamers, all of which are fitted with high-speed steel blades.

Buckeye Engine Co., Salem, O. Catalogue of Buckeye electric blue-printing machine. A complete description of the construction of this machine is given as well as prices of and directions for operating same.

The Cincinnati Ball Crank Co., 1644-46 Central Avenue, Cincinnati, O. Pamphlet illustrating and giving specifications for steel ball crank machine handles, compound rest handles, machine handles and two-ball levers.

Narragansett Machine Co., Providence, R. I. Locker catalogue listing and illustrating their standard sizes of lockers. It is the aim of the company to produce a high grade steel locker, and special care is given to details, as will be seen by the illustrations on pages 4 to 7.

Norton Grinding Co., Worcester, Mass. Catalogue of Norton plain machines for cylindrical grinding. Specifications and excellent half-tone engravings of the different machines are given. Following the introduction are brief descriptions of the various parts of the machines and a list of their points of superiority.

Waterbury Farrel Foundry & Machine Co., Waterbury, Conn. Catalogue Section A describing "cold process" automatic nut bolt rivet machinery. The several styles of headers have been improved and redesigned throughout and now possess greater strength, durability, speed, ease of operation and adjustment.

Hammacher, Schlemmer & Co., 4th Avenue and 13th Street, New York. Catalogue No. 310 on high-grade woodworking tools in sets. This includes tool outfits for home use as well as for the trades. The special feature of these outfits is the quality of the tools, only those of high grade being included. Price lists and illustrations of several of the outfits are given.

L. H. Gilmer & Co., Philadelphia, Pa. Report of test made of Gilmer endless belts at the Springfield Armory. The test demonstrated that the Gilmer endless belt is superior to leather belts for use on machines having pulleys of small diameter inasmuch as it is less liable to stretch, is light and the joint is of the same thickness as the remainder of the belt.

Ingersoll-Rand Co., 11 Broadway, New York. Bulletin No. 2008, Imperial hoists and stationary motors, gives a complete description of the Imperial motor hoist with illustrations and tables of sizes and dimensions. The Imperial stationary motor, also described, is a small motor of the standard Imperial type designed for all purposes requiring a small but powerful engine for intermittent service. Illustrated part lists of each machine are also included. Bulletin No. 2011, the "Little Jap" hammer drill discusses fully the construction, operation and advantages of this tool.

Joseph Dixon Crucible Co., Jersey City, N. J. The tenth edition of "Graphite as a Lubricant. The subject of lubrication in general, and graphite lubrication in particular, is exhaustively treated. All the good features of the previous edition are retained, but the very latest information—both scientific and practical—that has to do with the subject is added, making it valuable to the student of theory and the man of practice. The publication is arranged and indexed so as to readily enable the reader to find the information he is most interested in. Those who desire to post themselves on better lubrication should secure a copy.

The Western Electric Co., Chicago, Ill. Booklet entitled "Hawthorne Works," being a general description of the Western Electric Co.'s plant at Hawthorne, Ill., which was described in Machinery, for July, 1906. This plant is erected at the extreme west of the city of Chicago, a tract of 110 acres having been purchased five years ago for it and to which more land has since been added. The plant is modern in every respect. The machine shop is 860 feet long, 130 feet wide and is equipped with up-to-date tools for the manufacture of electrical apparatus. The company put special stress on the fact that they are in position to build heavy electrical apparatus and have all the facilities for such work.

The Cincinnati Milling Machine Co., Cincinnati, Ohio. "Examples of Rapid Milling," being an illustrated pamphlet containing sixty illustrations of work done on the Cincinnati milling machine, taken from actual practice. Each example is a half-tone illustration showing the work, the machine, cutters and fixture or jig used for holding the work. One page is given up to each example and data are given, showing the nature of the job, size of cutter, speed in revolutions per minute, surface speed and feed. The pamphlet is a valuable contribution to technical literature, giving data on milling machine production of much value. Needless to say it is an effective argument for the milling machine on the class of work illustrated.

The American Locomotive Co., 111 Broadway, New York, have just published a pamphlet "Consolidation Type Freight Locomotives" describing consolidation locomotives weighing more than 175,000 pounds. It is a companion to the one issued in October presenting the design of this type weighing less than 175,000 pounds. Twenty-eight consolidation locomotives built for various railroads and ranging from 175,000 pounds to 250,000 pounds are illustrated and the principal dimensions of each given. The series now covers the Atlantic, Pacific and Consolidation types and copies of any or all of these pamphlets will be sent upon request.

B. F. Sturtevant Co., Hyde Park, Mass. Catalogue No. 140 on Sturtevant high-pressure blowers. This catalogue is one of the Sturtevant engineering series, and is gotten up with a view of not only advertising the Sturtevant high-pressure blower, but of also presenting engineering data of value on the movement of air by blowers. It describes in detail the Sturtevant high-pressure blower which was described in the February, 1906, issue of Machinery and gives data on diameters of blast pipes, data of value to foundrymen regarding the composition of pig-iron, composition of resulting iron, etc. It also gives a chapter on the construction of the Sturtevant vertical engine. The concluding chapter on testing blowers is of much technical interest and value, giving formulas for determining the volume of air and tables and diagrams determining the weight per cubic foot of dry air under different pressures and temperatures, the flow of air through orifices, etc. It is altogether a most attractive, interesting and valuable catalogue.

The Committee of Manufacturers, 21 William Street, New York City, has sent us a copy of regulations No. 30 U. S. Internal Revenue, entitled "Regulations and Instructions concerning Denatured Alcohol." The law passed by Congress last winter relieving properly denatured alcohol of the internal revenue tax opens up a large field for its use in the arts, and the regulations and instructions concerning denaturing alcohol are of importance to those who intend to enter into manufacture requiring its use. A completely denatured alcohol consists of 100 parts ethyl or grain alcohol (not less than 180 degrees proof or 90 per cent pure), 10 parts methyl or wood alcohol, and ½ part of benzine. Other denaturing substances for alcohol users who cannot use a mixture of grain and wood alcohol, will be taken up in the near future by the Internal Revenue Bureau. The spirit of the law was to render the preparation of denatured alcohol cheap, but the restrictions surrounding it seem to us to favor a distillery trust and to tend in a measure to defeat the aim. However, the matter is a difficult one to handle, and perhaps the prescribed Government regulations are all strictly necessary.

RAILWAY MACHINERY.

A special edition of MACHINERY devoted to Locomotive and Car Equipment and Mechanics.

January, 1907.

FOUR-CYLINDER BALANCED ENGINE RAILWAY MOTOR CAR.

CHARLES R. KING.

A new type of engine for self-propelled railway car has been designed and built for the trunk line services of the Bavarian State Railways by the firm of J. A. Maffëi at Munich, Bavaria. Its peculiarity consists in the complete elimination of the disturbances due to the alternate push and pull on the crank-pins common in all engine arrangements in vogue at the present, which disturbances communicated to the car frame are apt to be very unpleasant to the passengers when the engine is working hard—the pounding on the crank-pins then being such as to give electrical transmission the preference for self-propelled vehicles on railways.

By introducing the steam between two pistons, or simultaneously on their two outside surfaces so that they always travel in opposite directions, the thrusts on the engine frames are completely equalized. In the new Maffëi engine this is done by means of two pistons working in practically one cylinder, the main-rods of each pair of pistons being con-

Fig. 1. Four-cylinder Balanced Engine and Turgan Water-tube Boiler.

Fig. 2. Balanced Engine Motor Car for Bavarian State Railways.

nected to a different driving axle so that all motor efforts are absolutely balanced. At first sight this may seem a trifling consideration, but it is by no means ignored by those who are interested in electrical propulsion and whose claims must be met if steam is to survive in the struggle between the two. The mechanical details of this new engine have been worked out with admirable skill, and the drawings here reproduced will be found to be very instructive.

The half-tone, Fig. 1, shows the boiler, which is of the Turgan water-tube type much employed in France for heavy road motor cars. A superheater (Schmidt type) is fitted to the boiler. The sills of the car are supported on brackets bolted to the cylinder casting at the height of the piston valve chests. This is shown in the cross section but is more clearly understood from the photograph of the motor. The side movements of the frame upon these brackets are flexibly controlled by plate springs, with small bumpers affixed, and aligned longitudinally above the cylinder casting.

The cylinder valves are of the piston type. There is one for each of the four cylinders, the two valves being screwed to the same spindle above the same pair of cylinders. The forward valve is double-ended and the rearward valve single-ended; this arrangement is best described by the cut, Fig. 3 (longitudinal section). The valves are driven from single eccentrics on the rear axle. The valve gear is of the usual Walschaerts or Heusinger type, but the lead-lever is in this case, not connected to a cross-head pin, a feature which is worth copying where great accuracy in the distribution is desirable. The main-rods drive on the crank-pins close up to the wheel face. The pins carry heavy cranks for the side-rods which are provided in order to insure the due position of all engine cranks. The side-rods are situated at sufficient distance from the wheel faces to just clear the outsides of the cylinders. The main-rods have "Y little-ends" of strap pattern with double gibs, and cotter for adjustments; the big

ends being of fork pattern so that the main rods can be taken down readily. Each end of the cylinders as well as their centers are provided with relief pressure and suction valves; and although a Schmidt superheater is employed the usual cocks for the drainage of the cylinders are fitted. The plunger for the boiler pump is fitted at the front extremity of the valve stem. The motorman's platform is situated at the front end of the car which has to be turned at the terminus station. There is, of course, only one attendant; the stoking is automatic as the coal is carried in a hopper on the front of the boiler (firebox end) from which it falls by gravity onto the fire. All the usual gages and levers necessary for the running control of the engine are grouped under the attendant's hands in front of the driving platform.

The Maffëi engines with Turgan water-tube boilers and superheater weigh 1,760 pounds less than the same powered engines with ordinary locomotive-type boiler and superheater. Both classes of motor have been found to be very economical in working. They are designed for all speeds up to 47 miles per hour. The same Maffëi balanced engine is applied to small light-service tank locomotives of the Bavarian State with the single difference that the coupling rods are placed inside of the engine frames.

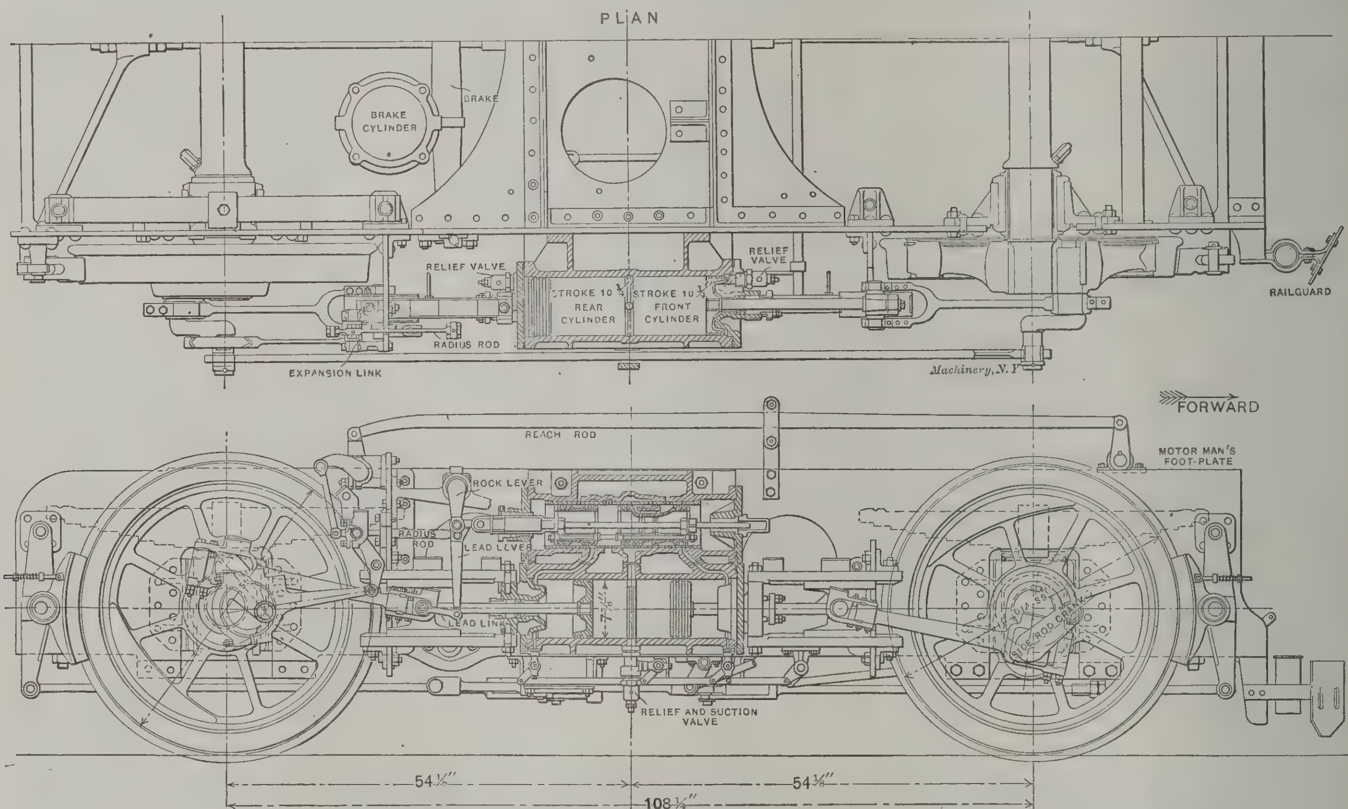


Fig. 3. Half-plan and Sectional Side Elevation of Four-cylinder Balanced Engine and Truck.

MOTOR.

Cylinders, diameter	7⅞ inches
Piston stroke	10¼ inches
Driving wheels, diameter	39 inches
Boiler pressure	135 pounds
Tractive power	3,700 pounds
Grate area	8.9 square feet
Heating surfaces of water tubes in contact with fire	456 square feet
Superheating surfaces	79.6 square feet
Total heating surfaces	535.6 square feet
Weight empty	15.75 metric tons
Weight loaded	17.40 metric tons
Water tank capacity	8,800 pounds
Coal bunker capacity	1,300 pounds
Wheel base of motor	108¼ inches
Minimum radius of curves	590 feet

CAR

Seating capacity	55
Baggage room	59 square feet
Truck wheels, diameter	39 inches
Truck wheels, wheel base	98.4 inches
Total wheel-base of car	51.5 feet
Total length of car over all	65.6 feet
Weight of motor car, empty	45.9 metric tons
Weight of motor car in working order	51.5 metric tons
Weight of trailer car	40 metric tons

COUNTERBALANCING LOCOMOTIVE DRIVERS.

W. M. H.

While working as a machinist in various locomotive repair shops I have seldom met with journeymen who are so well acquainted with locomotive counterbalancing as to confidently undertake the counterbalancing of a set of driving wheels. The practice mostly met with has been to assume that the correct weights have been supplied by the office or drawing department, and to let the wheel men merely apply these weights to the wheels.

However, it is very pleasing to find an interest manifested in this subject by many of the more progressive machinists and apprentices, and I know of no other mechanical subject more eagerly discussed by these than counterbalancing. Seeing so little that is of practical value to the average machinist in the shop published in the mechanical journals on this subject, prompts me to submit both the method adopted by a road I formerly worked for and the actual figures used in applying the method to an eight-wheel (four-wheel connected) engine reported as being out of balance. I also show half-tones (Figs. 1 and 2) of the method used in weighing the wheels and rods, as some may not even understand how this is done. There may be other methods used but the results obtained from the one submitted has proved most satisfactory indeed.

The manner of leveling the wheels, it will be noted, is by the use of the adjusting screws at the bottom of the iron trestles. The straight-edge used has the offset so that the crank-pin does not interfere. One main-rod is also shown on the floor ready for weighing.

Method for Counterbalancing Eight-wheel (4–4–0) Locomotive Driving Wheels.

The revolving weights to be considered are crank-pin hub, crank-pins complete with washers, nuts and cotters, side-rods complete with strap bolts, nuts, keys, set-screws, brasses, liners and oil-cups.

The reciprocating weights to be considered are the piston complete with follower, bull- and packing-rings, liners, bolts and piston-rods, crosshead complete with gibs, oil-cup, wrist-pin, nuts, washers, piston-rod keys and cotters, front end of main-rod complete with brasses, strap keys, bolts, nuts and oil cups.

To find the center of gravity of the counterbalance, make a thin wood or plate templet of the same shape and area as the entire counterbalance block area; suspend this templet from

various points near its several edges and note where the plumbed lines, made from the same points of suspension, intersect on the surface of the templet, when the latter is suspended in the different positions. The intersection of these lines will be the center of gravity of the counterbalance block, provided it is of the same thickness throughout.

To Weigh the Rods.

To weigh the side-rods, level the rods to be weighed on suitable knife-edge supports placed centrally through the crank-pin opening, putting all the parts of the rod which go to make the revolving weight, in the proper places and block up under the supports so that each block may be removed in turn and the weight resting on the support indicated on the weigh scales. The weight so taken, less the weight of the support, will be the weight of the rod on that crank-pin. To weigh the main-rods, weigh each end of the main-rod in the same manner as for the side-rods.

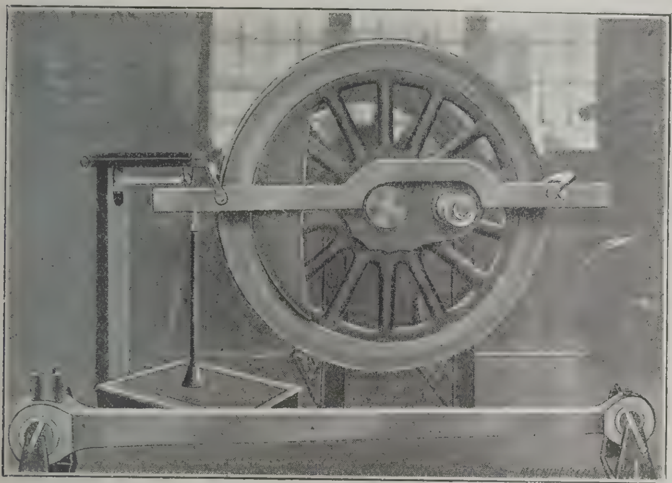

Fig. 1. Weighing the Main-rod and the Counterbalance.

Distribution of the Reciprocating Weight.

Two-thirds of the total reciprocating weight belonging to each side will be the proportion to be balanced in the wheels on that side. Each wheel will be balanced for all of its revolving weight and its proportion of the two-thirds of the reciprocating weight. The portion of the reciprocating weight to be balanced will be divided between the main and rear wheels in proportion to the revolving weight to be carried by each crank-pin.

The Revolving Weight to be Carried by the Main Crank-pin.

The revolving weight to be carried by the main crank-pin will be the front end of the side-rod and the back end of the main-rod. The revolving weight to be carried by the rear crank-pin will be the back end of the side-rod.

Rule for Working Out the Required Weight to be Put On.

1. Find the weight of the main-rod, side-rod and the reciprocating parts.

2. Find the proportion of the two-thirds part of the reciprocating parts to be carried by each wheel. To do this multiply the revolving weight on the front wheel by the two-thirds part of the reciprocating weight and divide by the total revolving weight of both wheels, and the quotient will be the proportion of the reciprocating weight to be divided which is to be carried by the front wheel; subtract the quotient from two-thirds of the reciprocating weight and this remainder will be the proportion of the reciprocating weight to be put on the back wheels.

3. To find the weight required at a radial distance of 36 inches on the front wheel, add the revolving weight on the front wheel to its proportion of the reciprocating weight and divide the sum by 3 (for 12-inch cranks) and the quotient will be the weight required at 36 inches; then subtract the weight already in the wheel from this result and multiply the remainder by 3 and that product by 12, the crank-pin distance, and divide by the distance to the center of gravity and the quotient will be the amount to be put on at center of gravity.

To Find the Correct Amount of Counterweight.

The wheels to be counterbalanced must be on the axles and have the crank-pins, with washers, nuts and cotters applied. Place the wheels with the journals resting on suitable trestles and level up in each direction. Clamp a straightedge on the wheel to be worked on, in line with the crank-pin and axle centers. Then at a point on the counterbalance side, exactly three times the length of the crank-pin radius from the center of the axle, place a perpendicular support to rest on the scales; when the straightedge has been leveled this weight less the support will give the weight already in the wheel at 3 times the crank-pin distance.

Applying the Formula to an Actual Case.

Engine No. 114 was sent in to the shop as being out of balance, and orders were given to have the wheels weighed up and made correct. The crank-pins of this engine were 12 inches from the center of the axle, and the wheels shown in the half-tones are being weighed at a point 36 inches from the center of axle. It does not matter what distance they are weighed at, so long as this distance is taken into consideration when making the calculations. I will now give the exact figures used in doing this work. The reciprocating weights were:

Front (crosshead) end of main-rod....	203.5	pounds
Crosshead complete	259	pounds
Piston complete	328	pounds
Total	790.5	pounds

Two-thirds of which = 527 pounds.

The revolving weights on the front wheel were:

One end of side-rod..................	143.5	pounds
Back (crank-pin) end of main-rod....	358.5	pounds
Total	502	pounds

The revolving weight on the front wheel multiplied by two-thirds of the reciprocating weight is $502 \times 527 = 264{,}554$; dividing by the total revolving weight on both wheels, which for the front wheel is 502 and for the back wheel (one end of side-rod) is $143.5 = 645.5$ pounds we have $264{,}554 \div 645.5 = 409.8$ pounds, the reciprocating weight to be counterbalanced in the front wheel.

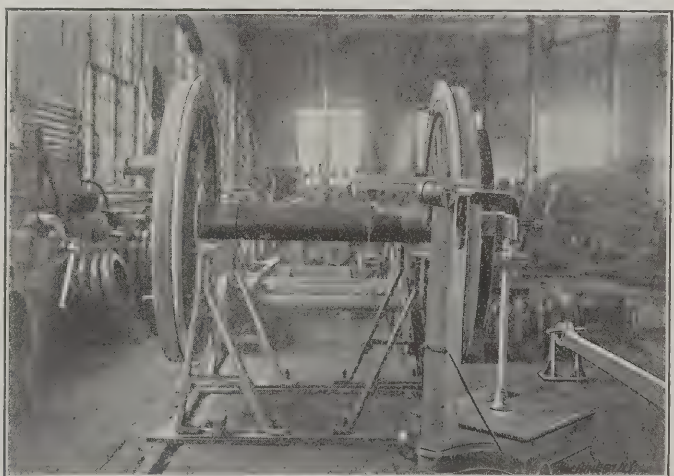

Fig. 2. Weighing the Main-rod and the Counterbalance.

Subtracting this reciprocating weight to be counterbalanced from two-thirds of the reciprocating weight we get $527 - 409.8 = 117.2$ pounds reciprocating weight to be counterbalanced in the back wheel; adding the revolving weight on the front wheel to the reciprocating weight or $502 + 409.8 = 911.8$; divide this by 3 and the quotient 303.9 pounds will be the weight required at 36 inches from the axle center.

Taking 107.5 the weight already in the wheel at 36 inches from 303.9 will give us 196.4 *light* at 36 inches radius; this multiplied by $3 = 589.2$, and again by 12 gives 70,604; divided by the distance to the center of gravity which is 20 inches the quotient is 353.4 pounds *light* or the amount that has to be added to each front wheel at the center of gravity.

The weights to be considered in the back wheel were:

Reciprocating weight	117.2 pounds
Revolving weight one end of side-rod..	143.5 pounds
Total	260.7 pounds

This total weight divided by $3 = 86.9$ pounds, the required weight at 36 inches; subtracting the weight already in the wheel which was 37 pounds, as shown by the scales, $86.9 - 37 = 49.9$ pounds at 36 inches; this multiplied by 3 and 12 and divided by 20, the distance of the center of gravity from the center of the axle, gives the weight required to be applied at the center of gravity, or 89.8 pounds required weight to be added to each rear wheel.

For practical purposes the decimal figures could be discarded but I put them in as I promised to give the actual figures used on the job. It will be seen that this engine was badly out of balance. It has now been running several years, and when I left the service of that company it was giving good satisfaction. If I have not made the subject clear to all interested I would be pleased to give further explanations, but I feel that some at least will be able to follow my somewhat rambling description of locomotive counterbalancing as it was carried out some years ago.

[It should be remembered that where the author speaks of multiplying the revolving weight on each wheel by two-thirds of the total reciprocating weight, and dividing the product by the total revolving weight that it is so worded in order to express a proportion. Of course, strictly speaking, pounds cannot be multiplied by pounds, but what is done is to obtain that fractional part of the total reciprocating weight represented by the individual revolving weight divided by the total revolving weight. Expressed as a proportion we have:

$w : W = r : R$

in which w = revolving weight in individual wheel,

W = total revolving weight in both wheels,

r = part of reciprocating weight to be counterbalanced in individual wheels,

R = 2/3 total reciprocating weight.

Then $r = \dfrac{wR}{W}$. —EDITOR.]

Machinery, N.Y.

is its conciseness, all the dimensions for each axle being given in the table, reference letters indicating the location of each dimension for the four sizes. For example, the diameters of the wheel fit are found in column I, being 5⅛, 5¾, 6½ and 7 inches respectively, and so on.

PACIFIC TYPE (4–6–2) LOCOMOTIVE FOR NATIONAL RAILWAY OF MEXICO.

An order of five Pacific type locomotives has recently been completed at the Schenectady works of the American Locomotive Company for the National Railway of Mexico. These are the first of their type to go into service on this road, up to the present time the ten-wheeler having been used in handling their passenger traffic. The order consists of three different classes, as follows: three simple engines with Richardson

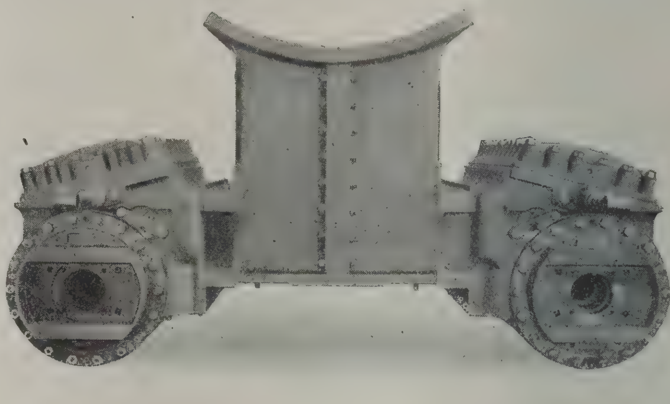

Fig. 1. End View of Pair of Typical Allfree-Hubbell Cylinders.

slide valve, one with Allfree-Hubbell valves and cylinders, and one Cole four-cylinder balanced compound engine with Walschaerts valve gear. As these three classes are of the same specifications except for the difference in cylinders and valve gear an exceptional opportunity is afforded for comparison between them as regards cost of maintenance and operation.

The cylinders of the two classes of simple engines are 22 inches in diameter by 28 inches stroke, and except for the differences in the design of the cylinders and valves the two classes are identical.

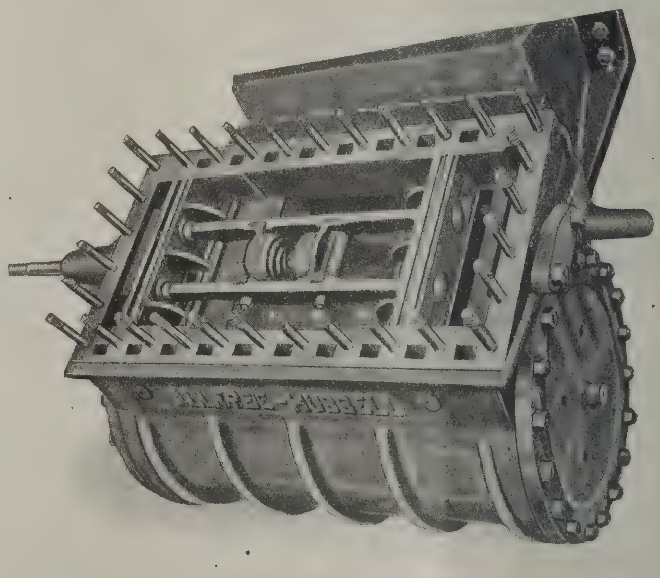

Fig. 2. Side View of Typical Allfree-Hubbell Cylinder with Steam-chest Cover Removed.

The principal features of the Allfree-Hubbell design are that the point of both exhaust opening and closure occurs later in the stroke for all points of cut-off and the amount of cylinder clearance is reduced from 8 per cent and over, as in the ordinary design of cylinder, to about 2½ per cent.

The main steam valve is very long and has inside admission and the delayed exhaust opening is obtained by giving it about 7/16 inch exhaust lap. The delayed exhaust closure is effected by means of compression controlling valves. These are piston valves located in the wall between the steam port and exhaust passage and are operated by a dash-pot connection with the main steam valve. This connection is so arranged that the compression controlling valves open simultaneously with the exhaust edge of the main steam valves but do not close until the main valve has covered about 1¼ inch of the exhaust steam ports. They thus serve the double purpose of delaying the closure of the exhaust until about

90 per cent of the stroke has been completed in short cut-offs and increasing the area of the exhaust opening, thereby allowing the cylinders to quickly free themselves. The reduction of cylinder clearance is effected by means of very short steam ports opening directly into the ends of the cylinders and by less space between the valve seat and the cylinder than in the ordinary design, the top wall of the cylinder in the Allfree-Hubbell design being the bottom wall of the steam chest. The steam chest cover, which also acts as a balance plate to the valve, and is in reality the exhaust chest, is cored out in such a manner that the exhaust passage is passenger and freight locomotives on several roads of the country.

The Cole four-cylinder balanced compound engine is the second instance of the application of this system of compounding to the Pacific type. The first Pacific type engines with this arrangement of cylinders were built for the Northern Pacific Railway. These engines were illustrated in RAILWAY MACHINERY June 1904 and December 1906, and the particular features of this system of compounding fully described, so that it is not necessary in this article to go into a detailed description of the design.

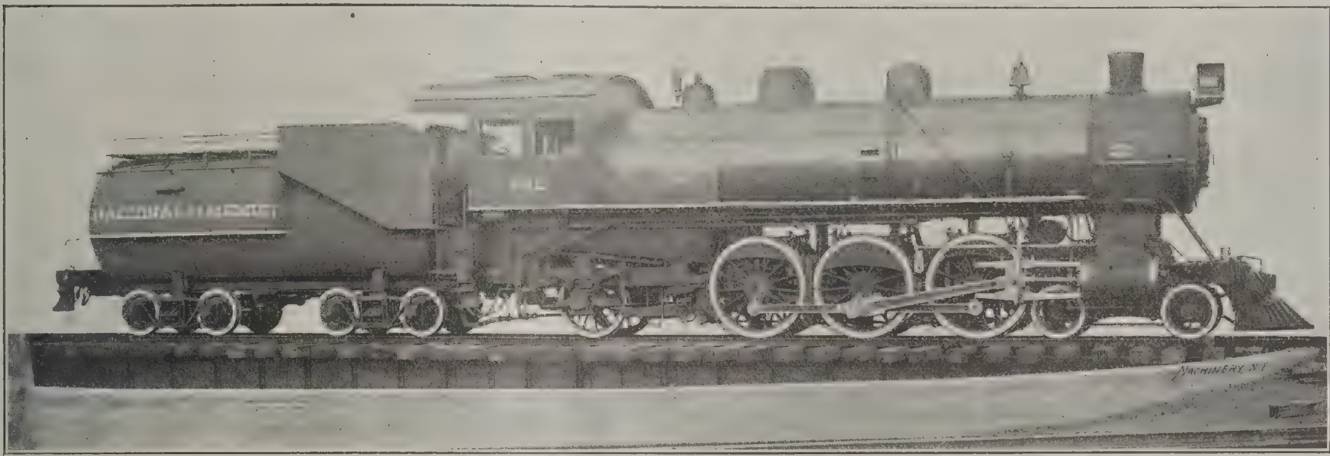

Fig. 3. Simple Slide-valve, Pacific Type Locomotive, National Railway of Mexico.

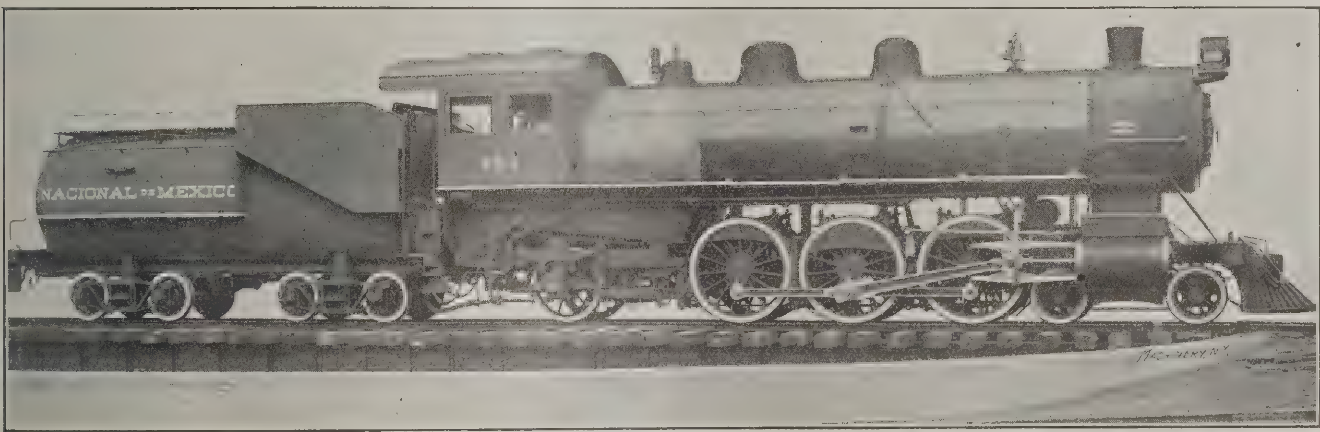

Fig. 4. Allfree-Hubbell Valve Gear, Pacific Type Locomotive, National Railway of Mexico.

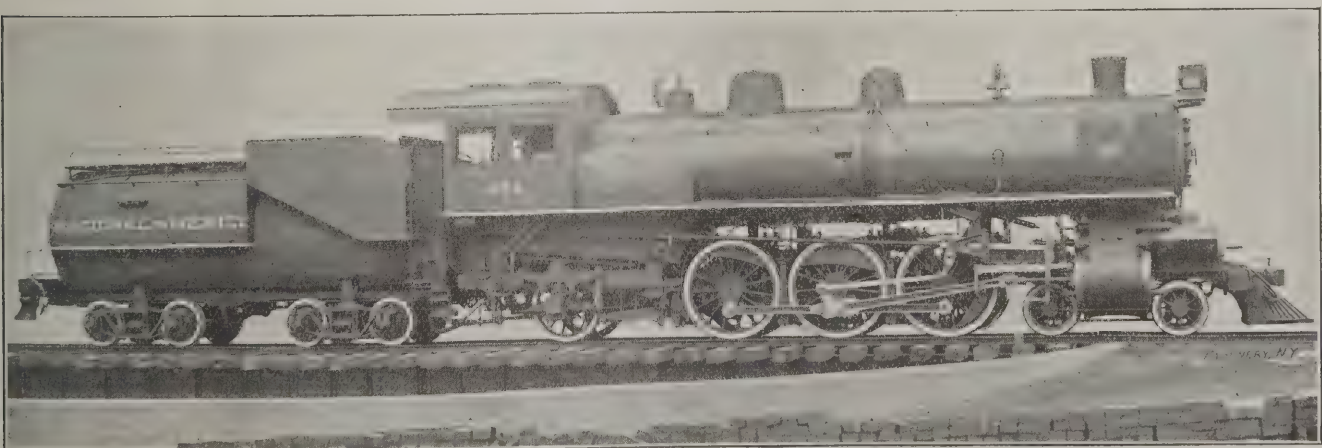

Fig. 5. Cole Balanced Compound Locomotive, Pacific Type, National Railway of Mexico.

insulated from the live steam surface by a dead air space. As the valves have inside admission, the exhaust steam is thus conveyed from the ends of the exhaust chest without coming in contact with the walls of the cylinder or valve chamber, while the live steam forms a jacket over about one-third of the cylinder from port to port. Although to the best of our knowledge this is the first instance in which the Allfree-Hubbell design has been applied to the Pacific type, this system of steam distribution has been tried in other types of both

The modifications in the design necessitated by the application of the balanced and divided principle are chiefly as follows: In order to provide a good length of high-pressure main-rod the cylinders have been moved 12 inches ahead and the forward pair of driving-wheels have been moved back 3 inches, thereby increasing the distance between the forward driving-wheels and the center of the cylinders 15 inches. The boiler is practically identical in design with that of the simple engine except for an increase of 12 inches in the length of

the front barrel sheet as a result of the cylinders having been moved ahead that amount. The important feature of this design in which it differs from the Northern Pacific engines and all other previous Cole balanced compounds is that the high- and low-pressure cylinders have different lengths of stroke. The stroke of the high-pressure cylinders is 26 inches, while that of the low-pressure is 28 inches. This results in making the angularity of the high- and low-pressure rods more nearly equal.

A table of comparison between the principal dimensions and ratios of this design and the Northern Pacific engines is given.

HEAVY MALLET ARTICULATED COMPOUND FOR ERIE RAILROAD.

The Erie Railroad has placed an order with the American Locomotive Company for three Mallet articulated compounds, for freight service on their Susquehanna division. The satisfactory service of the Mallet articulated compound, built by this company for the Baltimore & Ohio Railroad, has proved the advantages of this type for service under most difficult grade and curvature conditions, and it is to meet such conditions that the Erie has ordered these three engines. In weight and hauling capacity, however, these engines will greatly exceed the one on the Baltimore & Ohio, or the latest example in this country of this type of locomotive, the Great Northern engines built by the Baldwin Locomotive Works, which were recently illustrated and described.

The proposed design, which is here illustrated, is for an

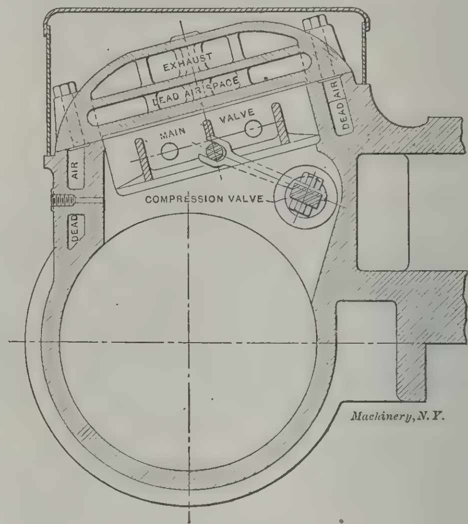

Fig. 7. Cross-section, Allfree-Hubbell Cylinder, showing Compression Controlling Valve.

engine weighing 410,000 pounds, with a tractive effort of 98,000 pounds. As the design of these engines is in the preliminary stage, very little can be given in regard to the details at this time, but a comparison of the principal dimensions with the Baltimore & Ohio and the Great Northern engines will be of interest.

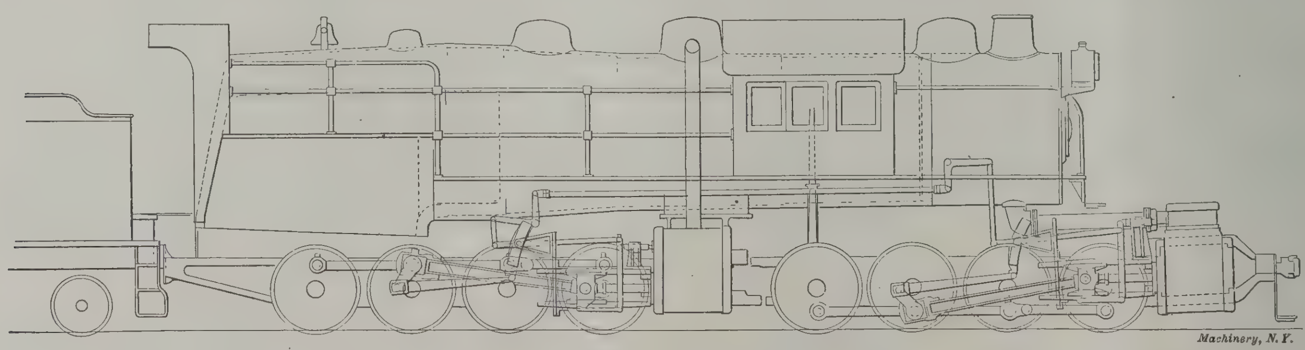
DEATH OF A. J. CASSATT.

A. J. Cassatt, president of the Pennsylvania R.R., died suddenly of heart disease, December 28, at his home in Philadelphia. He was born in Pittsburg 1839 and received a partial education in Germany. His civil engineering education was obtained at the Rensselaer Polytechnic Institute, Troy, N. Y. He began in the service of the Pennsylvania R. R. as a rodman in 1861 and soon attracted the attention of Mr. Thomas A. Scott, president of the road. From that time on his rise was rapid and he soon became an important factor



Heavy Mallet Articulated Compound for Erie Railroad.

in the executive control. In 1882 when President Roberts died it was supposed that Cassatt would naturally follow as president, but for some reason the directors chose Frank Thompson, and Mr. Cassatt resigned and retired to private life in 1882. In 1899, after having reached the age of 60 and having been out of the service of the Pennsylvania R. R. for 17 years, he was chosen president upon the death of Mr. Thompson and immediately started in on a career of expansion that is unequaled in the railway world. Space will not permit of even a brief review of this work of expansion. That connected with the tunnel and terminal work in New York City alone is a work of stupendous magnitude, the like of which does not exist elsewhere. Mr. Cassatt has the distinction of being the first railroad manager to take up the air brake.

* * *

STATISTICS OF RAILWAYS IN THE UNITED STATES FOR THE YEAR ENDING JUNE 30, 1905.

The figures in this abstract are based on summaries included in the Eighteenth Annual Statistical Report of the Interstate Commerce Commission, prepared by its statistician, as the complete report for the year ending June 30, 1905. This report is similar to preceding reports in the series. It contains tables showing details of mileage, capitalization, earnings, and expenses by roads, and besides includes many summaries of statistics for the roads as a whole.

Mileage and Capitalization of Roads.

On June 30, 1905, the report shows that the total single-track railway mileage in the United States was 218,101.04 miles, or 4,196.70 miles more than at the end of the previous year.

The operated mileage for which substantially complete returns were rendered to the Commission was 216,973.61 miles, including 7,568.95 miles of line used under trackage rights. The aggregate length of railway mileage, including tracks of all kinds, was 306,796.74 miles. This mileage was thus classified: Single track, 216,973.61 miles, as just mentioned; second track, 17,056.30 miles; third track, 1,609.63 miles; fourth track, 1,215.53 miles, and yard track and sidings, 69,941.67 miles. These figures indicate that there was an increase of 9,723.40 miles in the aggregate length of all tracks, of which 3,449.21 miles, or 35.48 per cent, represented the extension of yard track and sidings.

Equipment.

On June 30, 1905, there were in the service of the carriers 48,357 locomotives, the increase being 1,614. These locomotives, excepting 947, were classified as: Passenger, 11,618; freight, 27,869 and switching, 7,923.

The total number of cars of all classes was 1,842,871, or 44,310 more than for the year 1904. This rolling stock was thus assigned: Passenger service, 40,713 cars; freight service, 1,731,409 cars, and company's service, 70,749 cars.

The average number of locomotives per 1,000 miles of line was 223 and the average number of cars per 1,000 miles of line was 8,494. The number of passenger-miles per passenger locomotive was 2,048,558, showing an increase of 100,174 miles, as compared with the previous year. The number of ton-miles per freight locomotive was 6,690,700, showing an increase of 233,854 miles.

The number of locomotives and cars in the service of the railways aggregated 1,891,228, of which 1,641,395 were fitted with train brakes, or an increase for the year of 86,623, and 1,871,590 were fitted with automatic couplers, or an increase of 48,560.

Employes.

The reported number of persons on the pay rolls of the railways in the United States on June 30, 1905, was 1,382,196, which is equivalent to an average of 637 employes per 100 miles of line. These figures show an increase in the number of employes as compared with the year 1904 of 86,075, or 26 per 100 miles of line. Of the employes 54,817 were enginemen, 57,892 firemen, 41,061 conductors, and 111,405 were other trainmen. There were 45,532 switch tenders, crossing tenders, and watchmen.

The report includes summaries showing the average daily compensation of eighteen classes of employes for a series of years, and also the aggregate amount of compensation stated for the several classes. The total amount of wages and salaries reported as paid to employes during the year ending June 30, 1905, was $839,944,680.

Capitalization of Railway Property.

On June 30, 1905, the par value of the amount of railway capital outstanding was $13,805,258,121, which is equivalent to a capitalization of $65,926 per mile for the railways in the United States. Of this capital, there existed as stock $6,554,557,051, of which $5,180,933,907 was common, and $1,373,623,144 preferred; the remaining part, $7,250,701,070, represented funded debt, consisting of mortgage bonds, $6,024,449,023; miscellaneous obligations, $786,241,442; income bonds, $253,707,699; and equipment trust obligations, $186,302,906.

Of the total capital stock outstanding, $2,435,470,337, or 37.16 per cent, paid no dividends. The amount of dividends declared during the year was $237,964,482, being equivalent to 5.78 per cent on dividend-paying stock. For the year ending June 30, 1904, the amount of dividends declared was $221,941,049. Of the total amount of stock outstanding, $6,554,557,051, 9.72 per cent paid from 1 to 4 per cent; 14.77 per cent from 4 to 5 per cent; 10.74 per cent from 5 to 6 per cent; 8.79 per cent from 6 to 7 per cent, and 11.68 per cent from 7 to 8 per cent. The total amount of funded debt (omitting equipment trust obligations) that paid no interest was $449,100,396, or 6.36 per cent. Of mortgage bonds, $326,863,401, or 5.43 per cent; of miscellaneous obligations, $54,214,525, or 6.89 per cent, and of income bonds $68,022,470, or 26.81 per cent, paid no interest.

Public Service of Railways.

The number of passengers reported as carried by the railways in the year ending June 30, 1905, was 738,834,667, this item being 23,414,985 more than for the year ending June 30, 1904.

The number of tons of freight reported as carried (including freight received from connections) was 1,427,731,905, which exceeds the tonnage of the year 1904 by 117,832,740 tons. The ton-mileage, or the number of tons carried one mile, was 186,463,109,510, the increase being 11,941,019,933 ton-miles. The number of tons carried one mile per mile of line was 861,396, indicating an increase in the density of freight traffic of 31,920 ton-miles per mile of line.

The average revenue per passenger per mile for the year ending June 30, 1905, was 1.962 cents. For the preceding year the average was 2.006 cents. The average revenue per ton mile was 0.766 cent; the like average for the year 1904 was 0.780 cent. The earnings per train mile show an increase both for passenger and for freight trains. The figures show a slight increase in the average cost of running a train one mile. The ratio of operating expenses to earnings for the year 1905 was 66.78 per cent. For 1904 this ratio was 67.79 per cent.

Earnings and Expenses.

The gross earnings of the railways in the United States from the operation of 216,973.61 miles of line were, for the year ending June 30, 1905, $2,082,482,406, being $107,308,315 greater than for the year 1904, and for the first time exceeding the two billion mark. Their operating expenses were $1,390,602,152, or $51,705,899 more than in 1904. The following figures present a statement of gross earnings in detail and show the increase of the several items over those of the previous year: Passenger revenue, $472,694,732—increase, $28,367,741; mail, $45,426,125—increase, $926,393; express, $45,149,155—increase, $3,273,519; other earnings from passenger service, $11,040,142—increase, $125,396; freight revenue, $1,450,772,838—increase, $71,770,145; other earnings from freight service, $5,080,266—increase, $511,984; other earnings from operation, $52,319,148—increase, $2,333,137. Gross earnings from operation per mile of line averaged $9,598, the corresponding average for the year 1904 being $292 less.

The operating expenses assigned to the four general classes were: For maintenance of way and structures, $275,046,036;

maintenance of equipment, $288,441,273; conducting transportation, $771,228,666; general expenses, $55,319,805; undistributed $566,372. Operating expenses averaged $6,409 per mile of line, this average showing an increase of $101 per mile in comparison with the year 1904.

The income from operation or the net earnings of the railways amounted to $691,880,254. This amount exceeds the corresponding one for the previous year by $55,602,416. The net earnings per mile of line for 1905 averaged $3,189; for 1904, $2,998, and for 1903, $3,133. The amount of income attributable to other sources than operation was $231,898,553. There are included in this amount the following items: Income from lease of road, $114,473,139; dividends on stocks owned, $56,842,694; interest on bonds owned, $18,786,644 and miscellaneous income $41,796,076. The total income of the railways ($923,778,807)—that is, the net earnings and income from lease, investments, and miscellaneous sources—is the amount from which fixed and other charges against income are taken to ascertain the sum available for dividends. Such deductions aggregated $596,688,420, thus leaving $327,090,387 as the net income for the year ending June 30, 1905, available for dividends or surplus.

The amount of dividends declared during the year under review (including $82,415 representing other earnings to stockholders) was $238,046,897, leaving as the surplus from the operations of the year ending June 30, 1905, $89,043,490. The surplus from operations as shown for the preceding year was $56,729,331. The amount of deductions from income as stated above, $596,688,420, comprises these items: Salaries and maintenance of organization, $612,518; interest accrued on funded debt, $310,631,802; interest on current liabilities, $11,451,400; rents paid for lease of road, $116,380,644; taxes, $63,474,679; permanent improvements charged to income account, $37,720,624; other deductions, $56,416,753.

It should be understood that the preceding figures for the income and the expenditures of railway companies are compiled from the annual reports of leased roads as well as of operating roads, and thus, necessarily, include duplications in certain items of income and also of expenditure on account of the fact that, in general, the income of a leased road is the rent which it receives from the company by which it is operated.

Railway Accidents.

In their annual report to the Interstate Commerce Commission, carriers are expected to include all casualties to passengers, employes, trespassers, and other persons. The following figures, therefore, are not comparable with the returns shown in the Commission's Accident Bulletins, which are based on monthly reports, and mainly relate to casualties to passengers and to employes while on duty on or about trains:

The total number of casualties to persons on the railways for the year ending June 30, 1905, was 95,711, of which 9,703 represented the number of persons killed and 86,008 the number injured. Casualties occurred among three general classes of railway employes, as follows: Trainmen, 1,990 killed and 29,853 injured; switch tenders, crossing tenders and watchmen, 136 killed, 883 injured; other employes, 1,235 killed, 36,097 injured. The casualties to employes coupling and uncoupling cars were: Employes killed, 230; injured, 3,543. The casualties connected with coupling and uncoupling cars are assigned as follows: Trainmen killed, 217; injured, 3,316; switch tenders, crossing tenders and watchmen killed, 6; injured, 128; other employes killed, 7; injured, 99.

The casualties due to falling from trains, locomotives, or cars in motion were: Trainmen killed, 407; injured, 4,645; switch tenders, crossing tenders and watchmen killed, 12; injured, 126; other employes killed, 60; injured, 559. The casualties due to jumping on or off trains, locomotives or cars in motion were: Trainmen killed, 119; injured, 3,798; switch tenders, crossing tenders and watchmen killed, 4; injured, 111; other employes killed, 49; injured, 628. The casualties to the same three classes of employes in consequence of collisions and derailments were: Trainmen killed, 579; injured, 4,736; switch tenders, crossing tenders and watchmen killed, 8; injured, 37; other employes killed, 85; injured, 750.

The number of passengers killed in the course of the year 1905, was 537 and the number injured 10,457. In the previous year 441 passengers were killed and 9,111 injured. There were 341 passengers killed and 6,053 injured because of collisions and derailments. The total number of persons other than employes and passengers killed was 5,805; injured, 8,718. These figures include the casualties to persons trespassing, of whom 4,865 were killed and 5,251 were injured. The total number of casualties to persons other than employes from being struck by trains, locomotives or cars was 4,569 killed and 4,163 injured.

In 1905, one passenger was killed for every 1,375,856 carried, and one injured for every 70,655 carried. For 1904 the figures show that 1,622,267 passengers were carried for one killed, and 78,523 passengers were carried for one injured. For 1895, one passenger was killed for every 2,984,832 carried, and one injured for every 213,651 carried. With respect to the number of miles traveled, the figures for 1905 show that 44,320,576 passenger miles were accomplished for each passenger killed, and 2,276,002 passenger miles for each passenger injured. For 1904 the figures were 49,712,502 passenger miles for each passenger killed, and 2,406,236 passenger miles for each passenger injured. The figures for 1895 show that 71,696,743 passenger miles were accomplished for each passenger killed, and 5,131,977 passenger miles for each passenger injured.

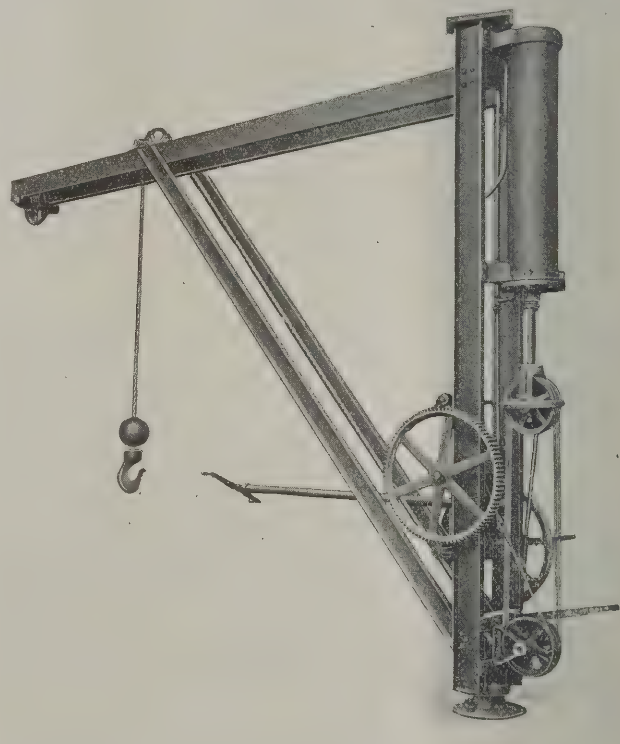
CURTIS COMBINATION PNEUMATIC AND HAND-POWER PITTING CRANE.

This crane was designed for pitting car wheels, but it can also be adapted for car-wheel molding. The mast, jib, and struts are made of channels riveted in place in a thorough manner; the gib is latticed on top. The upper and lower pintles are of the makers' ball-and-socket type, which allows for sagging or settling of the upper supporting member. Two



Curtis Pitting Crane.

sheathes are fitted on the jib so that an inner circle of wheels can be pitted. A Curtis air-balanced geared hoist is mounted on the back of the mast, and a hand-power winch is fitted in case of failure of air supply, or for night use. The hook is of steel, and a weight is furnished to cause the rope to descend promptly after being released. The operator does not need to move from his position to control the power lift, as the long lever connected to the hoist valve is placed in a convenient position. A brake is furnished for hand power so that the lowering speed can be regulated, and a ratchet pawl is furnished in connection with the winch, enabling the load to be held indefinitely at any point. This style of crane is made by Curtis & Co. Mfg. Co., St. Louis, Mo.

A SKEW BEVEL GEAR MODEL.

JOHN F. ARTHUR.

John F. Arthur.

In the gear model shown in Fig. 1, we have two shafts at right angles to each other in planes about 1¾ inch apart, connected at their intersection with the normal to the two planes by a pair of spiral gears, and at their outer extremities by a pair of approximate skew bevel gears. It is not possible to show the condition in the cut, but if the eye be placed at the outer end of a tooth of one of the bevel gears, it will be seen that there is a corresponding tooth of the spiral gear on the same shaft directly in line with it, and inclined at the same angle with the axis. In other words, straight teeth might be drawn from the outer edge of the bevel gear to the central spiral gear, filling all the space between them. The pitch surface on which these teeth would have to be made, though they are themselves straight, would not have a straight cross section but would be in the form of a hyperboloid. To illustrate the nature of the pitch surfaces required for a pair of skew bevel gears, I have constructed and show herewith a pair of models illustrated in Figs. 2 and 3.

To a U-frame of strap iron are fastened by clamp bolts and wing nuts the two wooden disks shown, these disks having the same axis. A groove is turned in the outer face of each disk close to the outer edge, and 20 equi-distant saw cuts are made in the periphery to a depth sufficient to just enter the grooves; this construction is best seen in Fig. 3. An endless elastic cord is interwoven in the saw cuts, being prevented from unloosening and falling out by the groove, whose lip makes a ledge to retain it in place. As shown in Fig. 3, in the normal condition the disks are so arranged that the elastic cords are all stretched parallel with the axis. A model in this condition may be considered as representing a spur gear of 20 teeth, each string representing a tooth. If two such models be placed side by side with the peripheries of the disks tangent, they may be rolled upon each other, when the strings of one may be made to coincide with the corresponding strings of the other as they revolve.

If now the left hand disk, for instance, of each model be unloosened and rotated in the same direction through a given number of degrees, the two models may again be placed in contact with each other with their axes askew by such an amount as will bring a string of one model coincident with a string of the other. With the axes fixed in these positions the two models might be revolved, when each string in turn during a complete revolution would coincide with a corresponding string on the other model. The greater the angular displacement of the adjustable disks the greater will be the angle which the axes of the two models make with each other in parallel planes. If the pitch diameters of the disks are greater than the distance between them a point will be reached, as shown in Fig. 2, when enough twist has been given each of the movable disks to bring the axes of the two models at right angles when they are put together with corresponding strings coincident. When in this condition, the outline of the surface generated by the strings as the model is rotated about its axis gives the hyperboloid or pitch surface on which it would be necessary to place teeth in the model shown in Fig. 1, if it were desired to fill up the space included between the spiral gear and the bevel gears. The shape of this surface will be understood from the left-hand view in Fig. 3, where one of the two models of Fig. 2 is shown separately.

This hyperboloidal surface may be understood by considering another method of generating it. If we take between the centers of a lathe the wooden cylinder *A B C D* as shown by the dotted lines in Fig. 4 and feed into it a knife blade *E* set at an angle as shown, this knife blade would generate a spool shaped solid having the outline indicated, and its exterior surface would be a hyperboloid. The mark which might be made by pressing with the knife into the surface of this figure when generated, the blade being in the position shown, would represent the line of contact between this solid and another one generated in the same manner, if they were put together with their curved surfaces tangent to each other. This line may also be taken as representing one of the strings in the model just described. The models and the turning lathe illustration just given demonstrate very clearly the fact that two hyperboloidal surfaces properly proportioned will touch each other on a straight line of contact.

Fig. 1. Two Shafts Connected by both Spiral and Skew Bevel Gears.

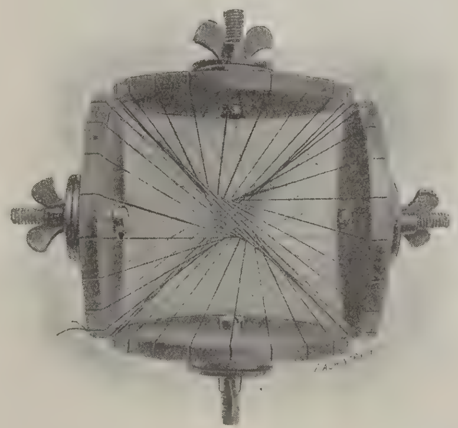


Fig. 2. Model Illustrating Two Skew Bevel Gear Pitch Surfaces in Contact.

While the set of gears shown in Fig. 1 (in combination with the string model) demonstrates the pitch surface required, it has not been given teeth which accurately fulfil the requirements of the case. The spiral gears at the center, instead of having curved pitch surfaces, have been cut with cylindrical ones which theoretically only touch at a single point in the center. With a little use, however, they wear themselves to an indescribable shape, depending on the material of which they are made, and this shape doubtless approximates the skew bevel action required. In the case of the two outer bevel gears accuracy is impossible, since the teeth slide laterally on each other, thus bringing different pitches in contact, the conditions varying constantly between the times of entering and leaving. These skew bevel gears are therefore a kind of compromise mechanism which will transmit a moderate power, but must be cut with the spaces more than half of the pitch, with the thickness of the teeth less than the standard by the same amount.

If one of the disks in the model shown at the right in

JOHN F. ARTHUR, secretary of the Arthur Co., New York was born in Glasgow, Scotland- 1870. The family came to the United States when he was eighteen months old, and settled in New York. He took up the machine business under the direction of his father, Mr. James Arthur, and went through a regular machine shop training. Mr. Arthur is a machine designer, and has taken out several patents on devices pertaining to the business of the concern, which is largely gear cutting. He has always given the subject of gear making special attention, and has constructed a number of interesting gear models, besides the above, to illustrate principles.

Fig. 3 is turned around 180 degrees, we bring all the elastic strings to a common point of intersection in the center, thus altering our skew bevel hyperboloid pitch surfaces until they become the conical pitch surfaces of bevel gears. It is of course understood that, since the elastic cord used has a sensible thickness, all of the strands cannot be brought to a common point in the case of the bevel gear. The principle illustrated, however, will readily be grasped. The skew bevel pitch

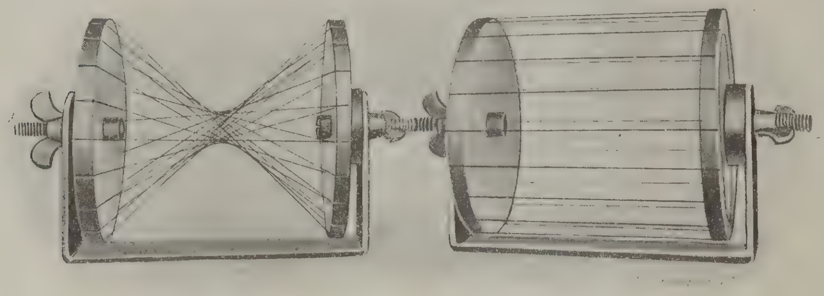

Fig. 3. Models set to show Skew Bevel Gear and Spur Gear Pitch Surfaces.

surface shown in Fig. 3 may thus be altered to the spur gear pitch surface in the same Fig. or the bevel gear pitch surface just described, all the intermediate forms being hyperboloids. The skew bevel gear is thus, in a sense, the progenitor of all other forms of gearing.

[There is a possible form of tooth which may be given to the hyperboloid pitch surface, so nicely shown by Mr. Arthur, which will give the constant angular velocity required and will permit, as well, the sliding action described as taking place between the two gears. This form of tooth, invented by Olivier, is described in Grant's "Treatise on Gear Wheels," paragraphs 175 and 176. It has no practical use, however, since it vanishes to infinitesimal dimensions at the smallest diameter of the gear, and has a great obliquity of action at the larger diameters. A modification of this form of tooth

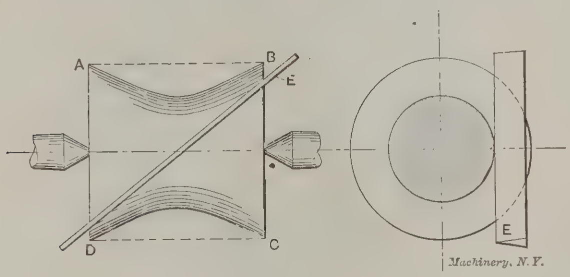

Fig. 4. Generating the Hyperboloid from a Straight Line.

was devised and tried by Mr. Beale of the Brown & Sharpe Mfg. Co., but, while it has great scientific interest, the form has little practical value, on account of the small size and weakness of the teeth and the difficulty of generating them. Considerable information is given in the book referred to above in relation to the determination of hyperboloid pitch surfaces for various shaft angles and velocity ratios. The spiral gear, however, with the exception of the worm gear, appears to be the only practical solution to the problem of connecting by a single pair of gears two shafts not in the same plane.—Editor.]

* * *

In the days of our forefathers, when rifle balls were spherical, and long, cylindrical, conical-headed bullets and rifled barrels were undreamed of, the gunsmith adopted a curious but convenient method of designating the gage or diameter of the bore. He expressed it by stating how many bullets, of a size that would fit a particular musket, would go to make a pound. Thus, a 10-bore musket would be one of such a bore that ten of its bullets would go to make a pound weight; a 16-bore gun would be one whose bullets would run sixteen to the pound, and so on. Hence we get the anomaly, that the larger denomination musket has the smaller bore. Although the day of the spherical bullet has long passed away, and the only smooth-bore remaining is the shotgun, the old method of designation has been retained until the present time.—*Scientific American.*

MAKING SMALL RELIEVED GEAR CUTTERS IN THE SLOAN & CHACE SHOPS.

The machinist who has been accustomed to the ordinary run of work, say that included in the range between the sewing machine and the ocean steamer, is likely to feel himself better acquainted with anything between these two extremes than he is with work that tends toward the microscopic, such as the making of tools and parts for clocks and watches, for instance. One of the things which aroused the particular wonder of the writer while he was still an apprentice to the machinist trade, was the minuteness of the formed and relieved gear cutters which he saw in a clock factory to which he had made a casual visit. Even taking for granted the use of the magnifying glass in making these cutters, how could the hand of the toolmaker be kept steady enough to draw correctly the proper outline or file a templet or form tool to that outline after it was drawn? With this perplexity of his apprentice days still in mind it was with renewed interest that he watched the methods used in making these small cutters in the shops of the Sloan and Chace Mfg. Co. at Newark, N. J.

In the first place, of course, there is no direct use of hand work in the actual forming of the outline of the cutter, or the form tool with which it is made. That is to be expected, and the pantograph idea would at once occur to a mechanic as being the most suitable principle to use in obtaining cor-

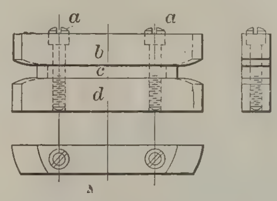

Fig. 1. A Built-up Form Tool.

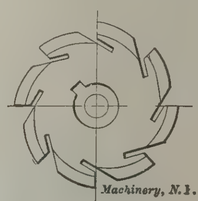

Fig. 2. Design of a Minute Formed Cutter.

rect outlines on the very small scale which has to be used. The way in which the pantograph idea is applied, however, is very ingenious, and all of the tools used in the production of these cutters show evidence of being the result of thought and experience. It must not be imagined, however, that these machines are new. They are none of them new, some of them being as old as twenty years or more. Their age, however, does not detract from their interest, and their

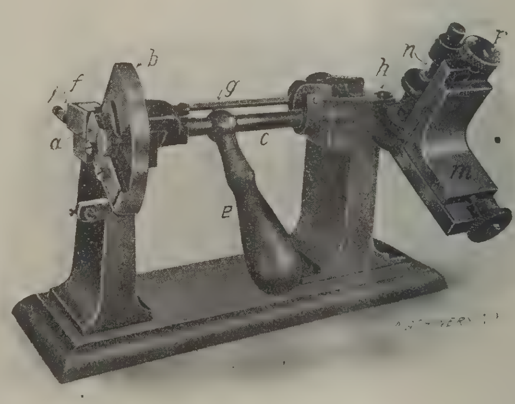

Fig. 3. Pantograph Machine for Lapping Form Tools.

construction and operation will without doubt be a matter of absolute novelty to the greater number of the readers of Machinery.

Fig. 1 shows the form tool with which the cutter is shaped and Fig. 2 shows the general type of cutter produced. After the blank has been turned up, angular saw cuts are made in its periphery to furnish a clearance space to run the emery wheel into when grinding. The ends of the projecting tooth

thus formed are then finished off to a radial line, and the blank, with the general outline shown in the cut, is ready for the relieving lathe, where it is formed by the tool in Fig. 1. This tool, as shown, is made of three parts held together by screws *a a*. Of these three parts, *b* and *d* are identical so far as the shape of their cutting edges is concerned, but are reversed in form, one being right-hand and the other left-hand. At *c* is a filling piece which forms the top of the cutter and separates the two side pieces to give the proper width

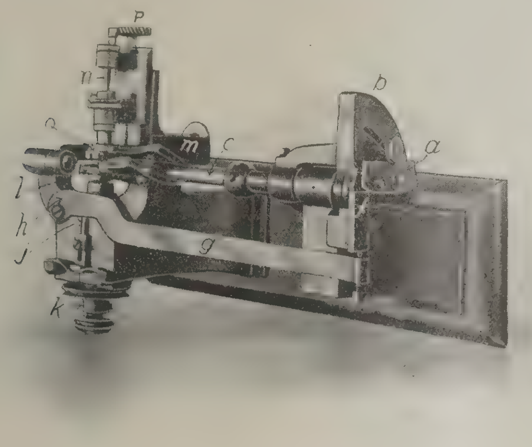

Fig. 4. Top View of Pantograph Machine.

to the top of the cutter and the bottom of the tooth space. Piece *c* is made by direct measurement; in forming the curved outlines on pieces *b* and *d*, the pantograph machine comes into play. The double-ended design of the tool is inherent in the construction of the pantograph machine, and gives it the advantage of a double life, since when one end is worn out the tool may be reversed, when the same form will be found at the other end.

The construction and operation of the pantograph machine will be understood from the photographs which are reproduced in Figs. 3 and 4. In these two views similar parts have been given the same reference letters. At *a* is a templet whose edge has been worked out to the desired outline for the side of the tooth for which the cutter to be made is intended. This outline is made on a scale of 10 to 1, this reduction being great enough to avoid any greater irregularities than would be produced by the most perfect mechanical methods possible. Templet *a* is fastened to a sector *b*, which is in turn attached to a shaft *c* and may be rotated with it by handle *e*. The templet *a* bears with its working edge upon another plate *f* which, as handle *e* is rocked up or down, transmits the motion received to the reducing lever *g*, which is pivoted at *h*. At a point one-tenth of the distance from *h*

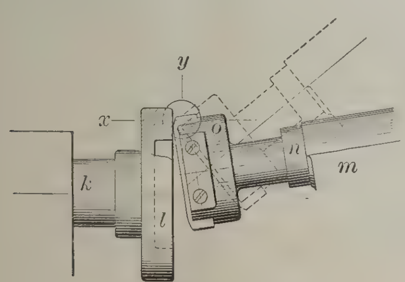

Fig. 5. Action of Diamond Lap on the Tool Blades.

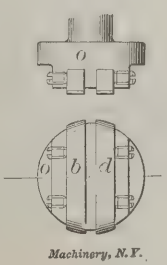

Fig. 6. Chuck for Holding Tool Blades.

to the bearing point on the plate *f* a contact pin *j* bears upon the lever, this contact pin giving the reduced motion due to the rotation of form *a* to a spindle *k*, driven as shown by a grooved wheel at its outer extremity. This spindle carries on its inner end a lapping plate *l* shown in detail in the line cut Fig. 5. This lap has its plane front surface charged with diamond dust and is the cutting member employed in shaping the form tool blades. To the further extremity of rock shaft *c* is attached a bracket *m* with suitable adjusting slides. This bracket carries a second revolving spindle *n* driven by a round belt and carrying on its inner end the chuck *o* which carries the two blades, *b* and *d* of Fig. 1, which are to be ground. These blades are held in transverse slots in the face of the chuck, being tightened in position by the headless setscrews shown. This construction will be more plainly understood by reference to line cuts 5 and 6. It will now be evident with a little thought, that, with the machine properly adjusted and the lap, tools, and templet in place as shown, if spindles *k* and *n* are revolved, the handle *e* rocked up and down, and the cross slide screw *p* fed in slowly, the outline of templet *a* will be reproduced by lap *l* on tools *b* and *d* on a scale one-tenth of the original. The intersection of the axes *x* and *y* in Fig. 5 represents the center line of the rock shaft *c*. The revolving of shaft *o* continues this form in a circular direction about the center of rotation so that *b* and *d* practically form parts of a circular form tool which may be ground in the same way that a circular form tool is without losing shape. The tools *b* and *d* are of course hardened before this operation is performed. Filling piece *c* shown in Fig. 1 is simply a portion of a plain circular disk.

After the form tool has thus been made and assembled, a blank for the cutter, made as shown in Fig. 2, is placed in the relieving machine in Fig. 7 where the outline of the form tool is given to it. All the motions of this machine are driven from pulley *a*. The further end, not shown, carries the first of a train of change gears meshing with large gear *b*. These change gears may be arranged to give, if the cutter for instance is to have twelve teeth, twelve revolutions of *a* to one of *b*. Shaft *c* carries, just back of pulley *a*, a cam which acts on a roller at the further end of lever *d*. This

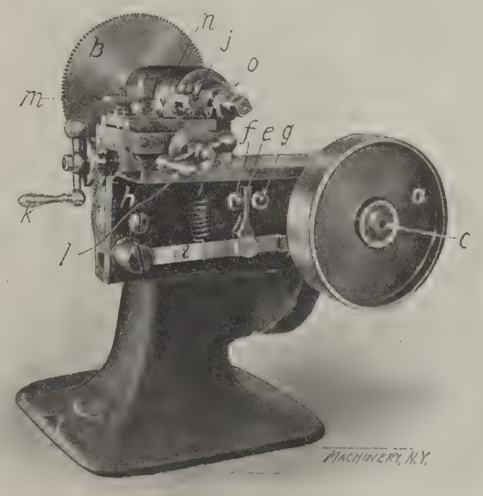

Fig. 7. Relieving Machine for Minute Formed Cutters.

lever has pivoted to it a little wedge *e* which works between stationary roller *f* and roller *g* which is fast to slide *h*. It will thus be seen that a suitable in-and-out motion for the relieving of the teeth is given to slide *h* by the rotation of pulley *a*. Slide *h* carries the tool post *j* and the two slides and their adjusting screws operated by handles *k* and *l*. The tool post *j* has also a tipping adjustment controlled by thumb-screw *m*. Form tool *n*, made by the process previously described, is placed in the tool post while the blank is held at *o* on the front end of the same spindle which carries dividing wheel *b*. The operation of the machine and the various adjustments of which it is capable will be easily understood from the cut.

It will be seen that, with this way of making, the only hand work involved in giving form to the cutter is that employed in shaping the outline of templet *a* in Figs. 3 and 4, and since this is done on a scale ten times actual size there is little chance for error. Of course the various adjustments have to be intelligently made. For instance, in the pantograph machine, the longitudinal position of lap *l* must be such that, when bearing plate *f* is moved into the center line of rock shaft *c*, the face of lap *l* will also pass through the same center line or be coincident with axis *y*, shown in Fig. 5. To provide for this, plate *f* is located on the center line and a circular plug milled down to its axis is inserted in a hole

at the further end of shaft *e*, when the lap is adjusted by the nut at the outer end of shaft *k* until it is exactly in contact with it. The necessary adjustments will suggest themselves from the various stops and screws shown in the cuts.

Such cutters as those we have just been describing will do for comparatively coarse gears and pinions, for use in the cruder sorts of time-keeping apparatus, such as alarm clocks, common eight-day clocks, etc. For fine watch gears, however, nothing but the slow-cutting single-tooth fly cutter is used. No matter how painstakingly a multiple-tooth cutter may have

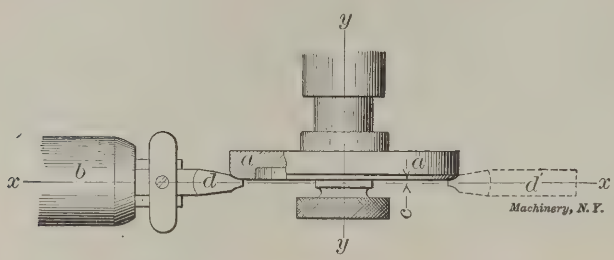

Fig. 8. Method of Lapping Fly Cutters.

been made and mounted in the machine it is to be used in, it will always run out sidewise more or less, and this means that the width of the space will not be a constant quantity. Each time the cutter is removed to be sharpened or each time the machine is set up, a different thickness of tooth will be cut. This error, of course, does not appear in the action of the fly cutter with its single cutting edge. The way in which the pantograph machine is used to make a fly cutter will be understood by reference to the line cut Fig. 8 and the halftone cut of the lapping machine in Fig. 9. At *a* is a lap with its front face formed to the required tooth curve. To give it the form desired, it was mounted at the end of spindle *n* in the place occupied by chuck *o* in Fig. 5. The tooth curve was transferred to it in the same way that the cutters are shaped, the action of lap *l* on this second lap *a* being identical with the action of lap *l* on blades *b* and *d*. Referring again to Figs. 8 and 9, *b* is an arm swinging in a horizontal plane on a vertical axis at the intersection of lines *x x* and *y y*. The distance *c* from axis *x x* to the face of the lap is made equal (when the lapping has finally been completed) to one-half the width of the tooth space at the root of the tooth. The fly tool *d*, which is being lapped into shape, is held by a collar and setscrew in a suitable recess formed in the end of mandrel *e*, which is placed in bearings on arm *b*. In operation, with lap *a* revolving, the arm is swung around

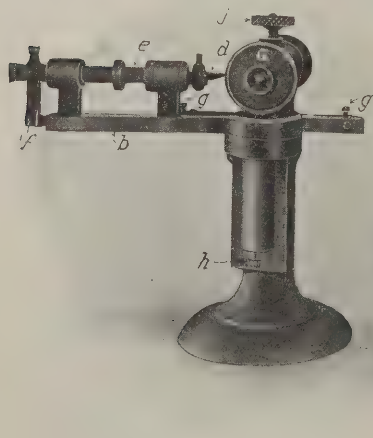

Fig. 9. Machine for Lapping Fly Cutters.

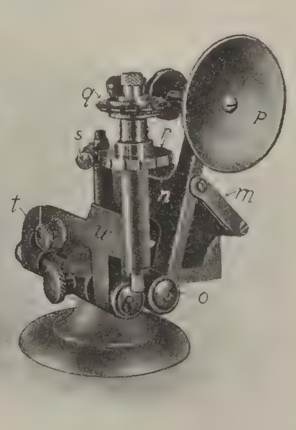

Fig. 10. Machine for Grinding Formed Cutters.

until the lap is in contact with tool *d*, when, being charged with diamond dust, it gradually under gentle pressure works it down to the form required. When one side has been thus shaped, arm *b* is swung around its vertical axis until the fly cutter is brought to position *d′* on the other side of the lap, when the other side of the tool is also formed.

To give the side relief required, an arm *f* is fastened to the outer extremity of spindle *e*. The lower end of this arm has a notch in it which is somewhat larger than the pin enclosed by it, which is driven into slide *b*. When the tool is pressed up against the lap in the position shown in Fig. 9, the lower end of this arm *f* is pushed over until this side of the notch is in contact with the pin; likewise, when, on the other hand, arm *b* is swung around to the right-hand side of the wheel, the arm is pushed over until the other side is in contact with the pin; thus spindle *e* is rotated very slightly to give clearance to the sides of the cut. The other adjustments of this machine will be readily understood. Provision is made for endwise movement of the spindle carrying lap *a*, to bring dimension *c* correct as shown in Fig. 8. Stop screws *g g* are provided, which accurately limit the swing of arm *b* in either direction to 90 degrees either side of *y y* as is required. Set screw *h* brings the cutting edge of the tool *d* in proper relation with the center line of the lap spindle. Means are provided at *j* for the very important adjustment requiring that the center line of the pivot on which arm *b* rotates shall exactly intersect axis *y y* of the lapping spindle. The fly tool is made with a triangular body which assures its being fastened always in its holder in such a way that the front cutting face is parallel with the axis of rotation.

In Fig. 10 is shown a little grinding machine used for sharpening form cutters. This operation will be readily apparent. From a pulley, not shown, motion is given to a crankshaft at the rear of the device which through crank *m* rocks frame *n* about pivot *o*. This frame carries a cupped emery wheel *p*. The cutter to be ground, shown at *q*, is mounted on the end of a vertical spindle carrying a ratchet *r* having the same

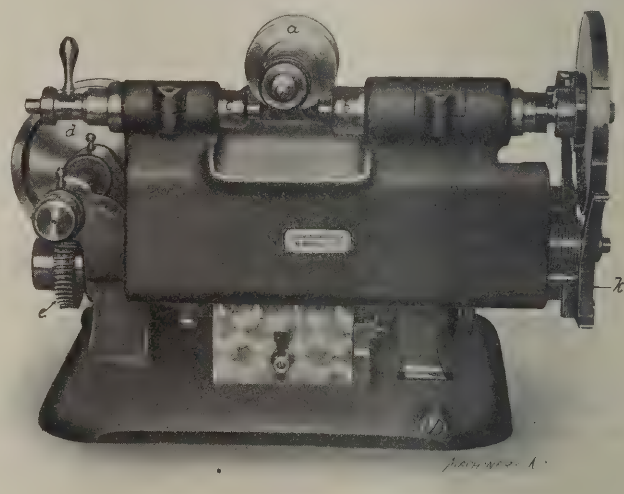

Fig. 11. Front View of Automatic Clock and Watch Pinion Cutter.

number of teeth as the cutter. Pawl *s* acts as a stop for the ratchet. Adjusting screw *t* furnishes an inward stop for frame *u* which is also pivoted at *b*, thus regulating the depth of the movement of emery wheel *p*. As the emery wheel is swung in and out by the crank, the hand of the operator indexes the cutter, stopping each tooth of the ratchet in turn against pawl *s*.

The machinery in which clock and watch gears are cut is interesting in a number of respects. Figs. 11, 12 and 13 show three views of an automatic pinion cutter made by the Sloan & Chase Mfg. Co.; of these Fig. 11 shows the working side of the machine. The pulley which drives the cutter spindle is shown at *a*. The work (which may be either in the form of staffs with pinion blanks integral with them, or in the form of blanks mounted on arbors) is gripped at either end in chucks *b* and *c*, the one at the headstock end and the other at the tailstock end. These two spindles and the work held by them are indexed by the mechanism at the right in this view. Pulley *d* drives the feeding and indexing mechanism through the worm gearing shown at *e*. This worm gear drives a shaft on which are mounted the various gears and cams for controlling the movements, which are shown to better advantage in Figs. 12 and 13. Indexing cam *f* is fast to the cam shaft just mentioned. As it revolves it comes in contact with tappet *g* on the indexing lever *h*, which, by means of a pawl rotates a ratchet fast to the work spindle. On its inward movement, before the pawl strikes the ratchet tooth, the dog *j* at the lower end of lever *h* withdraws the locking lever *k*

from the notch in the indexing dial, to permit the rotation to take place. Continuing, the forward movement of the indexing lever *h*, as it rotates the spindle through the pawl and ratchet described, brings the upper end of dog *j* in contact with a stop screw which releases the locking lever *k*, allowing its detent to drop into the notch on the periphery of the dial the moment the rotating movement has ceased. As the motion of the indexing cam is continued in the direction shown, the lever *h* returns to its normal position, dog *j* again dropping over the lower end of lever *k* as in the cut. The feed cam *l*, acting through the feed lever and the connecting link shown, gives the required horizontal movement for feeding the work past the cutters.

The machine shown is provided with a movement much used in watch gear cutting to insure extreme accuracy in the shape of the teeth, modified for this particular machine with considerable ingenuity. Three cutters may be mounted side by side on the cutter spindle. The first for taking a roughing cut, the second for an intermediate cut, and the third for the final finishing. The blank is first roughed out all the way around, then the second cut is taken, winding up with the finishing cut. The slide *n*, on which the spindle is mounted, being advanced each time an amount sufficient to bring the cutter desired to a position central with the axis of the work. At *o* in Fig. 12 is shown a six-tooth ratchet attached to a short shaft carrying three cams, located under the outer end of the spindle slide. These cams are so arranged that, as the ratchet is rotated, for each sixth of a revolution one after another of the three acts upon the inner end of one of screws *p*, thus giving the slide a longitudinal position dependent on the adjustment of the screw *p* which is being acted on at the time. Lock screws *q* are provided as shown for fastening screws *p* in position. Since the cams driven by ratchet *o* are double, the same cycle of three positions is followed in the second half of its rotation that occurred in the first half. A stiff spring keeps the spindle slide *n* in as advanced a position as is allowed by the cams and stop screws.

The action of the mechanism which changes these stops will be understood by comparing the Figs. 12 and 13. Stop dog *r* is rotated by a shaft passing through from the opposite side of the machine. This shaft makes a revolution for each revolution of the work spindle, being driven by an intermittent

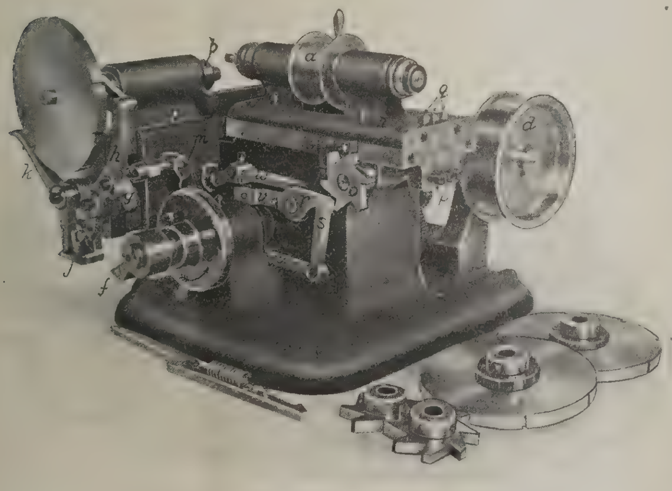

Fig. 12. Side View showing Indexing and Feeding Movement of Pinion Cutter.

gear, not shown in the cuts, from the shaft on which cams *f* and *l* are mounted. This gearing is adjustable to suit the number of teeth being cut. As this dog revolves, at the conclusion of the roughing of the teeth, it gives a sixth of a revolution to ratchet *o*, bringing a new cam and stop screw into action and centering the second cutter over the work. At the conclusion of the cut with that cutter, another sixth revolution is given to *o* in the same manner, when a third cam is presented which brings the new or finishing cutter into central position. It will be noted that by means of screws *p* the adjustment for each of these cutters is independent of the rest.

Provision is made for adjusting the depth of cut of the three cutters independently also. Lever *s*, with its fulcrum at *t*, is acted upon by the movement of the cutter slide in and out, as it brings the three different cutters into position. Rod *u*, attached to the lower end of the lever, carries on its further end three stop screws for the vertical motion of the work-holding slide on the front of the machine frame. The slide is elevated through the action of levers *v* and *w*, moved by a cam on the operating shaft, which mechanism serves to relieve the cutter on the return movement as well as to alter the adjustment when the cutters are changed. The depth of cut for each operation is determined by the three stop screws just mentioned, the one in action depending on which of the cutters is working at the time. These screws are not plainly visible in the cut.

A little thought will show that a pinion or gear cutting machine of the type shown in Figs. 11, 12 and 13, is very much

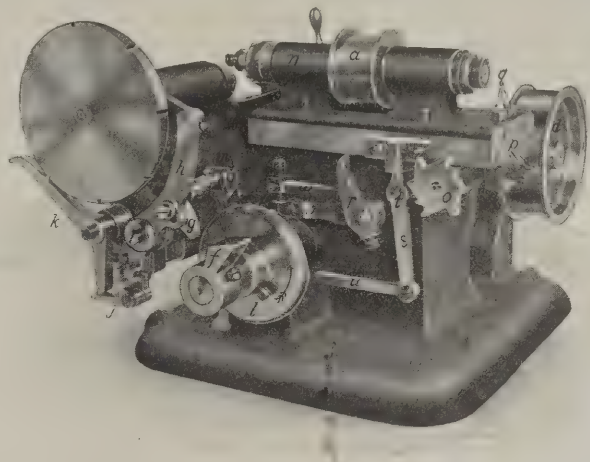

Fig. 13. Side View showing Operation of Cutter Shifting Mechanism.

more costly in proportion to its weight than the larger automatic gear cutters with which the machinist is familiar. There is, as we all know, no such thing as a perfect fit. When the slides and journals of a machine tool are fitted together, an amount of care is used depending on the purpose for which the machine is intended. If a three-pitch cutter is to be used on steel castings, a certain allowance, determined by experience, is made in fixing the diameters of the journals of the cutter spindle and box or bushing in which it revolves. The space left between the journal and the somewhat larger bearing is the oil allowance, and is filled with the lubricant provided for the bearing. If the fitting were more carefully done and a smaller allowance made at this place, not only might this oil allowance be too small to insure a film of lubricant over the whole bearing surface and so give rise to the danger of roughing it up, but the extra accuracy thus obtained would be a useless as well as an expensive luxury, since the heavy strains imposed on the structure of the machine by the action of the large cutter on the hard metal would produce deflections great enough to make of no avail the slight gain obtained by the means just described. In general, the lighter the parts are which are to be machined, the more accurately the machine may be made and must be made. In the case of a minute watch gear, an error of one-fourth of a thousandth in any dimension is a matter of as much importance as a sixty-fourth of an inch would be in the back gearing of a 28-inch lathe. Not only is accuracy thus a necessity, but the conditions that make it necessary also make it possible. In this smaller work, the slight strains imposed by the cutting action are almost lost in the comparative stiffness and rigidity of the framing of the machine, thus giving a chance for accuracy in fitting of the wearing surface to show its full measure of usefulness. The consequence is, that a carefulness of fitting in machines of this type is demanded and obtained, which makes them as expensive to build and purchase as ordinary gear cutting machines of far greater size.

* * *

It is reported from St. Petersburg that an official inquiry at Tomsk into the conduct of the Siberian Railway during the war has brought to light the fact that the government was at one station alone defrauded of $350,000, and that, on the whole line, some 1,500 cars disappeared!

VITAL NEEDS OF EVENING SCHOOLS FOR INDUSTRIAL WORKERS.

A. D. DEAN.

The next educational move in the immediate future will, I venture to say, be in the direction of improving the instruction in evening schools. Their methods should be recast. They should adapt themselves to modern industrial conditions, and through proper instruction of practical subjects touch more closely the economic and social life of the times. The evening school student attends to satisfy a definite need. Through meeting this need, a more permanent need will be created. These students have already received a more or less formal education in the public schools. They are receiving in their daily work incidental experience, and have learned from this thorough teacher that they are deficient in some lines; hence this endeavor, outside of their working hours, to fit themselves for definite lines of activity.

I shall outline what I consider to be vital needs in the organization and methods of conducting evening school work. The evening school deals with two rather distinct classes: First, those who are naturally students and seek with a definite purpose educational advantages in lines of general education; second, those who are not naturally students and yet who seek with a more or less definite aim educational help in a solution of some present problem which involves special service.

Courses Must be of Two Kinds.

The recognition of these two classes means that the courses of instruction must be of two kinds, one comparing favorably with the day school work in its general scheme, the other and major part differing decidedly from the methods ordinarily pursued. The evening work of the non-student class must have its own distinct ideals, methods, and estimates of value based upon current community conditions and individual needs rather than based on the regular school standards which are applicable primarily to the student class.

Day school teachers are employed too much at present in evening schools. These teachers can meet the needs of the student class, but they cannot properly teach the non-student class. I believe that to the custom of employing day school teachers must be laid much of the lack of definiteness in the planning of evening school work. It is a very simple matter for the average day school teacher to adopt the regular text books, and to use the regular outlines and methods. This is a perfectly consistent action, for few regular teachers have opportunity to know the vital needs of their students through their own experience. In some cities where it has not been deemed wise to employ the day teachers, the policy has been to engage young students of law, undergraduates of colleges, and retired teachers to do this most important work. Now the only people competent to teach in our evening schools are the men and women who know from their contact with modern industrial and commercial life vital points of interest which concern these workers who come to the evening schools to meet definite needs.

Evening School Instruction Must Appeal at Once.

Evening school instruction must appeal to the student immediately at the beginning of his work. The subject matter of the early lessons must satisfy his need as he has defined it. This statement may appear radical, but on second thought it will be seen to be true. For example, a young machinist has received a reprimand from his foreman because he cannot read a working drawing with sufficient skill to do properly his daily work. He enrolls in a drafting course to meet that deficiency and finds that the first two lessons are concerned with lettering plates, the next three with drawing straight and curved lines and the handling of instruments, and that the remainder of the term is to be spent on the projection of points, lines, surfaces and solids. During this time he is receiving in his daily work the same reprimands, and is therefore debating in his own mind the value of his evening instruction. It is undoubtedly true that the drawing course I have here outlined, is a proper one for teaching mechanical drawing for those who are to be draftsmen, but the average apprentice machinist does not see the direct application of this instruction to his work. He enrolled for a definite purpose. To be sure it was a narrow one, but nevertheless it had economic value to him. It would have been perfectly possible to give in the first evening some elementary instruction in the reading of simple drawings; to teach him in five lessons where to look for the dimensions denoting length, breadth and thickness; to have shown the principles of simple sectional drawings and to have him comprehend the laying out of holes for drilling. Instead of leaving school at the end of the fifth lesson with no instruction which appealed to him, he would have received enough in those five lessons to fit him to meet the needs of his foreman, and more than likely he would have remained in the drafting class to receive the more definite and thorough instruction in the theory of mechanical drawing such as must be gained if one is fully to comprehend and cover the entire range of the subject. Give to the apprentice the kind of training that will make him a good apprentice and when this point has been reached there will arise a need for another type of training suitable for the next grade which he hopes to attain.

Courses Must be Elective and Flexible.

The various features of the course must be elective and flexible and presented in small and varied units. Instead of printing in a course of study "Arithmetic," "Geometry," etc., there should be printed, "Arithmetic for Mechanics," "Arithmetic for Clerks," "Mechanical Drawing for Apprentices," etc. Where it is possible even a finer differentiation is desirable, such as "Arithmetic for Plumbers," "Arithmetic for Errand Boys," "Mechanical Drawing for Machine Tenders," etc. Not only will this presentation serve to catch the eye of the prospective student, but it will also suggest to him that special effort is to be made in the class work to help him in his daily occupation.

The instruction in the various branches must be adapted to the needs of the various occupations. The terms used in the class room must savor of the shop, office and store. From personal experience, I know that the problem, "What is ¾ths of 37½?" does not appeal so much to a clerk as the problem, "What will ¾ of a yard of cloth cost at 37½c. a yard?" On the other hand, the latter problem does not awaken the interest of the mechanic as much as the problem involving the same operations, which reads, "If a copper casting weighs 37½ pounds and specific gravity of iron is ¾ that of copper, what will the casting weigh if made of iron?"

Departmental System not Suited.

The student will do better work if the instruction in the related branches of certain occupations is given under one teacher, rather than under the departmental system of specialists in each branch. The student should not elect more than two or three subjects, the major one, bearing directly upon his daily work, the other somewhat related to the main one. It is this major subject which has drawn the student into the school and it is this which will keep him there if along with it one or two allied subjects are taught in a practical manner by the teacher of the major subject. The student will understand better the connection between these subjects because the teacher has himself a clear conception of the relationship. A machinist enrolls in an evening school for mechanical drawing and finds that he needs to "brush up" in fractions and decimals and that he needs "square root" in order to work out a formula for screw threads. I know of no time more opportune to teach him these topics than when the need for them arises, and none is more qualified to give the required practical instruction in such topics than a competent drawing teacher. When large classes demand assistant teachers, these assistants should be assigned to teaching applied mathematics through individual instruction at the drawing table or else to giving instruction to small groups in an adjoining room, keeping before the mind of the student the direct connection between arithmetic and mechanical drawing. When the student has reached a place in a drafting course dealing with the subject of screw threads, it becomes necessary for him to apply some such formula as $P = 0.24\sqrt{d + 0.625} - 0.175$, where P is the pitch of the thread and d is the diameter of the bolt. This problem involves square root and decimals.

One hour of individual or small group instruction by the drawing teacher will give a student the necessary familiarity with these mathematical processes to make them sufficiently clear to him in application to the formula. That many students are not satisfied with this hasty and incomplete instruction has been my experience, and this is often made evident through their joining the regular class in mathematics the next year in order to gain an insight into the reasons involved in the process of square root. Instead of thorough preparation in mathematics for mechanical drawing I should have the mechanical drawing lead the students into mathematics. This reversal of the usual procedure, while it may not be pedagogical so far as the subject matter is concerned, is certainly true to experience when one deals with the characteristics of the average evening school student.

Sequential Arrangement of Courses Needed.

Evening schools should have a sequential arrangement of courses. If the student's transient need is well met, it will place him in a better position, only again to make him feel a renewed need of self-improvement. This means that he will return to the evening school in some subsequent year when he ought to be given advanced work. My own experience has taught me that evening schools are so overcrowded in the elementary courses and are trying to do so much to raise a student one round in the economic ladder that these advanced students suffer through insufficient attention. If specially provided for, they might become our foremen, superintendents and managers. Not only must each school-year's work be driven home and clinched, but each series of years' work be so clinched as to meet the needs of the captains of industry, who are demanding thoroughly trained men for foremanships.

Need of Recreative Element.

Evening schools often fail to have the subject matter and its treatment glow with the recreative element. We must offer educational features in connection with physical and social privileges. The continued interest of many people is often times dependent upon identification with an associated group of varied privileges offering not only self improvement, but recreation. School buildings in our large cities equipped with libraries, gymnasiums, assembly halls, and lunch rooms should be open from 5:30 to 10 P. M. The students should be allowed to enter the building immediately from their work, be furnished a lunch at a low price, encouraged to avail themselves of bathing and library privileges, and have the opportunity for social intercourse as well as educational classes. Under modern industrial conditions it must be remembered that the employed work under a stress which is nerve wearing and physically exhausting. Oftentimes teachers in evening schools complain of general dullness as expressed by nodding heads and listless manner. If they would stop to think of the long distances traveled between shop, home and school; hurried supper; the stifling atmosphere of the school room and the glow of the electric lights, they would readily see the reason for this dullness. The general introduction of the eight-hour day, while it would make work strenuous in the extreme, at the same time shortens the day's hours of labor and ought to bring more opportunity for recreation and education. It is a duty of the evening school so to combine these two features as to result in the profit of the worker. At present young people seek recreation independently of education much to the loss of their own best interests.

Need of Division of Classes by Ages.

There should be in the evening school work a separation in the class instruction of the immature from the mature non-student class. The latter are extremely self-conscious. They are often embarrassed at having to be instructed after passing the usual school age. Their feelings should be respected as far as possible. Is it any wonder that a foreman of a pattern shop does not take kindly to being instructed in mechanical drawing in the same class with a boy machine-tender over whom he has charge during the day? This point does not have to be considered in the German continuation schools where the ages of the students are more uniform. The young men in some parts of that country are required to attend evening schools for a definite period and consequently the grading of men according to ages is unnecessary, for a young man of sixteen in the elementary class is in contact with those of similar age, and the more mature men in advanced classes, having already received elementary training, are likewise graded with those similarly prepared.

Special Text Books Suited to Evening Schools.

There should be a series of textbooks written expressly for the kind of instruction demanded in evening schools. That few such books are on the market is clear testimony that as yet a small number of teachers have recognized that there is any difference between the methods of instruction in day and evening schools. When the fact is recognized, a series of books will be published. In a careful study of the value of existing textbooks meeting the needs in all branches of one class of men, *i. e.*, men engaged in the machine trades, I have been chagrined to find that I could readily count the entire list upon the fingers of my two hands. What is needed is, for instance, not an elaborate textbook in general arithmetic with all its topics of fractions, decimals, square root, percentage, interest, partial payments, etc., but rather a book which appeals to a man in the machine trades, then one which appeals to a plumber, or a clerk, or an errand boy; small enough to slip into the side pocket of a coat and cheap enough so that he can readily own a copy for reference in his daily work.

Provision for Irregular Attendance.

Provision should be made for students who can attend but once or twice a week. Some students stay away because they cannot attend "regularly." This applies to all domestic servants. It applies also to many industrial workers. In prosperous times shops are run evenings and the men employed are expected to work over-time. They can usually get away for one night in the week during such times. They cannot always tell definitely what nights they will be called upon to work.

I know of a few schools which allow their members to attend any night or nights during the week after the work is fairly started. Such a plan is perfectly feasible in shop or drawing courses where all the instruction is individual. Some schools allow the students to do their drawing work at home during the periods of overtime work in the shop, expecting that the students will attend some night in the week to get definite instruction or data for home work.

Classification by Vocations.

Students must be classified into vocational classes according to their trade or business. The old workingman's guilds were founded for the purpose of social intercourse and mental stimulus. Each trade had its own guild. The daily trade experiences of each member became the property of all members. Discussions relating to the practices of their chosen trade occupied their attention. Is it not true that working men to-day have common trade interests? Evening school students grouped according to occupation would have an opportunity to talk over these interests. The teacher could act as a leader and draw out the students into telling their trade experiences and through the expression of these various opinions the most practical solution of the particular problem at hand would be obtained. Teachers who have had evening school experience know how difficult it is to get the students to recite and express themselves at the blackboard. A free discussion of the point at issue makes the student lose his self-consciousness and before he is aware of it he is at the board illustrating his particular method of solution. Of course such discussions must be under wise guidance.

Fee System Preferable to Free Instruction.

While it may not be feasible to charge in the public school system a small fee for the evening work, at the same time I know from personal experience that such a procedure is very desirable. That the working people can afford to pay for such instruction is evident from the large numbers who are subscribing to various correspondence school courses, and also from the fact that 69 per cent of the parents interviewed in a recent investigation conducted by the Massachusetts Commission of Industrial and Technical Education stated that

they could have afforded more schooling for their children had it been of a more practical kind. A self-supporting person appreciates what he pays for and is not only more anxious to finish his course after he has paid for it, but is also quite likely to see to it that the teachers give him what he wants. The fee system acts as a stimulus to the student and teacher. It is not necessary to charge a fee covering the entire cost. German evening schools charge only a small fee. There should be no charges for administration, lights and heat. The instruction might also be free, the school charging only for the material consumed in the shop and laboratory courses. Many superintendents of schools have expressed a wish that some fee might be charged in evening schools simply because it assists in obtaining better attendance, more earnest work, and "weeds out" those who diminish the efficiency of the school.

Evening Classes should be Attractively Advertised.

There is a need of recognizing that in adapting educational features to peculiar conditions oftentimes conservative methods will not meet the personal attitudes of those who need the service. In the matter of presentation before the public it might be well for the public schools to imitate some of the advertising methods of our more successful correspondence schools. It is not a wise business policy for a city to spend $10 on the instruction of a student when with an additional 10 cents' worth of advertising the cost per pupil could have been reduced perhaps to $8 because of the larger number enrolled and hence lessened the cost per capita chargeable to the general items of administration, heat, light and interest. Neither is it the best policy for school authorities to insert a small, obscure advertisement in the daily paper, unattractive in its wording, lacking explanation regarding the nature of the instruction and expect a working man or woman who needs such instruction to understand it or even see it. On the contrary it is good business for a city to advertise its educational features in an attractive poster on various billboards, in the office, factory and store.

Doubtless some time in the future men who are responsible for the proper conducting of evening schools will begin to realize that the desirable locations for many educational features are in the natural assembling places of the working people, especially during their leisure hours, making as much as possible the educational effort in which they participate a natural adjunct to their daily life and not a separate and distinct enterprise. I prophesy that small libraries and reading rooms, will be added to stores and factories and that practical talks and lectures will be given to the employees of these establishments. This procedure is possible probably only when there is no equipment necessary in connection with the instruction.

Growth of Correspondence Schools an Argument for Evening Schools.

The significance of the growth of correspondence schools in this country must not be lost sight of. Their rise denotes that the working people are seeking education when it is presented to them in such a way as appeals to them as meeting their needs and also when brought into close contact with their daily habits. Just so long as correspondence schools flourish, just so long will their presence illustrate the need of better evening schools. Let us consider the amount of money which goes out of the community into the coffers of correspondence schools. For instance, in Massachusetts it is estimated that there are 55,000 subscribers to correspondence schools. If on the average each subscriber has paid $40 for his course, that means that $2,200,000 has gone out of the state into the pockets of private enterprise in other states. There are 28 important industrial centers in the state of Massachusetts. This sum of money distributed to each of these centers would approximate $78,000, which at 4 per cent would net $3,120 a year. This estimate is very conservative as it only assumes that the money has already been spent and does not take into account that which is leaving the state every day as subscriptions to the various courses in these schools. The amount mentioned, if directly applied to the meeting of the economic needs of the working people through evening school instruction would give practical work of high order to over 300 students in technical and commercial work. It would mean an evening school of trades and an evening commercial high school in each of these 28 important industrial centers in addition to the regular elementary work now furnished by the municipalities. Is it not casting reflections on the cities when private enterprises take the field of educational activity which rightfully belongs to the public enterprise?

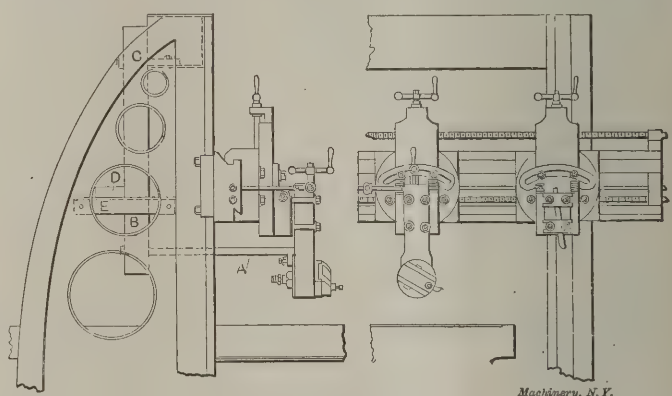
Public Schools not Meeting Present Needs.

More and more is it being recognized that the public schools are not meeting the needs of industrial life. One has only to note the tremendous growth of the correspondence schools, of the work done by the Young Men's Christian Associations with their forty thousand evening students, of the Cooper, Pratt, Lewis and Spring Garden Institutes with their class rooms and shops overflowing with evening students, the manufacturing concerns which are introducing apprenticeship systems, with evening instruction, to feel that there is a decided need for practical evening school instruction. If such education is not a function of the state, an inalienable right as it were, it might be well to acknowledge it. Is it not better to comprehend the significance of all these movements and find out the needs of the industrial workers and then meet the needs through progressive educational activity in evening schools?

* * *

BRACE FOR PLANER TOOL.

The accompanying cut taken from *Railway and Locomotive Engineering* illustrates a brace for a planer tool used by the Pennsylvania Railroad Co. in their Columbus, Ohio, shops. It is said to have increased the output of a certain class of planer work about one-third. It is employed for planing out the circular seat on driving boxes for the brasses. This seat is not a full circle, there being two lips at the lower side for holding the brasses which prevent this work from being done on a lathe or boring mill; hence the practice is to either slot



Brace for Planer Tool.

out this part or to plane it on a planer using a "radius" tool of the form shown in the cut. The feature to which particular attention is called is the brace *A* which stiffens and supports the tool, preventing heavy torsional stresses being imposed on the planer cross-rail by the roughing cuts. Its principle is similar to the planer bar with stiff support, illustrated in the October, 1904, issue of this journal. The thrust is transmitted to the housings in a different manner, however, there being a vertical member *B*, pivoted at *C* so that it can swing through an arc of limited extent, and backed up by a cross member *D* which is secured to the housings by suitable connections, as at *E*. The mechanism for operating the planer tool through the arc of a circle is not described but we infer that it is automatic in operation as it could easily be made so.

* * *

A common abbreviated method of writing dates is to write the month, day and year, thus, 9/23/06 for September 23, 1906, but an objection is that if this method is to be used it should be in logical order, *i.e.*, the day, month and year. All do not follow the same order, the consequence being that this method of recording dates is unsafe, as in some cases it is impossible to tell which is the month or year. A method followed by one of our German correspondents is to give the day, month and year, but to write the month in Roman characters, thus: 5/XI/06, *i.e.*, November 5, 1906.

ADVERTISING MACHINERY IN LARGE ESTABLISHMENTS.

Firms advertising machinery as a rule send their catalogues to the main office of the manufacturing plant where they wish to introduce their products. As a rule they are addressed to the firm, no particular individual being referred to. In the case of a small concern this works very well, no doubt. The manager of the small concern is not only giving a great deal of his time to the direct supervision of his shop, and knows what may be particularly needed, but he as a rule has a thorough technical knowledge of the requirements put on machinery. His duties, while manifold, are within a more limited sphere, and he will find time to give some personal attention to the various advertising literature reaching the office. But the case will be found to have a different aspect when we consider a large establishment. In the first place a greater amount of advertising literature reaches such a place, and secondly, the persons in charge of the concern cannot possibly be either personally in touch with the particular needs of various departments, nor possess a thorough technical knowledge as to the merits of all the various machines and appliances used in their plant. Even admitting that their ability were of more than the usual kind, and that they had mastered a great number of various fields of information, their duties are so exacting that it is doubtful whether they would give much time to studying advertising literature unless being particularly interested in some certain line of machinery. Besides these considerations we cannot overlook the fact that the leading men of large establishments are as a rule more men of business than of technical achievements, and their judgment of machinery would be largely influenced by many other considerations than those of mechanical superiority. From what has been said we may thus conclude that in a large industrial plant the advertising literature if sent to the office, largely fails to exert due influence. If reaching the office in a busy season it often finds its way too quickly to the waste basket. The man who would be interested in the catalogues never sees them, and if they are filed and indexed, as is the case in most well organized shops, but by no means in all, they are still performing no useful service, being often kept in the file only until old enough to be thrown away.

The men who largely influence the management in regard to the buying of machines in large concerns are the foremen of the various departments. They know exactly the needs of their particular part of the shop; they possess an intimate knowledge of the requirements of the machinery they use, and their interest in building up the business is greatly increased by their partaking in the selection of appliances for facilitating the output. They are the men whom the advertising literature should reach. But seldom or never will it reach them unless they send for it themselves, because their own firm as a rule does not recognize the good of sending the received catalogues to the men who would be best able to judge, and the advertisers have not as yet realized the necessity of getting in close touch with those who actually are, or at least ought to be, most active in the selection of machinery. It is therefore a timely suggestion to put forth, that our advertising manufacturers should add a request when sending their catalogues, that these latter be placed in the hands of the man actually in charge of the class of machinery advertised. Some of our leading firms have in fact already adopted this method in regard to certain kinds of their trade literature, but in the majority of cases the foremen and even the department superintendents are depending entirely upon the advertisements in the trade journals, and the catalogues which they send for themselves on account of these advertisements, for all knowledge about new advertised machines on the market. If it were not for the influence of the advertisements in the trade journals, it is likely that our manufacturers would long before this have realized that catalogues need go further than to the business office of a firm. By means of the trade journal which reaches further, the advertisers have reached the men which they should try to reach by their catalogues as well.

A EUROPEAN BEVEL GEAR GENERATING MACHINE.

The bevel gear planing machine shown herewith, built by the Ateliers de Construction Mecanique (*cidevant* Ducommun) at Mulhouse, Alsace, embodies in its design a number of features of considerable interest, among which are the linkage system which gives the proper movement to the blank, and the use of two tools, one for each side of the tooth. This ma-

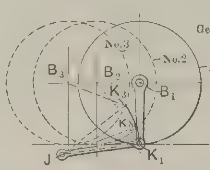


Fig. 1. Approximate Link Motion.

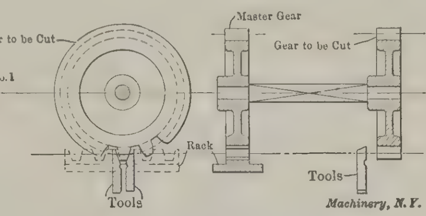

Fig. 2. Sang Method of Generating Spur Gears.

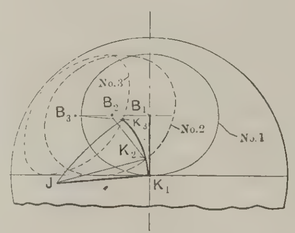

Fig. 3. Approximate Spherical Link Motion.

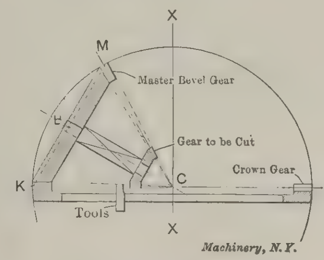

Fig. 4. Sang Method Applied to Bevel Gear Generating.

chine operates on what is known as the "Sang" system of gear generating which, in its simplest form as applied to spur gears, is illustrated in Fig. 2. The master wheel and the blank to be cut are given a lateral movement perpendicular to the axis of the shaft which connects them. This movement rolls the master gear over the rack, giving the blank a

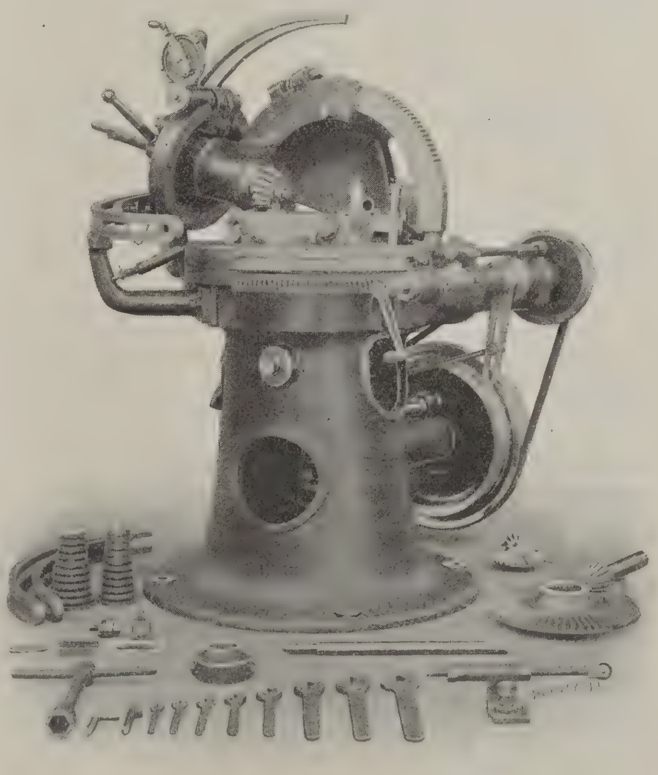

Fig. 5. A Machine Involving the Principles Illustrated in Figs. 3 and 4.

similar rolling movement over a pair of cutters which include a space corresponding in outline to the sides of the rack teeth. Thus these tools cut in the blank the tooth curves required to mesh properly with a rack whose teeth have the outline of the cutting tool edges. It is not necessary that a rack and master gear be used to give the rotary motion to the blank as its axis is translated. As shown in Fig. 1, when the pitch

circle of the master gear rolls on the pitch line of the rack, a point such as K_1 in the pitch circle of the master gear will trace a cycloid K_1, K_2, K_3. A point J can be found so located that, with this as a center, an arc can be drawn very closely approximating the cycloid. If then, instead of the master gear and rack, we substitute as shown in Fig. 1 a crank B_1 K_1 in place of the gear, and a link J K_1 to connect the crankpin with the point J determined as above described, then, when the axis of the blank is given the lateral movement described in connection with Fig. 2, the link will so restrain the movement of the crankpin K_1 that it will nearly follow the cycloid and in so doing will give the blank a close approximation to the rotary motion obtained by the gear and rack in Fig. 2.

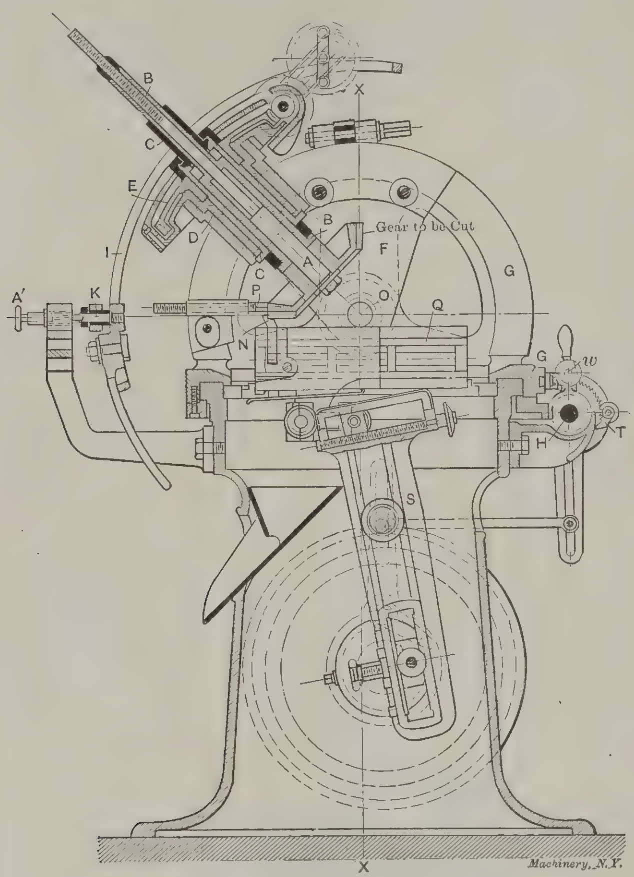

Fig. 6. Vertical Section through Plane of Work Spindle.

The Sang process as applied to the forming of bevel gears is shown in Fig. 4. The rack is replaced by a crown gear and the master gear is replaced by a master bevel gear whose axis passes through the central point of the crown gear. The gear to be cut is mounted on the axis of the master bevel gear and moves with it, and is so located that its pitch cone apex is at C, the center of the crown gear. If, then, the sides of the teeth of the crown gear be plane surfaces, a pair of tools with their cutting edges in the plane of the tooth faces of a rack space may be used to generate the teeth of the gear to be cut, when these tools are given a reciprocating motion which allows their cutting edges always to remain in the plane of the sides of the rack tooth. In this case the axis of the master gear and blank, instead of being given a rectilinear horizontal motion at right angles to the axis as in Fig. 2, is given a circular motion about vertical axis X X, so that line B C would describe a cone if it were completely revolved. The master bevel gear is thus given the proper rolling motion about the crown gear.

By a similar approximation to that illustrated in Fig. 1, we may do away with the crown gear and the master bevel gear. The pitch circle of the master bevel gear rolls about the pitch circle of the crown gear. In so doing a point K_1 in the pitch circle of the master bevel gear will, as shown in Fig. 3, describe a spherical cycloidal curve determined by points K_1, K_2, K_3, which are the positions that point K_1 takes in the three positions of the pitch circle marked No. 1, No. 2 and No. 3 in the sketch. It must be remembered, in following this action, that all the lines shown are supposed to be drawn on the surface of a sphere with C (Fig. 4) as center. Now, as in Fig. 1, we find a point J such that, with one point of the dividers located here, the other point will follow the spherical cycloid K_1, K_2, K_3 very closely. We may then, as in Fig. 1, dispense with the master and crown gears, replacing them with a crank or link, B_1 K_1, pivoted at one end to axis B C, and joined at the other end at point K_1 to the swing link pivoted at J. With this arrangement then, within reasonable limits, a rotation of axis B C in Fig. 4 about vertical axis X X will impart to the gear to be cut, through the restraining action of link J K_1, a motion similar to that given by a master bevel gear and crown gear, which will be suitable, as before explained, for shaping the correct form of tooth on the blank under the action of the two cutting tools.

The machine, Fig. 5, uses two tools, one for each side of the tooth. Since these tools, shown at N in Figs. 6 and 7, must move in separate paths converging toward point O, they are necessarily mounted on separate slides traveling on guides Q, which may be adjusted independently about the vertical axis X X of the mechanism, in the circular recess to which they are fitted in the top of the frame of the machine. This adjustment gives the necessary converging motion to cause the teeth which they form in the blank to disappear at the apex O of the crown gear and the blank. A separate adjustment, controlled by the tap bolts seen in the curved slots on the sides of the tool slide guides in Fig. 5, gives a rocking adjustment about axis O in the plane of the section in Fig. 6. This is required to make the tool follow the angle of the root of the tooth, and gives it a movement slightly out of the horizontal. The tool slides are reciprocated through ball pivoted connecting rods from slotted link S, which has the adjustment shown in Fig. 6 on its upper end for varying the position of the stroke, and an adjustable crankpin in its driving crank for varying the length of the stroke. The machine is driven through the three-step cone shown in Figs. 5 and 7.

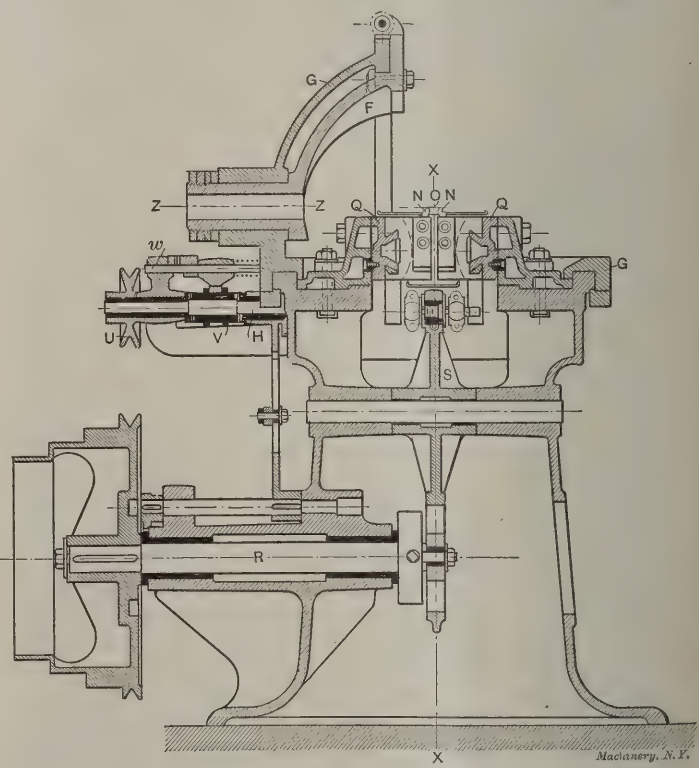

Fig. 7. Section showing Driving Mechanism.

Neglecting, for the time being, the adjustments required for suiting the machine to gears of different pitch cone angles, let us trace in the machine the action explained by the diagrams in Figs. 3 and 4. Axis B C in Fig. 4 is that passing through the gear to be cut in Fig. 6. The rotation of this axis about the vertical axis X X of the machine is effected by rotating the whole structure on which it is supported around the circular bearing provided at the top of the column of the machine. The table, carrying the structure for holding the gear blank, has a section for a worm wheel formed on a por-

tion of its periphery, as shown in Fig. 5. A worm on shaft H engages the worm wheel teeth. Shaft H may be driven either by pulley U, Fig. 7, from the belt cone for quick return movement, or by a cam in the face of the belt cone through the slotted link mechanism shown acting upon the ratchet and ratchet wheel at T, which arrangement gives the cutting feed. A clutch V connects either of these motions to shaft H. This clutch is operated by a rod w controlled by the dogs shown in Fig. 5, adjustable in the peripheral slot of the circular table. By means of these dogs the table, when started on the cutting feed, will stop itself at the conclusion of the cut and rapidly return to its first position ready for starting in on a new tooth.

So much for the movement about the axis X X. For the rolling motion which must be given the blank to agree with that of the master bevel gear rolling in a crown gear as shown in Fig. 4, the approximation outlined in Fig. 3 is used. Link I in Figs. 6 and 8 is link B_1 K_1 of Fig. 3. Point K in Figs. 6 and 8 is point K_1 in Fig. 3. In Fig. 8 pivot K has been raised from the position it should occupy directly back

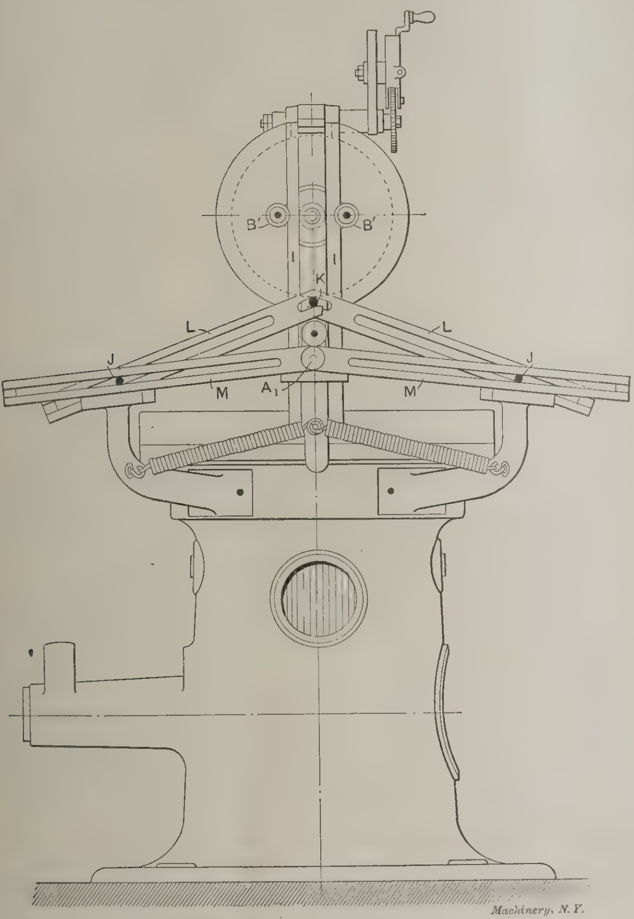

Fig. 8. Diagram showing Arrangement of Approximating Linkage.

of point A_1, to show the construction of links L. Considering however, that the mechanism is in its proper condition, when the blank is given its rotation about vertical axis X X, point K_1, if the proper rolling motion is given the blank, will trace a spherical cycloidal identical with K_1, K_2, K_3 in Fig. 3. To insure that point K shall follow with great exactness this cycloid, as the blank rolls to the left one of the pair of springs shown at the lower end of link I presses pivot K to the bottom of the open ended slot in link L, which is pivoted at point J, this point being selected in the same manner as point J in Fig. 3. It will thus be readily understood that the rotary and rolling motions required for the blank are very closely approximated. Of course the cut is not started from the middle as we have been considering. The blank is first swung to the extreme right, for instance, so that it clears the tools. Under those circumstances the pivot K will bear on the bottom of the open ended slot in the right-hand link L, being held there by the pressure of the right-hand spring. When it reaches the central position shown in Fig. 8 it will be under the restraining influence of both links L. As it continues to swing toward the left it will come under the control of left-hand link L and the left-hand spring.

The various cuts show quite clearly the adjustment required for gears of various pitch cone angles. Sector F is adjustable in a vertical plane about pitch cone apex O on its semi-circular bracket or support, which is integral with table G. This sector F carries the bearing for the blank. The entire indexing mechanism, together with the blank, is of course rotated with link I under the action of links L. The machine is semi-automatic, the indexing being done by hand through means clearly shown in the cuts. Before altering the adjustment of links L for a new pitch cone angle, the table G is first brought to the central position shown in Fig. 8. Pin A_1, shown as A' in Fig. 6, is inserted in a hole in pivot K, Nuts B' on the dividing wheel casing, through which motion is transmitted from links I to the blank, are then loosened. Sector F is adjusted and fastened in its new position on circular bracket G, and nuts B' are tightened in their new positions to correspond with the new angular setting of the head. Pivots J J are now shifted along the slots in guide bars M M to agree with graduations corresponding with the angle to which the blank-carrying spindle is set. After the pivots are tightened in their new locations, pin A_1 is withdrawn and the mechanism is ready for the gear of the new angle.

It is interesting to compare this machine with the Bilgram and Gleason bevel gear generators, both of which operate on the same principle. None of these three machines, however, bear the slightest resemblance to the others externally—an indication of the different ways in which the minds of different designers will act when the same problem is presented to each of them.

* * *

WE HAVE A NEW MAN IN OUR SHOP.

A. P. PRESS.

We had a new man come in last week. You see it is like this: Ours is a country shop, and it is hard work to get a good man; this fellow came along in the office and asked for a job, and said if the boss could stand for his coming in at 8:00 A. M. every morning he would like to go to work. He said it was not convenient for him to get in at 7:00.

Now lots of men come in on the train about 7:15, so the "Boss" said it would be all right, and the next morning at 7:55 in he came. He had a good kit of tools, knew how to use them, and was a good "all-round" man. He turned off more work that first day than I ever saw a new man do before. He had better clothes on than I had when I got married, but he took a clean pair of overalls out of his box, rolled up his sleeves, and showed he wasn't afraid of dirt.

I got to talking with him the first noon, and I found he knew things. One of the first jobs he had to do was to turn up a big, round brass ball about 6 inches diameter—a model of something or other, I think—and I thought he would be stuck. But, not a bit of it; he just put a piece of 2 x 6-inch plank on the faceplate, turned out a place in it that fitted the ball snugly, gave it a "chuck in" and then hand-tooled it up.

He had been here a week or two when our observing "Boss" noticed that he went in a certain house every night, and finally asked him if he lived there. "Sure!" he replied. "Well, if you live there, close to the shop, why don't you get in at 7:00 o'clock?" "Why! I told you when I hired out that it was not convenient for me to do so; you see it seems better for my constitution to lie abed until 7:00." Now, he is a big, strong fellow with the constitution of a giant. The "Boss" was wild and he started to "fling it" into him. "Hold up," said the new man. "Haven't I kept my agreement in both the letter and the spirit, and haven't I given you a dollar's worth of goods for every hundred cents I received? If you want to cancel that agreement, there is a first-class chance for you to do so, right now."

The "Boss" stopped right there and then, and so far the fellow has been coming in at 7:55 just the same, but whether he is a union man and is trying to make this a nine-hour shop, or whether he is plain lazy and doesn't want to work that other hour, we haven't made up our minds yet, but when we have, we will let you know.

DRILL JIGS.—3.

E. R. MARKHAM.

Form of the Jig.—The shape and style of the jig must depend on the character of the work, the number of pieces to be drilled, and the degree of accuracy essential. It may be that a simple slab jig of the design shown in Fig. 20 will answer the purpose; if so, it would be folly to make a more expensive tool. If we are to drill a piece of work of the design shown to the left in Fig. 21 and but one hole is to be drilled in each piece, then a jig made in the form of an angle iron, as shown to the right in Fig. 21, works nicely, and is cheaply made. As it is not necessary to move the jig around on the drill press table it may, after locating exactly, be securely fastened to the table. In designing such a jig, it is advisable, when possible, to have the work on the side of the upright shown in Fig. 21, rather than on the opposite side, as we do away with any tendency of the jig to tip when pressure is applied in the operation of drilling.

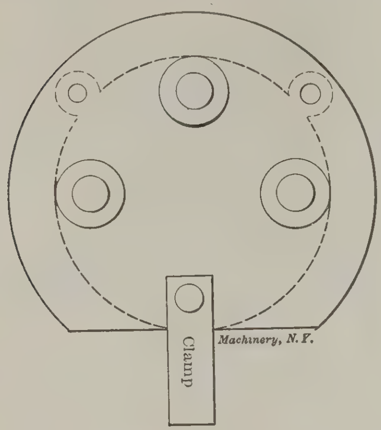

Fig. 20. Slab Jig of Simplest Design.

For many kinds of work a jig provided with a leaf, as shown in Fig. 22, gives best results, as the leaf may be raised, and the work removed, and any dirt cleaned from the working surfaces. After placing the piece to be drilled in the jig, the leaf is closed. As the bushings are in the leaf, it is apparent that it must always occupy the same relative position to the work for the different pieces, or they will not be duplicates; consequently the fulcrum pin, *a*, must be a perfect fit in the hole in the leaf, and a locating pin *b* is provided to prevent any tendency of the leaf to move from the action of the drill when cutting. Jigs provided with such a pin show less tendency to wear in the joint. The leaf should not close down onto the work, but onto a shoulder on pin *b* as shown, there being a space between the work and the jig leaf.

While the above is true for most work, a jig for drilling round pieces may be designed as shown in Fig. 23, the holding device being two V-shaped blocks, one located on the lower portion of the jig, while the other is on the leaf, as shown. In the case of a jig of this pattern the work is securely held by binding the cylindrical piece by pressing the handles of the jig together.

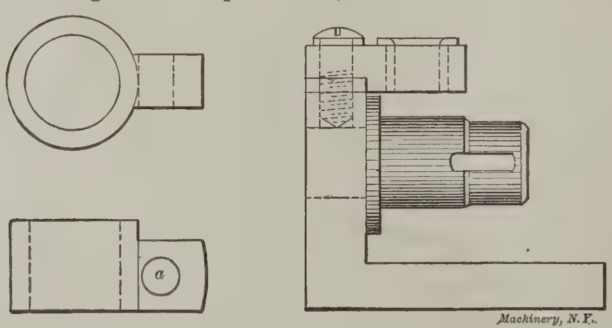

Fig. 21. Piece to be Drilled and Jig Used for this Work.

When jigs are to be moved around on the table of the drill press as is the case where several holes are to be drilled, legs are generally provided, as shown in Fig. 22. In order that the legs may not wear it is customary to harden them. The legs are hardened before they are placed in the jig, and are ground and lapped true while in the jig. As the only wear is on the ends, or where they come in contact with the drill press table, it is customary to harden only the ends which rest on the table. In most shops jig legs are made from tool steel, although a good grade of open-hearth steel containing sufficient carbon to insure its hardening answers as well for most purposes. But as few shops carry such steel in stock, crucible tool steel is generally used. The ends of the legs should be ground true with the seating surface—that is, where the work rests—of the jig. To accomplish this a surface grinder should be used. As the operation of grinding leaves a number of projections on the surface ground, and as these ridges or projections would wear away as the legs were moved back and forth on the drill press table, it is advisable to remove them by lapping on a flat lap, thus producing a perfectly smooth, true surface. In this way we reduce the wear to the minimum.

For certain classes of jigs the legs may be short, not more than ½ inch long; but for jigs of the style shown in Fig. 22, where the tool is held in the hand, it is necessary to make the legs longer to keep the fingers from coming in contact with the chips on the drill press table. The legs should be located so as to do away with any tendency of the jig to tip up when the work is being drilled.

While it is necessary to observe extreme care in designing drill jigs to prevent any tendency of the jig to tip, and to have the legs ground and lapped on a true plane, it is just as necessary that the drill press table should be perfectly at right angles to the spindle, and that it should be true and flat. Otherwise the holes will not be at the desired angle with the working surface of the work.

In shops where interchangeable work is produced, or where the work must in all respects be machined correctly, the condition of the various machines is closely watched, and especially such parts of the machines as affect the accuracy of the finished product. Drill press tables are planed over when out of true, or are lined up to insure their being at right angles to the spindles of the drill press. This may be done by placing a bent wire in the drill chuck, the wire being bent so that it will describe as large a circle as possible, and yet be free to swing. The end of the wire is bent so that a point will come in contact with the table. By loosening the screws holding the table, and inserting "shims," it may be trued as desired.

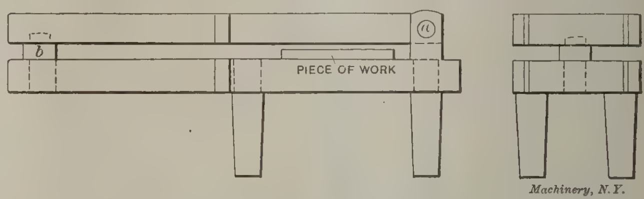

Fig. 22. Jig with Pivoted Leaf.

Locating the Holes for Drill Bushings.—When making jigs, the part of the work that calls for the best workmanship is locating the holes for drill bushings. The methods employed differ, but should depend on the character of the work. Where accuracy is not essential it is the custom many times to take a piece of work that is right, that is, one where the holes are drilled near enough right, place this in the jig and transfer the holes into the jig. As it is necessary to leave the bushing holes in the jig considerably larger than the holes in the work in order to have sufficient stock around the holes in the bushing, those in the jig may be enlarged by means of a counterbore, the pilot of which fits nicely in the transferred holes, and with a body the size of the desired hole. When this method would not insure desired accuracy, several other methods may be employed.

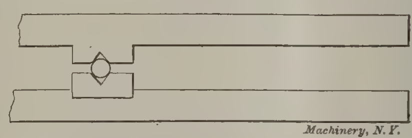

Fig. 23. Part of Jig with Pivoted Leaf, showing Method of Holding Round Work.

If a model of the work to be done is at hand a jig, as shown in Fig. 22, may be made in the following way. The leaf is raised and the model placed in it. The jig is fastened to the faceplate of the lathe, the leaf still being raised. By means of a center indicator the jig is located so that one hole of the model runs true, the leaf is then closed and the hole is drilled through it, and then bored with a boring tool to the desired size. Never ream a bushing hole in a jig, or

any similar hole in any piece of work, where the finished hole must be exactly located, as a reamer is liable to run out somewhat, and thus affect the accuracy of the work. A reamer, if properly made and used, will produce a round, true hole, accurate as to size, and is a valuable tool for many purposes, and holes of a uniform size may be produced. But on account of the stock being uneven in texture, or on account of blow holes in castings, a reamer is liable to alter its course and so change the location of the hole. While for many purposes this slight alteration of location might be of no account, yet for work where accuracy is essential, it is out of the question.

After drilling and boring the first hole the jig may be moved on the faceplate, and the other holes produced. It is obvious that in order to produce holes that will be at right angles to the base of the jig, the faceplate of the lathe must run true, and should be tested each time it is used for any work where accuracy must be observed.

Where there is no model, and it is not considered advisable to make working models of the various parts, the location of the bushing holes may be obtained by laying out the various points on the jig. In such cases a drawing is usually furnished, and the dimensions on same are transferred to the face of the jig. If it is not necessary to have the holes exact as to measurements, the laying out may be done with a

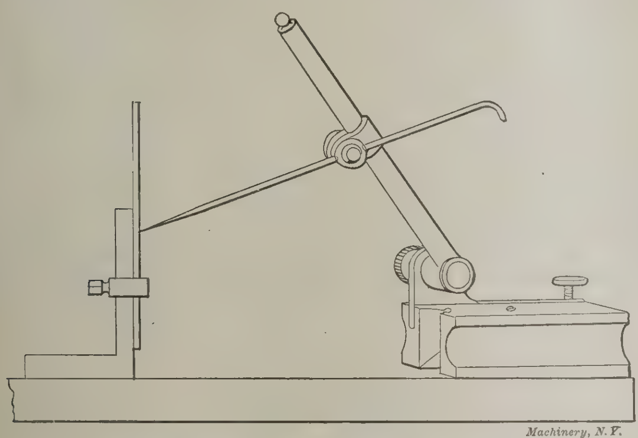

Fig. 24. Method of Taking Vertical Measurements.

surface gage, the point of the needle being set to a scale. The scale may be clamped against an angle iron, as shown in Fig. 24, or an angle iron may have a groove of the width of the scale cut across its face at right angles to the base, as shown in Fig. 25. The scale should be a good fit in the groove, so fitted that it will stay securely at any point from frictional contact with the sides of the slot, or a spring may be located as to insure the proper tension.

Where greater accuracy is essential the working points should be obtained by means of a height gage, as shown in Fig. 26. By means of such a tool the measurements may be fairly accurate, as the Vernier scale allows of readings to one thousandth inch.

When the lines have been scribed at the proper locations they are prick punched. In order to prick punch exactly at the intersection of lines the operator must wear a powerful

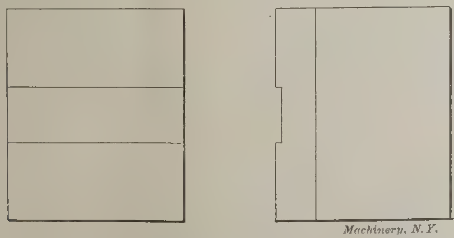

Fig. 25. Angle Iron with Groove for Scale.

eye-glass and use a carefully-pointed punch ground to an angle of 60 degrees. If the punch marks are made very light at first the exact location may be observed nicely. The punch marks should not be deep, as there is a liability of alteration of location if the punch is struck with heavy blows. After the various points have been located and punched the jig may be clamped to the faceplate of the lathe and the bushing holes carefully drilled and bored to size.

At times jigs are made of such size and design that it seems wise to core the bushing holes. In such cases it is necessary, in order that we may lay out the location of the centers of desired holes to press a piece of sheet steel or

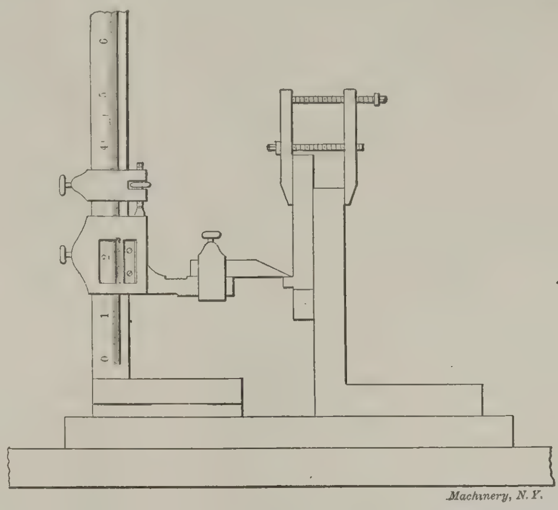

Fig. 26. Taking Vertical Measurements by Means of Height Gage.

sheet brass into the cored hole, as shown in Fig. 27, and locate the center on this piece. When the jig has been properly located for machining, the sheet metal may be removed and the hole machined to desired size. If an error of 0.001 or 0.002 inch is not permissible the method described above will not answer.

Where extreme accuracy is essential we must locate round pieces of steel on the face of our work. These pieces of steel are called buttons and are of exact size and perfectly round. To do away with any possibility of their becoming bruised in any way they are hardened and carefully ground to size. The buttons are attached to the work by means of machine screws, as shown in Fig. 28, the holes in the buttons being larger than the screws used; this difference in size allows us to move the button until it is accurately located. The diameter of the buttons should be some standard size,

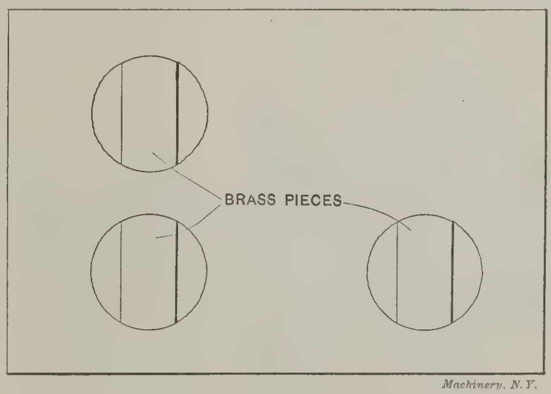

Fig. 27. Cored Holes with Inserted Brass Pieces for Centers.

easily divisible by two, because, in making our computations we only consider the distance from the center of the button to its circumference, that is, the radius.

When we start to lay out the centers for the bushing holes we first determine our working surface, then lay out on the face of the jig, by means of a surface gage, as described in a previous operation, the centers of the holes to be produced. We then drill and tap screw holes to receive the screws to be used in holding the buttons to the jig. When we have prick-punched the surface and before drilling the holes we scribe by means of dividers a circle of the size of the button on the face of the jig with the punch mark as center. This enables us to approximately locate the button. If the hole to be produced has its center 2 inches from the base *a* and 4 inches from vertical side *b*, Fig. 29, we would locate the button—provided it was ½ inch diameter—1¾ inches from *a*, and 3¾ inches from *b*. This can be done accurately by use

of a Vernier caliper, or we can lay the jig on the side *b*, and by means of a length gage, or a piece of wire filed to the right length, accurately determine the distance from *b* to the button. The jig is then placed on the base *a* and the other dimension obtained in the same manner. The buttons may be located more easily by the use of a Vernier height gage, if one is at hand.

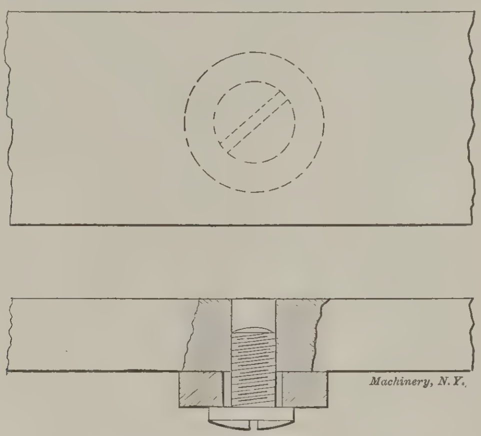

Fig. 28. Buttons for Locating Holes in Jigs.

If there are to be several bushings on the face of a jig a button may be accurately located where each hole is to be. The jig may be clamped to the faceplate of the lathe so that one button is located to run exactly true. This is done by means of a lathe indicator. When the jig has been so located that the button runs perfectly true, the button may be removed and the hole enlarged by means of a drill so that a boring tool can be used to bore it to the proper diameter.

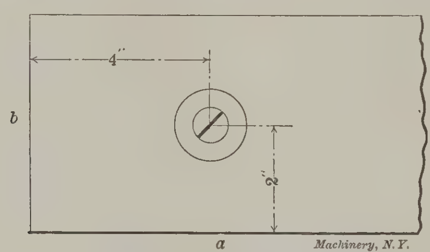

Fig. 29. Locating a Hole by Means of a Button.

In some shops it is not considered advisable to locate a button at the desired position of each bushing hole. One button is located and the jig is fastened to the table of a milling machine having a corrected screw for each adjustment. Then, after one hole is accurately located and bored, it is a comparatively easy matter, by means of graduated dials, to obtain the other locations; however, this method should never be used unless the machine has all its movements governed by "corrected" screws, as the screws ordinarily sent out on milling machines are not correct as to pitch, and if used serious defects in measurement will result.

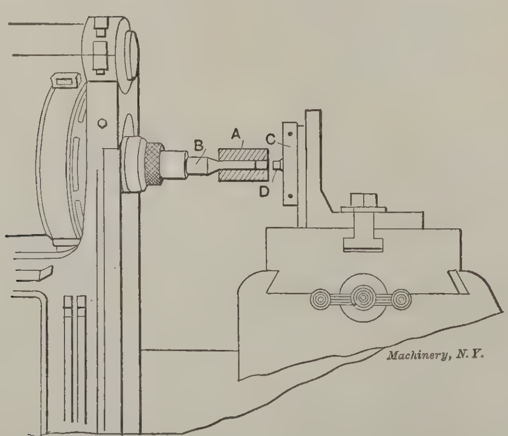

Fig. 30. Locating Holes in the Milling Machine.

Fig. 30 shows a jig clamped to an angle iron on the table of the milling machine. The angle iron is located exactly in line with the travel of the table, and the jig fastened to it. The button *D* which has previously been accurately located serves as a starting point, and the jig must be located so that the button is exactly in line with the spindle of the machine. This is accomplished by moving the table until the sleeve *A* on the arbor *B* will just slide over the button *D*. The hole in *A* must be a nice sliding fit on the arbor *B* and also on the button *D*. In order to insure accuracy, the arbor *B* must be turned to size in the spindle just as it is to be used, or, if a portable grinder is at hand the arbor may be fitted to the spindle hole or to the collet, as the case may be, the portion which receives the sleeve *A* may be left a trifle large and ground to size in place in the machine. The portable grinder is located on the table of the machine.

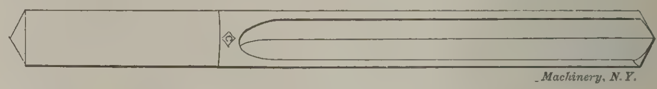

Fig. 31. Straight-fluted Drill for Jig Work.

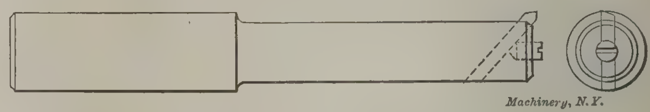

Fig. 32. Inserted Cutter Boring Tool.

After the jig has been accurately located so that the button *D* allows the sleeve *A* to slide over it, the arbor *B* may be removed from the spindle, and a drill be employed to increase the size of the tapped screw hole that received the screw used in fastening the button. Best results follow if a straight-fluted drill, as shown in Fig. 31, is used. The drill should not project from the chuck or collet any further than necessary, thus insuring the greatest rigidity possible. After drilling, a boring tool of the form shown in Fig. 32 may be substituted for the drill and the hole bored to size. The machine may now be moved to position for the next bushing hole by observing the dimensions given. The operator should bear in mind that the screw used in getting the spacings must be turned in the same direction at all times, otherwise the backlash will render accuracy out of the question.

While the foregoing relates to plain jigs the same principles apply to those of more complicated design.

* * *

How many readers of MACHINERY have ever noticed that a boiler plate sheet when formed into the shape of a boiler shell does not bend on its center line or nominal neutral axis? A boilermaker always takes the measure of the straight sheet for a certain outside girth, and makes little or no allowance for change of length due to bending. When a sheet is in the bending rolls it may be noted that practically all the scale cracks loose from the interior of the shell and very little drops off from the exterior. The fact that there is little or no change in length of the outside fibers indicates that the inner fibers are compressed and that the sheet as a whole is thickened slightly, and this is what actually takes place. It is somewhat difficult to understand why this peculiar action takes place until it is remembered that bending a bar of, say, approximately square section, narrows its exterior width and thickens the interior width inasmuch as it then bends on its neutral axis or center line, but the great width of the boiler sheet as compared with its thickness precludes the possibility of the sheet narrowing throughout its width in order to compensate for the stretching exterior fibers, the consequence being that the sheet does not change its cross section materially in shape beyond thickening it a slight amount as just indicated. Hence the exterior fibers are not changed in length, but the inner ones are shortened.

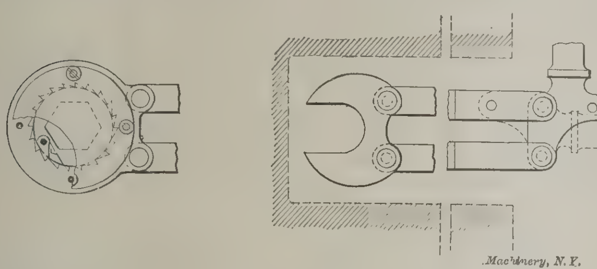
* * *

The great gulf that often exists between the theorist and the practical man is very well illustrated by an incident mentioned in the *Valve World*. It says that Lord Kelvin, the famous English scientist, once paid a visit to the schoolship for navigation officers at Portsmouth, England. On board there were several mechanical appliances of his own invention, but the workings had to be explained to him. He understood the theoretical principles of the mechanism, but had never seen them applied at work before and could not readily comprehend them when embodied in metal.

ITEMS OF MECHANICAL INTEREST.

A WRENCH FOR CONFINED SPACES.

The device shown in the cut will enable a workman to turn a nut or tap screw at the extreme end of a radial pocket of great length and small dimensions. It may be made, as shown, either as a ratchet wrench or as a solid jaw wrench, the part that engages the head of the nut in either case being rotated through a short arc of action by the two links, which are operated by the bell crank and handle at the outer end.

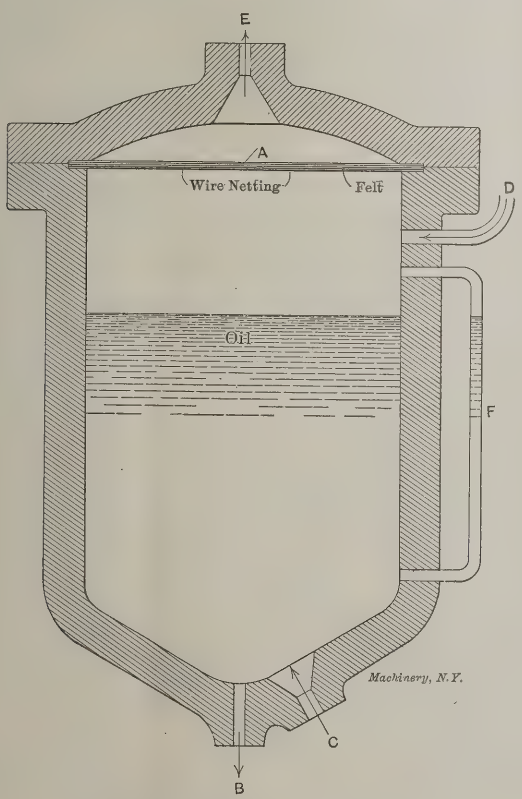


A Wrench for Confined Spaces.

This bell crank and its attached handle may be given either of two positions, as shown in the cut; the full lines indicate a position at right angles to the vibrating links, while the dotted lines show an alternative arrangement obtained by shifting one of the pivot pins. The choice of these two positions is determined by the amount of room available for swinging the handle. The idea has been patented in England and Germany.

SEPARATOR FOR WATER IN COMPRESSED AIR.

As is well-known, atmospheric air contains a certain amount of water and its capacity for water increases with the temperature of the air. When compressed, this water is carried with the air through the pipes to places where the air is to be used, and as the air is often cooled off to a great extent



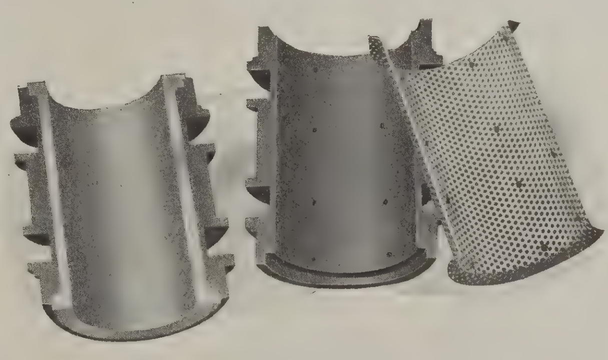
Separator for Water in Compressed Air.

during its passage through long pipe lines the water has a tendency to condense in a greater or less degree. When used in manufacturing establishments, for auto-pneumatic machinery, as has of late become more and more common, the condensed water following the air often causes troubles. When the machines are shut down the water is collecting and will cause rusting of the parts with consequent difficulty of starting the machine and making the pistons and valves move freely. To overcome the troubles thus met with, and in order to separate the condensed water from the air, a simple arrangement may be adopted. A cast iron receiver in the form of a cylinder, as shown in the cut, and provided with a cover, is nearly filled with oil, and air is caused to pass through the oil before passing into the machine. The condensed water will then stay with the oil, while the air will proceed through a filter, a shown in the cut at *A*. As the specific gravity of water is greater than that of oil, the water will evidently collect at the bottom of the receiver and can be let out whenever a sufficient amount is collected. In the cut the outlet for the water is shown at *B*, the main air supply at *C*, the pipe for the oil supply at *D*, and the outlet of the air to the machines at *E*. The oil is of course replaced only when the volume is diminished to a considerable degree owing to some particles of oil escaping at the time when the water is let out. An ordinary water gage, as indicated at *F* may be used to indicate the height of the oil or the amount of oil and water in the receiver. The felt filter is held in place between two sheets of fine wire netting which are fastened in small recesses, one to the cover and one to the receiver itself.

There may be a question about whether the oil plays any important role in the separation of the condensed water from the air, inasmuch as it is very likely that if the air containing condensed particles of water were simply discharged into the large receiver, the water would probably collect just the same. Where the writer has seen this receiver used it is always used with oil, but it would be of interest if experiments could be made to ascertain whether the oil is an essential part or not.

THE "GLYCO" SKELETON LINING FOR BEARINGS.

The accompanying cut shows an unusual and interesting way of securing the babbitt to a cast iron bearing. A tinned sheet iron lining is perforated and screwed onto the cast iron body of the bearing. The screws are provided with wood screw heads, and the holes in the cast iron body are countersunk so that the screws can bend the thin sheet metal downward around the head, and wedge it in between the head and the cast iron, thus holding the lining in place very securely. The babbitt is then poured on the tinned lining and fuses with it to a solid mass. The babbitt also fills all the small perforations and in doing so not only gets a very firm support on the cast iron below the lining, but will be still more firmly held in place than by the fusion of the metals alone, some-



The "Glyco" Skeleton Lining for Bearings.

what in a similar way as plaster is secured to the walls of a building. The advantages which are claimed for this way of making a bearing, which has its origin in Germany, are that the babbitt is held in place even more securely than if the cast iron body of the bearing were provided with dove-tail slots; the babbitt lining of the bearing can be thinner on account of the uniform way in which it is held to the body; the cast iron body itself can be made thinner, not being provided with grooves of any kind which impair its strength. This, of course, would decrease the cost of castings in cases of production on a large scale. The linings themselves can be produced very cheaply if made in quantities. They are known as the Glyco skeleton linings for bearings, and are manufactured by the Glyco Metall Gesellschaft, G. m. b. H., Wiesbaden, Germany.

Entered at the Post-Office in New York City as Second-Class Mail Matter.

RAILWAY MACHINERY

A SPECIAL EDITION OF MACHINERY FOR THE RAILWAY SHOP, DEVOTED TO LOCOMOTIVE AND CAR EQUIPMENT AND MECHANICS.

Published monthly by

THE INDUSTRIAL PRESS,

66-70 WEST BROADWAY, NEW YORK CITY.

DOMESTIC SUBSCRIPTIONS, $2.00 A YEAR. FOREIGN, $3.00 A YEAR.
SINGLE COPIES, TWENTY CENTS.

The receipt of a subscription is acknowledged by sending the current issue. Remittances should be made to THE INDUSTRIAL PRESS, and not to the Editors. Money enclosed in letters is at the risk of the sender. Changes of address must reach us by the 15th to take effect on the following month; give old address as well as new. Domestic trade is supplied by the American News Company or its branches.

We solicit communications from practical men on subjects pertaining to railway machine shop practice, for which the necessary illustrations will be made at our expense. All copy must reach us by the 5th of the month preceding publication.

JANUARY, 1907.

The Pennsylvania Railroad Co. ordered a 10 per cent increase of wages to its 110,000 employees to take effect December 1, 1906. The increase applies to all employees receiving less than $200 per month. Other railroads are increasing wages generally and it certainly seems necessary when it is considered that rent, food, clothing, and all the other necessities of life have probably increased considerably more than 10 per cent in cost within the past few years.

* * *

THE EFFECT OF WATERPOWER ON THE ELECTRIFICATION OF RAILROADS.

While electrification of railroads has been considered in many cases a matter of too great an expense to be seriously contemplated for the great trunk lines of the country on account of the cost of keeping the large power plants in operation, there are ample possibilities for the electrification of railroads in such countries where there is an abundance of water power. The Scandinavian Peninsula, as is well known, is in this respect better provided than any other country in the world, Switzerland excepted, and the people of Sweden have for this reason been contemplating for some time the electrification of the main trunk lines of the government railroads. It is intended, if possible, to eliminate steam motive power entirely, or at least to eliminate it for passenger service. As the state owns a large number of water falls and exerts a large control over the remaining ones, working upon the principle that these falls are natural gifts which belong only to the nation as a whole, the electrification can be carried out with far less expense than would otherwise be the case. Some of the private railroads have already contracted for electrical equipment and installation of electric traction.

* * *

THE ERA OF HEAVY LOCOMOTIVES.

The announcement that the Erie R. R. has ordered three very heavy Mallet type articulated locomotives weighing something over 200 tons and having a tractive power of 98,000 pounds, arouses further interest in heavy freight locomotives of this type. These machines will have sixteen driving wheels, eight in each group, and the entire weight will be carried on the driving wheels, as it should be in locomotives of this type. They will be able to pull a train of 225 loaded freight cars (whatever that means) on a level track and will be used on the heavy grades of the Erie so as to permit of handling 2,000-ton trains between Jersey City and Salamanca without breaking up.

It is with much hesitation that we differ from the judgment of practical railroad men who are carrying the idea of large locomotives and heavy trains to the extreme, but there is certainly room for argument in favor of moving all freight at uniform speed irrespective of its character. It is, of course, easy to figure out that the larger the train, and the heavier the locomotive (or rather the greater its tractive power), the cheaper will be the cost of freight movement, but this idea may be carried to an absurdity. The function of a railroad is not only to transport freight but to do it with some degree of rapidity. Already the country is crying out against the slow movement of freight, especially the smaller shipments. What we need most now is acceleration of freight movement rather than of the slow movement of a great bulk in enormous single-train units. The putting into commission of extremely heavy locomotives of this type must necessarily mean greatly increased stresses on the roadbed and bridges, for while it is possible that the distribution of weight can be so effected as to keep within the present wheel loads of the ordinary heavy locomotive type, it is not possible to avoid dangerous concentration of weight within a locomotive length. So unless the use of these large locomotives means freight acceleration as well as economical movement we shall be doubtful as to whether their extended use will be to the best interests of railways and their patrons.

* * *

CAUSE OF WRECKS ON CURVES.

The several accidents to high-speed trains on curves within the past year, notably the wreck on the London & Southwestern Railway at Salisbury, England, lead to the consideration of their cause and possible remedy. The first reason given is always high speed—but the curves are usually banked to counteract this and we are bound to consider the guiding of the engine itself by the trucks as this is supposed to be their special function.

Much has been said against the use of the pony truck for high-speed work, but it will be noticed that the most accidents have happened when there was a full truck under the front end. But this proved nothing for either truck as the fault or credit is due to conditions outside of the truck itself.

Old runners on the Lackawanna will remember how the old "original camels" had a way of going off a curve when running down hill as into the Scranton yard, and there was a reason. The drawbar between engine and tender was very low, under the ash-pan. The engine did much of the braking in those days and the cars would sometimes come bumping down against it. The drawbar was below the axle and the tendency was to raise the truck from the track which often happened until the drawbar connections were changed by Mr. Watts Cooke.

Now conditions are reversed. The train does most of the braking and holds the engine back—and in many cases the coupling between engines and tender is above the axle. When the conductor at Salisbury decided that the engine was running too fast and applied the emergency, the train suddenly dragged back the engine, lifted the trucks from the rail enough to prevent their guiding—and the rest we know. In a similar case that we know of the truck wheels were lifted so high they never marked the ties as they shot across and off at the curve—immediately after the engineer applied his brake rather heavily.

This is not a matter of theory but simply a case of leverages. Even suppose the coupling is below the center of axles, we often find the drawbar lower at the tender than on the engine. This affects it in the same way by bearing down at the back end. But leaving the braking out of the question, suppose the rear driving spring of a ten-wheel or Atlantic engine gives out, or the spring hanger breaks and the tendency is to reduce the weight on front truck. The same effect may be produced by the front driving-box sticking in the jaws, for the up-and-down-motion of the back drivers would tend to bring about the same conditions.

The remedy seems to be to so design a locomotive that, under no conditions, there can be less weight on the guiding wheels than will always keep them on the rails even on the worst curves.

The pony truck gives very little trouble if properly made because it is equalized with the drivers. In a ten-wheel or Atlantic type engine the easiest solution would seem to be to equalize the truck with the drivers so that it might always bear its share of the load. Unless a locomotive will tip forward when jacked up under the front driving axle, and none but an eight-wheeler will do this, the truck should be equalized with the front drivers if not with all. F. H. C.

THE COST ACCOUNT AND THE DRAWING ROOM.

There are probably very few draftsmen who have not, at some time or other, experienced that cooling effect on their enthusiasm which follows when the superintendent or the manager, after having looked over a new design, in one's own estimation particularly ingenious, pronounces it as "all right, but too expensive to build."

It is evident that the superintendent thinks that the draftsman has no idea of the cost of building the devices he designs. This may be true to a certain extent, but if a critical view is taken of the question, the draftsman is perhaps the one least to blame for this unfortunate condition.

The cost department in most of our large establishments is conducted, one might say, on a purely confidential basis. The cost of the tools or devices made, the cost of the manufactured product, and the margin of profit is considered as a secret not concerning anybody but the higher officials of the concern. While this may be a perfectly proper attitude from a certain point of view, it places the men who are supposed to design the new devices by which the production is to be increased, and the cost decreased, in a very difficult and undesirable position.

The designer or draftsman who is called upon to perfect the method for doing a certain operation will evidently try to devise a scheme as nearly perfect as his ability permits. The device or the machine which is the result of his work may be a very costly one, but it may cut down the cost of production so materially as to be a cheap improvement when used for a sufficiently long time. However, it may be that the device is to be used for the manufacture of a certain article which is not sold in any great quantities, nor at any considerable margin of profit. In such a case, the new proposition may be one extremely costly. But the draftsman cannot be expected to judge as to the relative cost of the design, unless he is permitted to inform himself upon the questions determining the advisability of going into great expenses. This is, however, in many cases denied him, and when he is sufficiently interested in the success of the work assigned to him to try to find out for himself, it is not unusual that he is made to understand that the business of the cost department is not within his territory.

The result, of course, is that the designer puts his best efforts in perfecting a device which is afterward to be pronounced as too expensive. It is, however, poor policy to determine upon the cost of a device after it is designed. It would be far better if the designer, before starting to put his ideas on paper, were given the opportunity to form a clear conception of the commercial results to be accomplished. This can be done only by permitting him to find out to what expense he may consistently go in his design, and this expense depends primarily upon all the little facts of present cost and margin of profit and the amount sold of the article produced.

By opening the way to such information to the designer, a great amount of uselessly spent energy could be used for better purposes. Knowing that the saving on a certain operation in the shop could be but a trifle, no matter how perfect the tools used might be, no time would be wasted on the invention of costly machines for the performance of such an operation. But on the other hand, in a case where the saving would be very considerable, and the production of the article so great that a very expensive device would be warranted, provided it were efficient, in such a case the designer would know that here was an opportunity for him to let the whole of his ingenuity come to the front. He would not feel deterred from doing his best, fearing that he would turn out something "too expensive."

While it would be indicative of poor business judgment to advocate that the accounts of the cost department should be open to whosoever wished to pry into its secrets, it may not be an uncalled for suggestion to point out that better results could in many cases be obtained, if such men, upon whom the development of the paying qualities of the shop largely depend, were not denied such information as would materially help them to satisfactorily solve the problems of decreasing the cost of production.

THE SECOND-CLASS POSTAL RATE AGITATION.

The present agitation by the United States post-office officials to increase the second-class postage rate which now applies to periodicals has brought forth a remarkable proposal from Mr. W. D. Boyce of Chicago. It cannot be supposed that the proposal is made with the expectation of its being accepted, and it must, therefore, be regarded largely in the nature of a gigantic "bluff," but nevertheless it is of interest, especially at this time, when the second-class rate is being so warmly discussed. Mr. Boyce proposes that the United States government turn the post-office business over to a $50,000,000 private corporation under full government regulation. In return he promises to reduce all postal rates one-half; to establish rural postal express; to pay full rental into the government treasury for all post-office quarters; to charge the government regular rates for its postal business; and to turn over to the government all profits above 7 per cent of capital invested. Mr. Boyce is a Chicago publisher and supposedly has intimate knowledge of the conditions of post-office working and of the enormous business due to second-class mail matter.

To effect this undertaking he would, in the first place, cut out all sinecures, which means that the political postmaster who draws a big salary and pays a deputy for attending to his work would get short shrift. The most important feature of the plan outlined, however, is putting the business on an equitable basis as to railway transportation. The business would first of all be put in charge of a railroad traffic manager, and some of the large juicy plums now going to certain railways for transportation for postal matter would be cut off. He estimates that the expenditure for railroad haulage could be cut down from $50,000,000 annually to about one-half that sum. It is also pointed out that one reason for the present inefficiency of postal management is that nine different postmaster-generals have occupied the position during twenty years. This of course is in keeping with our absurd system of political rotation in office, which formerly obtained in all grades of government employ, but it is not in keeping with good business methods. We can scarcely conceive of any successful business man who would change his general manager on an average of once in two years. A business that could succeed in spite of such adverse conditions must be something of the nature of a natural monopoly or one in which the management cut very little figure.

Most opponents of an increase of rate on second-class matter recognize the presumable fact that under *present* conditions the carrying of this class is done at a loss, but to offset this there is no question but that the carrying of second class matter is responsible for an enormous number of letters in direct response to advertising or other features incident to the business of a publication. All letters, of course, are subject to the first-class rate and this is highly profitable. It is a moot question whether the government would not lose largely by extinguishing a large quantity of second-class publications (as would undoubtedly result with a large increase in postal rate), because of the loss of first-class postal matter.

The present agitation may happily result in the reorganization of our postal system on sound economic principles and the elimination of useless expense and leaks which now no doubt are fully as much responsible for the present enormous annual deficit of something like $7,000,000 or $8,000,000 yearly as the so-called second-class privilege which is extended to publishers only.

* * *

A man, like a battleship, is supported by his own displacement; and, if he is to hold his own in the battle of life, with freeboard enough for winter weather, he must have a high box coefficient. His only foundation on the sea of life is his power of displacement. A man, when launched into the world, finds no empty place made ready to receive him. No one scoops out a hole in the water to receive the ship; when launched she must displace her weight of the element into which she plunges. So a man displaces his weight of whatever element is opposed to him.—*Extract from paper, "The Man and the Ship," read by Mr. George W. Dickie before the Technical Society of the Pacific Coast, March* 3, 1905.

ENGINEERING REVIEW.

CURRENT EVENTS, TECHNICAL AND MECHANICAL—LEADING ARTICLES OF THE MONTH.

It is stated in the *Times Engineering Supplement* that deposits of vanadium have been found in Peru. A syndicate of Pittsburg capitalists is reported to have obtained a concession from the Peruvian government for working the deposits.

According to the *Practical Engineer* the best efficiency in turbines is obtained by using Francis turbines for heads not considerably exceeding 300 feet, and Pelton wheels for heads between 175 and 1,600 feet.

An indication of what may become the common attitude of large cities as to steam locomotives is that of the District of Columbia. The commissioners of the district have announced that when the new Union Station is completed no steam locomotives will be allowed on any of the railroads within the city limits. All locomotives drawing trains must, therefore, be electric, compressed air, or some type in which there is no obnoxious combustion of fuel.

Last November the new Japanese battleship *Satsuma* was successfully launched from the Yokosuka Dockyard. This vessel, which is the only one afloat comparable with the English *Dreadnaught* has been designed and constructed exclusively by Japanese engineers. The armorplate, as well as the guns, have been produced in Japan, and in fact the Japanese have demonstrated to the world that they have become entirely independent of the Western hemisphere even in the field of highly specialized engineering. The vessel has a displacement of 19,200 tons.

In the operation of air compressors the best results are obtained, it is said, when the areas of the suction and discharge valves are equal and of such proportions that the velocity of the air does not exceed 5,500 feet per minute. On a compressor run with a piston speed of 550 feet per minute, this requires a valve area equal to 10 per cent of the piston area. The practice of making suction valve areas larger than those of the discharge valves is not advised as, while the incoming air is of greater volume, the discharge valves remain open for a very small proportion of the stroke.—*Engineering Record.*

The McKeesport plant of the National Tube Co. are now making and shipping pipe in 40-foot lengths. The use of long pipe is desirable, of course, on account of reducing the number of joints and the liability of leakage; the less number of joints also materially reduces the labor of installation. For these reasons the long lengths of pipes are being used in extensive pipe installations such as refrigerator plants, pneumatic and hydraulic pipe lines, etc. The 40-foot pipe is made in 1 to 3-inch sizes, standard and extra strength, but as yet no galvanized pipe of this length is made.

In an address on large gas engines at the Engineering and Machinery Exhibition at London, Mr. H. A. Humphrey stated that under favorable working conditions a large gas engine may develop a horsepower hour for 0.8 pound of coal, while a steam engine would require two pounds to develop the same power. He also said that he had information to the effect that the use of gas engines in rolling mills had reduced the cost of the finished product about $3.00 to $4.50 per ton. The large gas engine has had great success on the European Continent where coal is more expensive than in England and the United States.

According to *Chambers' Journal* the Niagara Electro Chemical Co. has recently introduced a new product named oxone. This is made from a specially prepared form of sodium peroxide. Its value lies in its power of giving out free oxygen in the presence of carbonic acid gas and water. By this means air in confined spaces may be kept furnished and supplied with oxygen for breathing purposes for an indefinite period provided, of course, that the carbon dioxide is absorbed in the process. This product promises to be of great service in mining, as miners equipped with oxone will be able to go into drives or slopes without the present evil effects. It also should be greatly serviceable in submarine boats.

Tests made (in 1904, continuing to 1906) by Messrs. Howe and Harrington at the Worcester Polytechnic Institute, to determine the specific heat of fire-brick gave, as might be expected, varying specific heats in the temperature range 0 to 1,100 degrees C. (32 to 2,012 degrees F.) From 0 to 100 degrees C. (32 to 212 degrees F.) the specific heat was 0.221; from 500 to 600 degrees C. (932 to 1,112 degrees F.) it was 0.251; and from 1,000 to 1,100 degrees C. (1,832 to 2,012 degrees F.) 0.281. Only one kind of fire-brick was tested, but it is not thought probable that other kinds will differ widely in their specific heats. The precise determination of the specific heat of fire-brick is of value in figuring the heat absorptive value of boiler settings, etc.

The cohesion and tenacity of concrete structures has been amply demonstrated in a case of a building o. reinforced concrete in Tunis, Africa. The building itself is five stories high and is constructed entirely of reinforced concrete. When nearly completed the foundation on one side settled to such an extent that the building slowly sunk on this side until the walls formed an angle of 25 degrees with the vertical line. By excavating the foundation and counterloading the floors on the opposite side of the building it was restored to a level position without any injury whatever to the structure itself. The possibility of doing this proves the presence of qualities of enormous endurance in buildings of reinforced concrete, presenting as they do a single solid structural unit.

We have of late referred several times to the possibilities for windmills, but have not called attention to the fact that there are at present windmills designed in rather large units. According to *Power*, one mill developing 50 horsepower was erected as an experiment in Golden Gate Park, San Francisco, for pumping water. This windmill fulfilled all expectations so well and proved so economical that another is being built. It is claimed that several thousand dollars per year are saved by this windmill, comparing the expense with that of other motive power. Apart from the pumping machinery, such a mill can be built for less than $1,500. In Holland windmills 50 feet in diameter and developing from 40 to 60 horsepower in good wind are not unusual, and are used not only for pumping purposes but for driving grist-mills, saw-mills, and many other kinds of small industrial plants.

The following empirical rules are suggested by Mr. Dugald Clerk for approximating the power of gas engines. For engines not exceeding 12 H. P.:

$$\text{H. P.} = \frac{D^2 \times N}{3}$$

and for engines exceeding 12 H. P.:

$$\text{H. P.} = \frac{D^2 \times N}{2.4}$$

in which

D = diameter of cylinders, in inches.

N = number of cylinders.

These formulas are based on the assumption that an average of about 70 pounds mean effective pressure and a piston speed of 800 feet apply to engines not exceeding 12 H. P.; and 70 pounds mean effective pressure and 1,000 feet to engines exceeding 12 H. P.

The longest concrete arch yet undertaken anywhere is that of the main span of the Walnut Lane bridge in Philadelphia. Not only is it the largest of its class, but it has the third place in the list of long-span arches of all classes of masonry, so that the structure must be regarded as one of the most

interesting engineering undertakings of to-day. The longest masonry bridge in the world is the structure at Plauen, Saxony; it has a clear span of 295.2 feet. The second place is held by the bridge over the Petrusse River in Luxemburg; it has a span of 275.5 feet and a rise of 101.8 feet. The third place is held by the Walnut Lane span of 233 feet. The fourth place is occupied by the Gruenwald bridge over the Isar River at Munich, which has a reinforced concrete span of 230 feet and a rise of 42 feet. The famous Cabin John bridge near Washington has now dropped back to fifth place. It is not at all improbable, however, that this list will see some important additions before many years have elapsed, for the construction of longspan reinforced concrete arches has not yet begun. The 230 feet of the Gruenwald bridge, the longest concrete structure with metal reinforcement, is of insignificant length when measured by the possibilities afforded by new methods of design.—*Engineering Record.*

An interesting comparison between steam turbines and reciprocating engines in regard to their dimensions and the space occupied is given in the *International Marine Engineering.* The comparison is made between the cruiser *Salem*, fitted with steam turbines, and the battleship *Vermont*, fitted with triple expansion reciprocating engines. The comparison is direct, inasmuch as the requirements are for about 8,000 horsepower in each case. The dimensions, as given, are as follows:

	Turbine.	Engine.
Length over all........	16 ft. 2¾ ins.	33 ft. 6½ ins.
Width over all........	13 ft. 6 ins.	11 ft. 3 ins.
Height over all........	12 ft. 6 ins.	21 ft. 9 ins.
Floor space............	219 sq. feet.	377 sq. feet.
End area..............	169 sq. feet.	245 sq. feet.
Side area, or target....	203 sq. feet.	730 sq. feet.
Over all volume........	2,735 cu. feet	8,200 cu. feet.

In the above tables the areas and volumes are figured out from the gross dimensions in each case, and are, therefore, strictly comparable. The turbine shaft over all measures 23 feet 7 inches, while the crankshaft of the engine is 31 feet 1 inch. The length from center to center of main bearings of the turbine is 18 feet 6 inches, corresponding to 25 feet 8½ inches from center to center of main bearings of the engine. The length over the stuffing boxes of the turbine is 14 feet 5½ inches. The length over all of the cylinders of the engine is 32 feet 9 inches. In the table the figures for the turbine are based on the over-all dimensions of the casing.

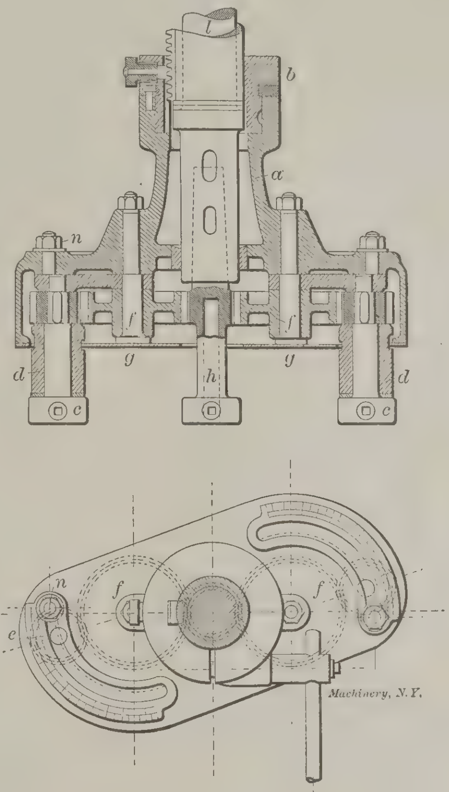
LEAKAGE IN COMPRESSED AIR PLANTS.

Some statements in *Compressed Air* in regard to the cost of leakage in compressed air plants are well worth consideration. Few people realize that leakage plays an important part in the efficient operation of a compressed air plant. Many concerns will go to great expense in installing high class air compressors with compound steam cylinders and two stage air cylinders, but when it comes to installing the pipe line the utmost carelessness is displayed, the same fittings being used that would apply to a steam line without the fact being taken into consideration that steam and air are two very different mediums. The heat of the steam tends, of its own accord, to keep joints tight which, if cold, would leak considerably. In manufacturing establishments, particularly, with a compressed air plant with a capacity of, say, about 500 cubic feet per minute, where the air plant is of a more incidental character than in the case of a central air power plant, the percentage of leakage is usually very high owing to the fact that less pains are taken in the installation of machinery and piping in smaller and cheaper plants than is the case with the larger and more expensive ones. Furthermore, most manufacturing establishments require a more complicated distribution of the compressed air and the installation of more valves, bends and outlets is needed. It is fair to consider the leakage as being 2 per cent in a manufacturing plant. The compressor will very likely be a single stage one and the horsepower required to compress the leakage of 10 cubic feet per minute to 100 pounds pressure will be $0.207 \times 10 = 2.07$. At 2 cents per horsepower per hour this leakage would cost 41.4 cents per ten hour day, or $124.20 per year.

THREE-SPINDLE DRILL HEAD.

Very often when three holes are required to be drilled in a line, they are spaced equidistant. In such a case a simpler arrangement than that of the ordinary multispindle drill for drilling all the holes at once can be devised. Such an arrangement is shown in *The Practical Engineer*, issue of November 16.

The sectional elevation and plan of the device show the general arrangement. The bushing *b* is mounted on the spindle sleeve of a drilling machine, and is held in position by means of a bolt tightened against the rack. On this bushing



Three-spindle Drill Head

the housing *a* is secured in such a manner that it can be turned round, and thus the drills adjusted to suit the work. The housing *a* can be firmly clamped on the bushing *b* in any desired position.

The driving of both adjustable spindles *c* is effected through the intermediate pinions *f*, meshing into the toothed chuck *h*, which is inserted in the lower end of the spindle *l*. The spindles *c*, with their bearings *d*, engage with the bolts *g*, and can be swung round these and thus be quickly and accurately adjusted, and be fixed in position by nuts *n* to the required pitch of holes by means of dials attached to the housing.

TIN LEAD ALLOYS AS SOLDERS.

The Iowa Engineer, September, 1906.

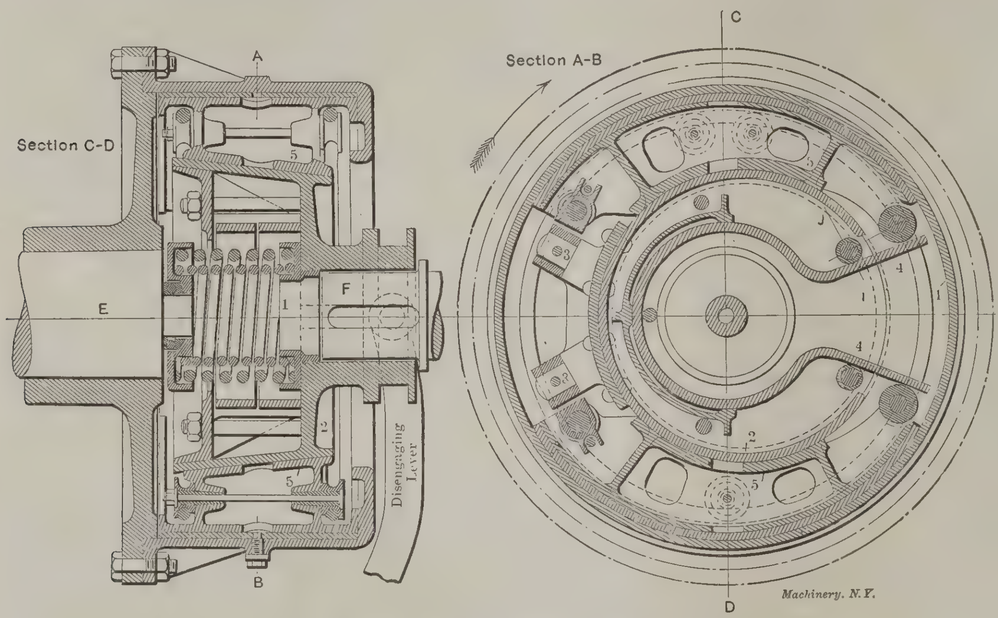
The properties of tin lead alloys used as solders have not been very extensively investigated, although their use is universal. For this reason experiments were made at the Iowa State College in order to ascertain which would be the most preferable method of making soldered joints, as well as their tensile strength. As to the methods of making soldered joints it was found that any pressure whatever upon the solder at the moment of setting greatly reduced the strength of the joint. When making a soldered joint, therefore, the upper piece should be supported above the lower one, the solder be fused by means of two blow torches and the pieces brought together with very gentle pressure. This method differs from the most common one or that of "sweating." In regard to the strength of soldered joints, it was found that the time element made a decided difference in the tests, and could not be eliminated. For instance, a decrease of 5 seconds in the total time of testing increased the strength 4,000 or 5,000 pounds per square inch, the total time of testing being from 20 to 25 seconds. The maximum strength obtained under

any circumstances was 25,900 pounds per square inch with a joint on copper with solder containing 60 per cent tin. The total time of this test was 20 seconds. As to the influence of the amount of tin in the solder the tests showed that the maximum strength increases with a percentage of tin, but if the time element is considered, the average strength increases only up to 60 per cent of tin and then decreases. For this reason 60 per cent of tin in the solder must be considered as most suitable for general work, but for work requiring little mechanical strength, such as "sealing," a lower percentage of tin might be used.

GRADUAL APPLICATION CLUTCH.

Attention is called by *Engineering* to a gradual application clutch, known as the Michel grip clutch, designed by a French engineer.

On the end of the shaft *E* is keyed a flange, to which is bolted a cylindrical casing, forming the exterior of the clutch. The sliding portion of the clutch keyed to the shaft *F* consists of a male cone, marked 2 in the cut, eccentric to the line of the shafts, and having a portion of one side cut away. In the interior of the cone is a curved plate-spring with the ends projecting through the opening, and constrained by two fixed stops just inside the cone. On the back of the cone, opposite the opening, is riveted a bracket, carrying two pins, marked 3, and surrounding each pin is a buffer, fastened to it by a taper pin. In the space on each side of the cone, between it and the casing, is a curved tapered shoe. These shoes carry buffers at their larger ends, opposite the cone-buffers just mentioned, and round collars, surrounding pins at the smaller ends of the shoes, act also as buffers against the ends of the plate spring. Pins with grooved collars at each end are fastened through the centers of the shoes, two through one shoe and one through the other. These are shown in side elevation and dotted in the section *A B*. A spring-ring passes round the grooves in the collars, and holds the shoes against the cone.



Michel Gradual Application Clutch.

The action of the clutch is as follows: When the disengaging lever is relieved, the helical springs, shown in section *C D* force the cone home against the inner faces of the shoes, and the latter are pushed outward in contact with the casing. If the casing is revolving in the direction of the arrow, as soon as the shoes come in contact with it, the upper one tends to be drawn into a narrower portion of the annular space against the action of the plate spring. It is thus tightened between the cone and the casing until there is sufficient friction to transmit the drive. The lower shoe, on the contrary, is loosened and pushed back against the cone buffer, so that it takes no part in the transmission of power. It is clear that if the revolution of the casing were in the other direction, the drive would be equally efficient, the lower shoe then transmitting the power.

TRADE SCHOOLS IN SWEDEN.

At the same time as the question regarding efficient trade schools is coming to the front in this country it has received a great deal of attention everywhere in Europe. According to *Teknisk Tidskrift* the city council of Stockholm, Sweden, is contemplating a system of completely organized trade education, the main features of which may be of interest wherever this question is considered.

The school contemplated for the mechanical trade would require the pupils to attend all the six days in the week for four years, the total number of hours per week being 50 for the two first and 54 for the two last years in the course. The practical work in special shops provided would occupy 32 hours during the two first years and 42 hours a week during the two last years. The remaining hours would be given up to studies on subjects connected with the trade. These subjects would be free hand and mechanical drawing, fundamental mathematics and the elements of mechanics, calculations of areas and weights, the first principles of machine design and subjects of general nature connected with mechanical work. The requirements for entering these trade schools are to be a complete grammar school course. For persons that have already entered in industrial work a course will be provided where attendance will be expected only one day a week. In this course the subjects will be exclusively theoretical, since the pupils will get a practical training during the five days in the week during which they engage in the trade. It must, of course, be expected that employers will realize the necessity, as well as the advantage to themselves, of this trade education so that there will be no difficulties in regard to setting apart one day for educational purposes. Should difficulties arise it is likely that the government will duly assert its influence in behalf of the young men looking for more complete education in the trade. The shops are to be equipped as modern and complete as possible. Only men of practical ability who have been a long time actually engaged in industrial pursuits will be engaged as instructors. This will insure that the schools will give instruction of an equally up-to-date nature as what could be obtained from actual experience in manufacturing establishments. The cost for establishing schools for the various trades is estimated to be about $350,000 and the yearly maintenance to about $35,000. The city authorities as well as the national government of the country will provide the means necessary. When in complete condition the schools will probably provide for about 500 students attending the daily courses and 1,200 additional attending the courses where instruction is given only one day a week. In order to insure earnestness of purpose of the students who enroll and add to their desire to follow up this purpose a fee of about $5.00 per year will be charged. This is not so much for the purpose of providing any income to the schools as to inculcate the idea of the value of the instruction, inasmuch as things that can be had for nothing as a rule are valued less than those for which a payment is required, even if this payment is only nominal.

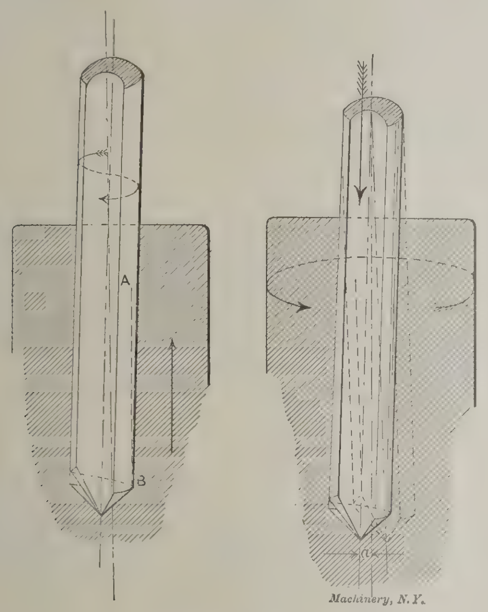
THE DRILLING OF DEEP HOLES.

The *Zeitschrift für Werkzeugmaschinen und Werkzeuge* gives an account of the drilling and boring of a hole 4¾ inches in diameter, through a shaft 147½ feet long. The principles governing the drilling and boring of deep holes are discussed, and are summarized in the following:

The difficulties to be overcome in producing deep drilled holes can be classified in three groups. In the first place the

drill has a great tendency to run out, thus producing a hole that is neither straight, nor uniform in diameter; in the second place great difficulties are encountered in trying to remove the chips in a satisfactory manner, and in the third place the heating of the cutting tool is difficult to prevent.

The principle involved in common drill presses where the drill is given a rotary motion simultaneously with the forward motion for feeding is the one least adapted to produce a straight and true hole. Better results are obtained by giving only a rotary motion to the drill, and feeding the work toward it. It has been found, however, that for drilling deep holes the reversal of this, that is, imparting a rotary motion



Drilling of Deep Holes.

to the work, and the feed motion to the drill will answer the purpose still better. It seems as if there could be no material difference between the latter two methods. An analysis of the conditions involved will show, however, that there is a decided difference in the action of the drill. If the drill rotates, and the work is fed forward as shown to the left in the cut, the drill when deviating from its true course will be caused to increase its deviation still more, by the wedge action of the part *B*, which tends to move in the direction *A B* when the work is fed forward. In the case of the work rotating and the drill being fed forward, as shown to the right in the cut, the point of the drill when not running true will be carried around by the work in a circle with the radius *a*, thus tending to bend the drill in various directions. The drill is by this action forced back into the course of "least resistance," as it is evident that the bending action, being exerted on the drill in all directions, will tend to carry the point back to the axis of the work where no bending action will appear. The chips, as is well known, are carried off by forcing a fluid into the hole, which upon its return carries with it the chips. This fluid being oil will serve the double purpose of carrying away the chips and lubricating the cutting tool, keeping it at a normal temperature.

THE WEIGHT OF A CROWD PER SQUARE FOOT.

From *Engineering*, September 21, 1906.

To the structural engineer the possible normal weight of a crowd of people is an important factor of calculation. The prevalent custom has been to accept as a basis the recommendations of Trautwine, who advanced the theory that on bridges for turnpikes and common roads no probable contingency could crowd people to such an extent as to weigh more than 80 pounds per square foot of floor and that this might safely be taken as the maximum load on spans of 20 feet or more. To compensate, however, for impact, he recommended to adopt 100 pounds as the limit for crowds. In engineering practice both in this country and America this formula is more or less accepted. Trautwine refers in substantiating this theory to a test made by a Mr. Nash who wedged as closely together as possible a group of men within a 20-foot diameter, the last man admitted being lowered down from above. In this extreme case a result of 120 pounds per square foot was obtained. But this weight has since been exceeded by a number of experimenters, notably by Prof. Johnson of Harvard, who, in 1904 obtained a weight of 164.9 pounds per square foot. When these results were published they caused considerable comment, by some American engineers in particular. Prof. Johnson therefore undertook to see exactly what the limit was.

A wooden compartment or pen 6 feet by 6 feet was constructed, placed on the ground securely braced to the walls of a building and furnished with a door which could be closed by a strong wooden bar. Various photographs were taken at different degrees of compactness from above. One hundred pounds was easily obtained without any discomfort to the men; 154.2 pounds per square foot was easily reached by 37 men who arranged themselves as they saw fit. Finally 40 men of more than average weight were forced within the area of 36 square feet and a final test gave a load of 183.3 pounds per square foot. This result is additionally remarkable from the fact that though tightly packed the 40 men experienced no serious discomfort and could move their limbs with little difficulty. The only distress which was met with was that suffered when they all tried to breath deeply at the same time. It is evident from Prof. Johnston's investigations that a weight of 140 pounds per square foot is quite feasible where there are throngs of people all headed one way, while a load of 80 pounds per square foot is quite a common thing in buildings and private houses where social gatherings are frequent.

LOADING OF ROPE.

A little taste of elementary mechanics is sometimes worth while. We must not forget that while the action of all mechanisms is controlled by simple principles, these principles are not always as well understood as they should be by men who have the handling and care of property worth many thousands of dollars, to say nothing of the danger to human life caused by seemingly inexcusable ignorance. These remarks apply with special force to the handling of material by cranes or derricks, using ropes and sheave blocks. A careless workman may see a load of several tons handled safely

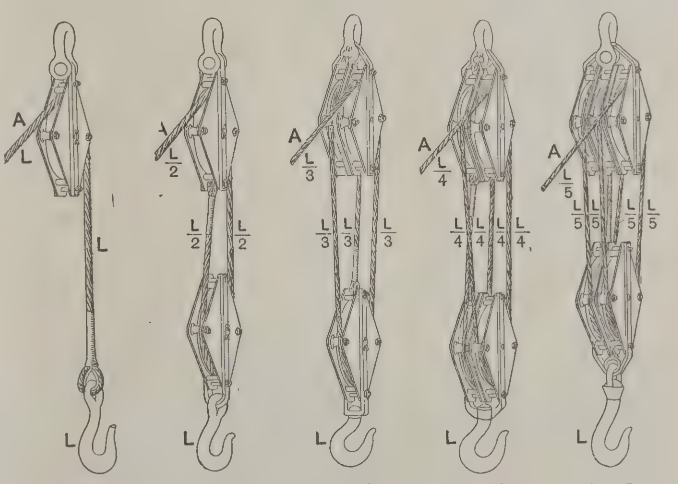


Fig. 1 Full load on rope · Fig. 2 Strain on rope is one-half the load · Fig. 3 Strain on rope is one-third the load · Fig. 4 Strain on rope is one-fourth the load · Fig. 5 Strain on rope is one-fifth the load

Machinery, N.Y.

with pulley blocks and a wire rope of perhaps not more than ½ inch diameter. The construction of the pulley blocks which permit of such a load being safely handled of course comprises a number of sheaves in both a stationary and moving block which divide the load among several ropes. For example, the accompanying cut taken from the *American Wire Rope News* (with a slight change) illustrates the conditions in loading on a rope with pulley blocks. The first figure shows that with one block the total load on the hook is transmitted to the rope at *A* but in Fig. 2 only half the load is so transmitted, and progressively up to Fig. 5 we find that only one-fifth of the load on the hook is carried by the rope at *A*. So supposing that the tackle will safely carry ten tons on the hook it by no means follows that the wire rope

alone will carry that load. On the contrary the chances are that it would not sustain it at all unless a high factor of safety was employed. The cuts show graphically the division of loading among the sheave ropes, being respectively $\frac{L}{2}$, $\frac{L}{3}$, $\frac{L}{4}$, and $\frac{L}{5}$.

THE LENTZ REVERSING MECHANISM.

A few months ago the *Zeitschrift des Vereines Deutscher Ingenieure* described the simple but ingenious Lentz reversing mechanism. Fig. 1 shows the general arrangement of the design, and in Fig. 2 a section of the detail which is particularly novel is given.

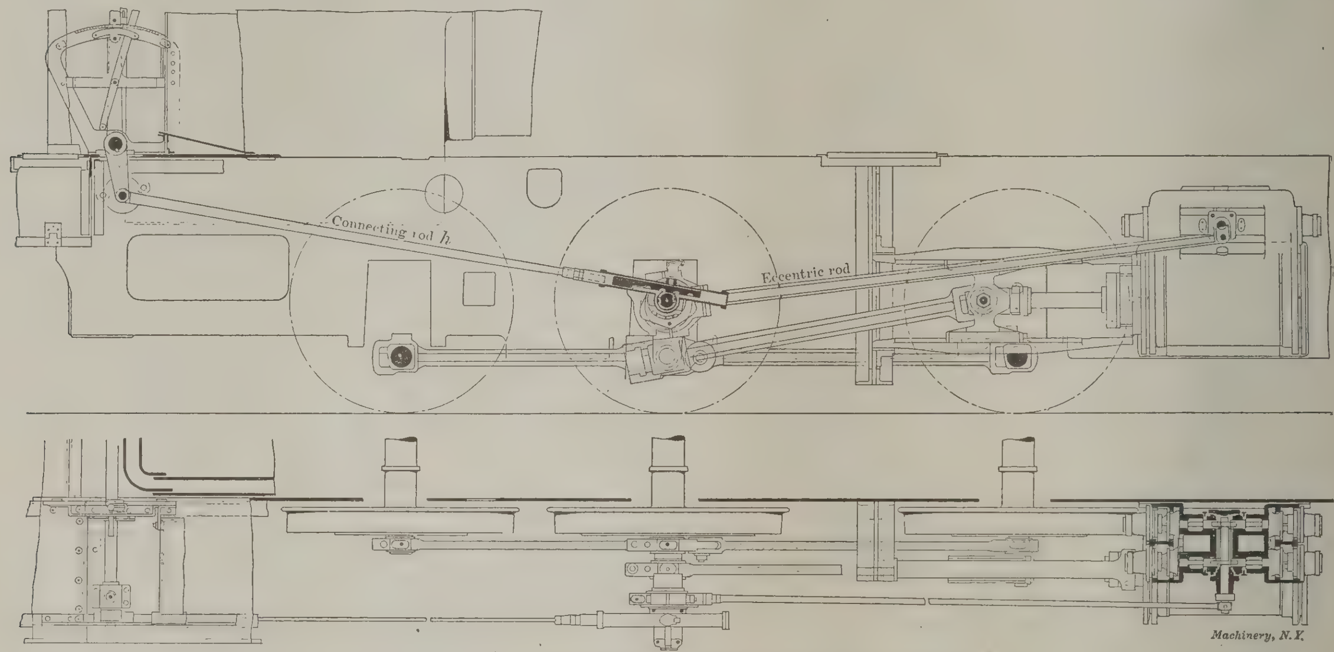

Fig. 1. General Arrangement of the Lentz Reversing Mechanism.

As seen from the cut, the crankpin is provided with an outside extension which carries a stud f. On this stud the eccentric a is mounted, and is free to move around the stud as a center. A bushing b is movable along the stud c, which is located in line with the wheel axle. This bushing is keyed to the stud by means of the key d, and will thus rotate with the wheels. The bushing is provided with spiral teeth on the outside, which mesh with teeth in the eccentric a. It is evident that a longitudinal movement of the bushing b will move the eccentric around the stud f. On the outside of the bushing b there is a second bushing e which is keyed to the final cover k, and is stationary in regard to the rotary motion of the bushing b, but moves with this latter bushing in a longitudinal direction by means of four flanges, g, on the outside surface.

This second bushing is in its turn provided with spiral teeth on the outside, which mesh with teeth in the rod h, connected with the regular reversing lever. It is now evident that a motion of the rod h in its longitudinal direction will cause the bushing e, and at the same time the bushing b, to move. The movement of the latter bushing, however, turns the eccentric around its support, and places it in any desired position. The valves themselves are operated by a horizontal shaft, turned by a small crank connected with the eccentric rod. The advantages claimed for this design are the comparatively small number of parts, and the possibility of making the mechanism perfectly dustproof. This construction has been practically tried in Germany in at least two instances, and proven to work entirely satisfactory. It is known as the Lentz reversing mechanism.

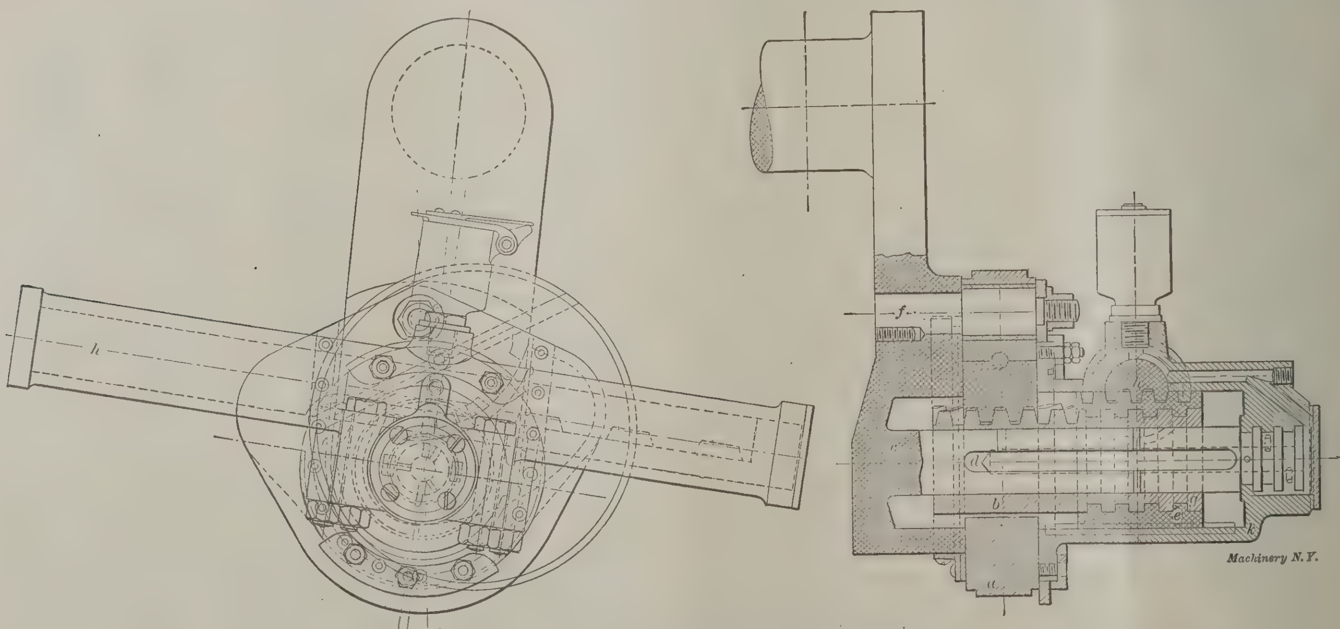

Fig. 2. Section and Side View of the Lentz Reversing Mechanism.

THE UNITED STATES CENSUS OF MANUFACTURES, 1905.

Bulletin 57, Department of Commerce and Labor

A few statistical figures from the latest bulletin of the Department of Commerce and Labor are of interest on account of the conclusions which can be drawn in regard to the in-

crease of the manufacturing in the United States during the last five years. The number of establishments in 1905 had increased by 4.2 per cent, the capital invested by 41.3 per cent, and the value of the products by 29.7 per cent, as compared with 1900. It will be noted that the value of the product had not increased in the same ratio as the invested capital, a fact which seems to point out that the large modern industrial establishments are not of necessity more productive than the smaller ones of former years. This conclusion is also borne out by a number of other statistical figures contained in the bulletin, particularly in reference to concerns of the corporation class, inasmuch as the figures given show that the large incorporated companies do not produce as much in proportion to the large capital investment as do the smaller firms and individual concerns. Thus 82.8 per cent of all the capital invested in industrial establishments comes on the corporations' share, but the value of the products of these same corporations is only 73.7 per cent of the total value of all manufactured goods. On the other hand, the firms with 9.4 per cent of the total capital produced 14.4 per cent of the total value of products, and individual concerns with only 7.6 of the capital produced 11.5 per cent of the total. This seems to indicate that the greater saving of expenses which was claimed to be incident to the large corporations is fictitious. In fact it is so much more a proof of the failure of the corporations as compared with some individual concerns as the figures do not show the unfeasibility of the large concern as such, but merely the unproductivity of establishments in corporate form. This statement is borne out by the fact that 1,899 concerns with an output valued at a million dollars or more each and controlling a capital of 37.7 per cent of the total, show value of the product of 38 per cent of the total. This seems to indicate that it is not the large concern as such which meets with difficulties, but it is the large concern when not individually conducted, but conducted as a corporation. The figures, however, show the greatest productivity in proportion to the invested capital for concerns the value of whose annual output does not exceed $20,000.

The average number of wage-earners employed during 1905 was 5,470,321 as compared with 4,715,023 in 1900. The increase of wage earners is thus proportionally far smaller than the increase of the value of the product which shows the tendency of modern machinery to displace manual labor, not by eliminating it but by making possible a larger per capita output. The greatest number of wage earners employed at any one time during 1905 was 7,017,138 and the least 4,599,091. This seems to indicate that a great number of people can secure only very unsteady employment, and that the modern manufacturing methods are augmenting the problem of the unemployed. The average number of children employed were 159,899, as compared with 161,276 in 1900, or a decrease of less than 1 per cent. Pennsylvania ranks first and Massachusetts second in the number of children employed. The greatest numbers in both of these states are shown for the textile industries. In regard to wages paid, these show an increase over the figures of 1900 very nearly in the same proportion as the increase in the value of the product.

The motive power employed in manufactures increased from 10,409,625 horsepower in 1900 to 14,464,940 horsepower in 1905, or an increase of 39 per cent, which is considerably higher than the increase in the value of the products. The statistical figures indicate that the large manufacturing plants have a tendency to remove from the large cities to rural places. While the increase of capital invested in urban establishments was 34.2 per cent, the increase for the rural plants is 58.7. In all respects the establishments located in rural districts show a higher percentage of increase than those in municipalities having a population of 8,000 inhabitants or more.

THE DEVELOPMENT OF THE FRAME OF AMERICAN FREIGHT LOCOMOTIVES.

The Railroad Gazette, October 19, 1906.

To the casual observer the frame of to-day would seem to be exactly like that of 25 years ago except in the matter of size. It consists of two bars, the upper one nearly square and the lower one of the same width as the upper, but narrower in vertical dimensions. These frames have always been made in two pieces, the back part containing the pedestals for carrying the axle boxes, and the front part rails to which the cylinders are fastened. It is the splice between these two pieces which has been the object of the study for improvement. In order to show how these details have been worked out step by step a series of illustrations are given showing the various changes in detail that have been made in the development of the fastening.

Fig. 1 is the type of fastening used in the late seventies. The frame was of wrought iron, and the front rail was joined to the main frame by a T foot whose upper arm was jumped on and held by countersunk bolts. In addition to the countersunk bolts through the pedestal, there were two vertical bolts holding the front rail to the drop of the main frame, and these bolts were supposed to be relieved of shear by the key that is shown between them. With the small cylinders in use at that time this frame gave little trouble, but with an increase in the diameter of the cylinders the repeated stresses would draw the countersunk bolts down and the nuts would come loose.

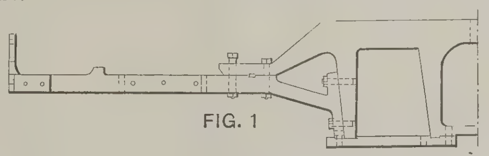

FIG. 1

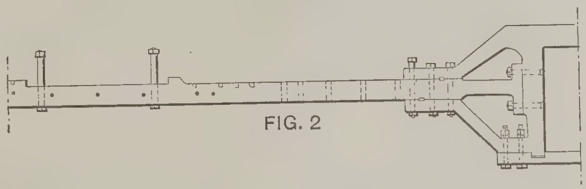

FIG. 2

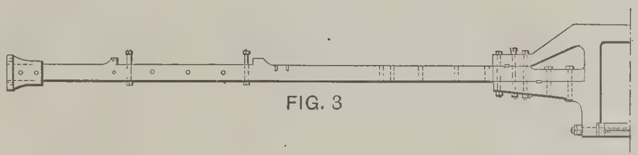

FIG. 3

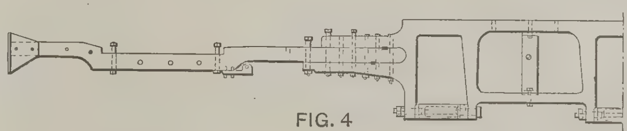

FIG. 4

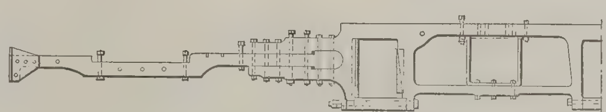

FIG. 5 *Machinery, N.Y.*

This form was followed by that shown in Fig. 2. But here the countersunk bolts joining the T foot to the main frame gave trouble by breaking, because the whole load would be carried by them in consequence of the springing of the two parts of the main frame. This construction was abandoned for that shown in Fig. 3, in which the lower portion was raised and made horizontal, with the front rail laid flat upon it and held by bolts, some of which went through the upper section of the frame, to which a key was added. This form gave excellent satisfaction, with cylinders up to 18 inches diameter. Heavier engines, however, required a stronger fastening, and a direct outgrowth of the form shown in Fig. 3 is that shown in Fig. 4, in which both upper and lower jaws of the main frame are horizontal, with the front rail between them and having a key on each side. This gave excellent service for a time, but again the increase in cylinder dimensions necessitated a change. The keys, which had but a half bearing in each of the two parts between which they were placed, would twist and throw the entire stress upon the bolts. To obviate this trouble the lower frame was given a T head, as in Fig. 5, and keyed against the lips on the arms of the main frame.

Where double rails were used they were at first attached, as shown in Fig. 6, in which the lower rail had the same T head as in Fig. 1, while the upper rail was simply laid on and bolted to an extension of the upper frame. It was the standard method of construction for many years, and the only trouble experienced with it was an occasional breaking off of a T head. When this method of fastening became too weak for the increasing diameter of cylinders, the lower arm was made horizontal, but an upward bend of the front rail still left an opportunity to use the countersunk bolt through the pedestal leg, as shown in Fig. 7. This form soon yielded to that shown in Fig. 8, in which the T head was dispensed with and the front lower rail laid on like the upper one and bolted fast. This gave way to that shown in Fig. 9, in which the upper front rail was extended back over the jaw of the forward axle, while the upper arm of the main frame was run out to abut against the cylinder casting. The lower arm was lipped up into the lower rail so as to form a bearing there for all back thrust of the cylinders. This in turn was followed by that shown in Fig. 10, in which the front upper rail was lipped down over the upper arm of the main frame, as in the case of the single rail frame of Fig. 5. Strong as this construction was, the stresses imposed by the cylinders were too great and, on the latest type of heavy engines, we find the form shown in Fig. 11 in use. Here the two front rails have been united in a single deep slab, to which the cylinders are bolted. These parts are no longer cast solid with a half saddle but are separate with a saddle between. The first frames of this sort that were built had the fastenings to the main frame as in Fig. 11, but they have been followed by that of Fig. 12, in which the upper rail has been carried back over the top of the jaws and keyed as shown.

During all this period of development there has been more or less activity in attempting to produce a cast-steel frame.

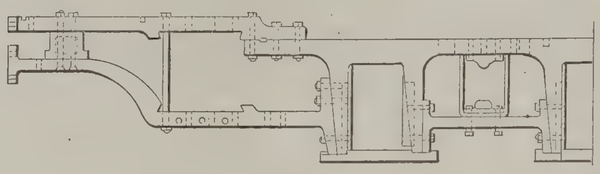

FIG. 6

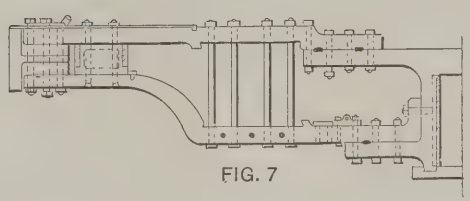

FIG. 7

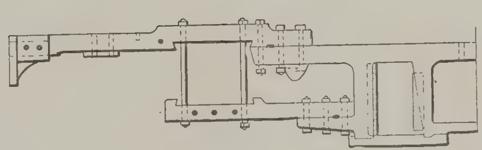

FIG. 8

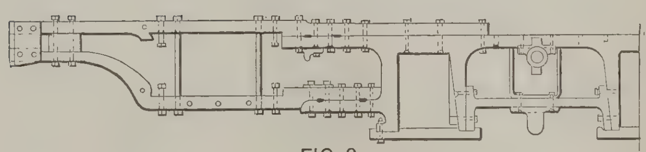

FIG. 9

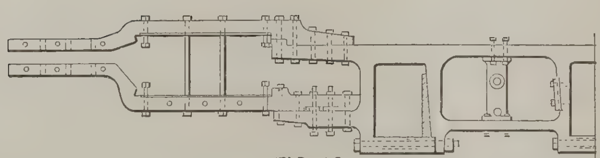

FIG. 10 *Machinery, N.Y.*

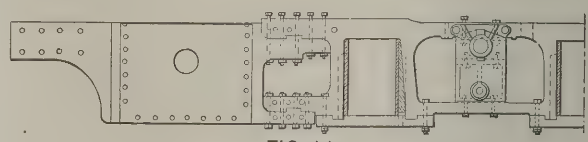

FIG. 11

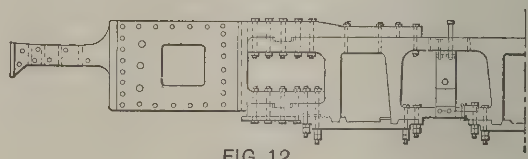

FIG. 12

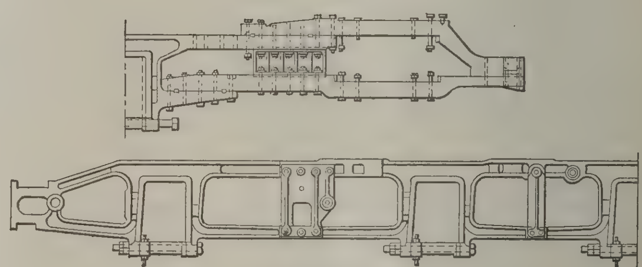

FIG. 13

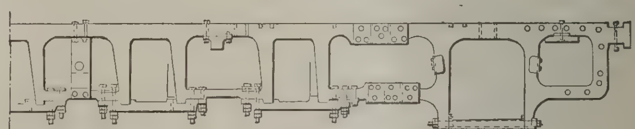

FIG. 14

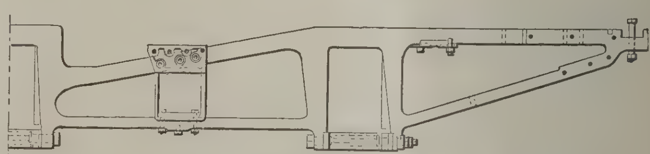

FIG. 15 *Machinery, N.Y.*

First efforts were not altogether successful, but the desirability of securing such a frame, on account of the facility with which provision could be made for the attachments, together with the probable decrease in the cost of machining encouraged makers to persist in the work until now cast-steel frames like that shown in Fig. 13 are constructed, which can be made complete for less than the cost of finishing a frame of the older type. The result is that, though these frames are far from having come into general use, they may be considered to represent the latest type of the frame of the American locomotive.

The back part of the frame has changed but little in form. That of the early engines is shown in Fig. 14, and this still holds with such modifications as may be required to accommodate the trailing truck of the later classes of engines or to add to the depth of the firebox by the use of the drop in the upper rail, as shown in Fig. 15.

The examples given show the tremendous amount of tentative work that has been required in order to develop the locomotive to its present condition, and the end is not yet.

* * *

LAKE OF QUICKSILVER! WHO CAN BEAT THIS YARN?

"A lake of quicksilver, covering an area of more than three acres and having a depth ranging from ten to fifty feet, has been discovered in the mountains of the state of Vera Cruz. The value of the product is estimated at millions. This lake has been known to the Indians for many generations. It is situated far up in the mountains in an almost inaccessible position. Its surface is partly covered by stones. It is believed that volcanic action in the mountains above smelted the quicksilver out of the cinnabar ore and that it ran down and filled this depression. A tunnel will be driven through the base of the mountain, and the quicksilver will be brought down by means of gravity."—*News Item.*

ANNUAL MEETING OF THE A. S. M. E.

The annual meeting of the American Society of Mechanical Engineers was held in New York, December 4 to 7 at the Edison Building, No. 44 West 27th Street. The registration showed that something over 1,200 members and guests were in attendance. The entertainments provided included an inspection of the Port Morris, N. Y., power house of the electrified section of the New York Central R. R., a special train being provided for the guests on the afternoon of December 6. The crowning feature was unique, being a trip to Sandy Hook proving ground by way of the Central Railroad of New Jersey. Special arrangements were made with the United States government to show the guests the various features of the fortifications and to fire a number of large guns for their edification. The annual ball at Sherry's was held Thursday night.

The New Engineering Building.

Although not yet completed at the time of the meeting, the new Engineering Building on West 39th St., between Fifth and Sixth Aves., was open for inspection, and it naturally attracted a considerable number of the members and guests.

Fig. 1. New Engineering Building, West 39th Street, New York.

These were practically unanimous in praise of its excellence of design and construction. The building is the result of a gift of $1,500,000 by Andrew Carnegie for the founding of a joint society building which would shelter a large engineering library and be the headquarters of societies accepting the gift. These are the American Society of Electrical Engineers, American Institute of Mining Engineers and American Society of Mechanical Engineers. It will also be the headquarters of a number of minor societies interested in engineering or science. These associate societies will pay rental to the holding company in the form of yearly assessments.

This building has thirteen floors above the street level, and Fig. 1, reproduced from the architect's drawings, shows a perspective view looking northwest (see MACHINERY, January, 1906.) The library, the plan of which is shown in Fig. 2, is located on the top floor to avoid the noise, dust and confusion which would be incident to location on the lower floors. The floor given up to the American Society of Mechanical Engineers is the eleventh and the accompanying plan, Fig. 3, shows the arrangement of the rooms. The auditorium, Fig. 4, which is common to all large gatherings of the societies occupying the building, is on the second floor and seats 1,000. It has a gallery and is arranged for the utmost convenience of speakers and members. It was decided that a room having a seating capacity of 1,000 was about the limit of size in which papers could be read and discussed advantageously; a larger room would cause straining of a speaker's voice and difficulty in following the discussion. The auditorium will

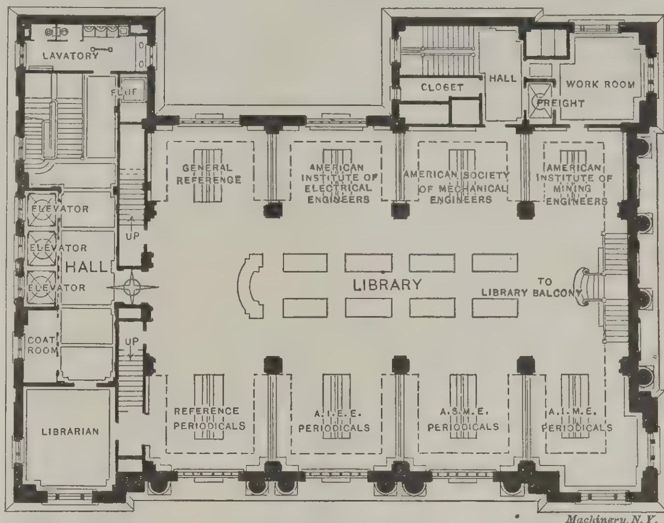

Fig. 2. Plan of Library.

hold considerably over 1,000, but the seating capacity is nominally the number given. High-speed elevators and other modern conveniences make this building a notable example of modern high-class structures. It will be a credit to all the societies connected therewith and its location only one block removed from the New York Public Library and its direct communication with the Engineering Club Building on 40th St. make a location that is ideal for convenience of research, etc. It will be easily reached from out of town, being only a short distance from the 42d St. terminal of the New York Central and New Haven Railroads and a slightly greater distance

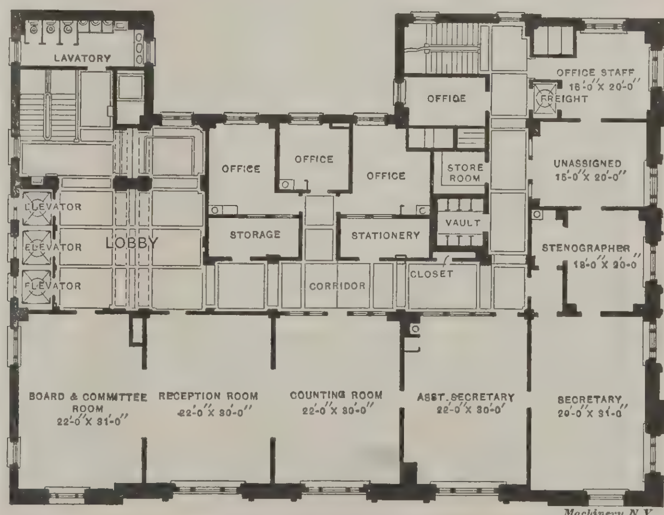

Fig. 3. Plan of A. S. M. E. Floor.

from the new Pennsylvania R. R. terminal. By the time this description appears the American Society of Mechanical Engineers will have moved into their new quarters.

REVIEW OF THE PAPERS.

On the Art of Cutting Metals, by Mr. Fred. W. Taylor.

This voluminous paper, forming the presidential address, reviews the work of Mr. Taylor and his associates in determining the elements or factors which affect the efficiency of metal-working tools on roughing cuts. These investigations have extended over a period of twenty-six years and during that time over 800,000 pounds of steel and iron have been cut into chips on experimental lathes at a cost of $150,000 to

$200,000. In carrying on this work more than ten machines were fitted up at various times and literally thousands of experiments were recorded. More than 16,000 experiments were recorded with one company, the Bethlehem Steel Co. Quite as remarkable as the result is the fact that for twenty-six years the discovered laws have been kept secret and the accumulated knowledge has been used as a lever for extending the investigations. The plan was to give to each company availing themselves of the acquired knowledge of Mr. Taylor and his associates this knowledge in return for the privilege of making more experiments at the present company's expense. The paper is very voluminous, containing about 100,000 words and twenty-four large folding sheets of halftones, drawings and tables. It is one of the most notable papers ever presented before the society and it doubtless will have a great effect on future machine tool design and practice. The investigations show that there are twelve separate and distinct elements or variables affecting the efficiency of the lathe and the same applies to any metal-working tool. A full abstract of this remarkable paper will be given in sections as space permits.

Report of the Committee of Standard Proportions of Machine Screws.

At a joint meeting of representative machine screw manufacturers and individuals connected therewith, held in New York, April 11, 1904, certain diameters, pitches and limits for standard machine screws were adopted. Since that date it has been found advisable to modify the list of machine screw sizes which were agreed on at that time before final action was taken by the society; Mr. George M. Bond of the committee reported that the matter was still under discussion and that a final report could not be made until the spring meeting, 1907. See MACHINERY, June, 1906, for an abstract of the proposed machine screw standards.

The Evolution of Gas Power, by Mr. F. E. Junge.

The author points out the remarkable development of the gas engine within the memory of the past generation and shows that it has become a factor of consequence in the world's total energy output. In Germany alone at the present time there is a total of about 400 gas engines with a combined capacity of about 420,000 horsepower. He states that the variety of earlier forms of large gas engines has now been

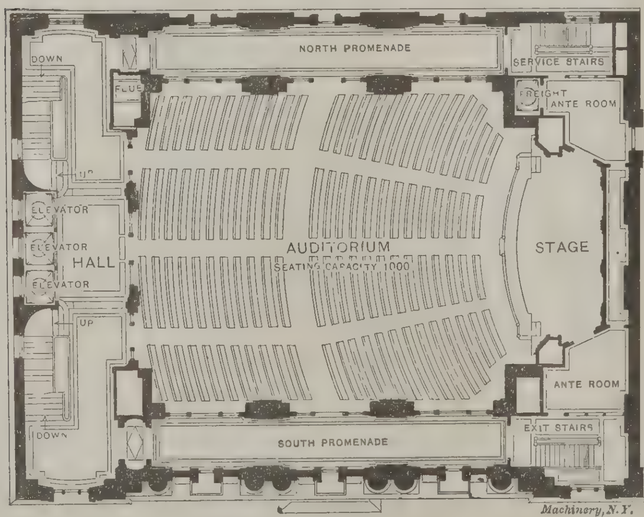

Fig. 4. Plan of Auditorium.

reduced to two classes, these being the double-acting tandem four-cycle and the double-acting two-cycle types. The single-acting type of each is only applicable in the smaller sizes. The peculiar process of charging with an open exhaust limits the two-cycle engine to speeds of from 80 to 100 as a maximum, and therefore puts this type at a disadvantage where the maximum power output is required for a given weight and space.

Producer Gas Power Plants, by Mr. J. R. Bibbins.

This timely paper on the simple producer plant calls renewed attention to its value. The author endeavors to show that the gas power plant using producer gas is a thoroughly practical form of motor power equipment; that it is reliable in operation; is suited to fluctuating loads; is comparatively simple to operate; and is more economical in point of fuel efficiency than the average steam plant of the same size and capacity.

Tests of High Duty Air Compressors, by Prof. O. P. Hood.

In the copper country of Michigan several compressed air plants exceed 1,000 horsepower each and there is one of about 5,000 horsepower. This paper reports the result of tests of a high-duty air compressor installed at the Champion copper

Prof. Frederick R. Hutton, Newly-elected President of the A. S. M. E.*

mine at Painesdale, Mich. The machine, built by the Nordberg Mfg. Co., Milwaukee, Wis., consists of four horizontal engines placed side by side and connected to a crankshaft carrying three flywheels. The engine was designed to use steam at 300 pounds pressure and was guaranteed to develop 180,000,000 foot-pounds for each million heat units used and to compress 9,000 cubic feet per minute to a pressure of 80 pounds gage at 76 revolutions per minute. The report of the tests is given in detail. It was found that owing to boiler leakage the calculated pressure of 300 pounds could not be carried and it was necessary to use the reduced pressure of 250 pounds. It was under these conditions that the contract was carried out and the tests made. The standard efficiency tests were, heat consumed by engine per I.H.P., 10,157 B.T.U.; heat consumed per hour per B.H.P., 11,382 B.T.U.; equivalent coal consumption per I.H.P., 1.016 pound; the same per B.H.P., 1.138 pound. The duty developed per million heat units supplied to the engine was 194,930,000 foot-pounds. This engine establishes a new low record for heat consumed per hour per I.H.P., being 9 per cent lower than that used by the Wildwood pumping engine reported in 1900.

Boiler and Setting, by Mr. A. Bement.

The objects proposed in this design of boiler setting are the attainment of a perfect and smokeless combustion, and the full utilization of boiler heating surfaces. The setting is applied to a water-tube boiler of the Heine type, equipped with chain grate stokers. The setting is so constructed that the gases from the firebox traverse backward to the rear of the boiler, passing under a furnace roof of peculiar construction, upward through the water tubes, then downward, repeating this circuitous path around the baffle plates until all the gases

* Frederick Remsen Hutton was born in New York City, 1853. He graduated from Columbia College in 1876; later he was made instructor in mechanical engineering and in 1892 succeeded to the chair of engineering of that institution. The American Society of Mechanical Engineers was organized in 1880 and in 1883 Prof. Hutton was made secretary, which position he has held up to the assumption of the presidency of the society at the conclusion of the December meeting. During his incumbency as secretary of the society it has grown enormously in membership and prestige. A magnificent society building of which the American Society of Mechanical Engineers is one-third owner has been constructed. Prof. Hutton is the author of a number of technical books, including Heat and Heat Engines; Gas Engines; Mechanical Engineering of Power Plants, etc. Notwithstanding his manifold duties as head of the mechanical department of Columbia University and secretary of the society, he has been active in other work connected with his profession.

have passed around the water tubes five times, when they escape past the boiler into the stack. The results are gratifying in point of smokelessness and efficiency of fuel consumption. The principal feature is the refractory tile roof construction employed for making the gases traverse to the rear of the furnace under the water tube, before coming in contact with cooling surfaces. In short the design of the furnace is such as to secure perfect combustion first; then the utmost utilization of the heat produced.

Steam Plant of the White Motor Car, by Prof. R. C. Carpenter.

This paper describes in detail the remarkable superheated steam boiler and compound engine plant with which the White automobile is equipped. The boiler is of the continuous flow or single-tube type, or what is sometimes called the "flash" type. The engine is compound with piston valves. It exhausts into an air condenser. The dimensions of the engine tested were 3 and 6 inches diameter by 4½ inches stroke, with a rating of 30 horsepower. Its weight complete was 328 pounds and the total weight of the boiler is 275 pounds, making the total weight of the combined engine and boiler 603 pounds. The pressure averaged 303 pounds per square inch and the steam was superheated, the temperature at the steam chest averaged 757 degrees F. The results were remarkable. The best showing was an average of 12.7 pounds of steam consumption per developed horsepower per hour.

Ventilation of the Boston Subway, by Mr. H. A. Carson.

The Boston Subway system is about 3½ miles long and the general scheme of ventilation is that the fresh air shall be drawn in at the stations or portals and the vitiated air shall be discharged at points midway between the passenger stations. The paper is illustrated with photographs and drawings showing how the ventilation scheme was worked out.

Flow of Liquids in Venturi Tubes, by Mr. E. P. Coleman.

This paper is an investigation of the properties of the Venturi tube and its object was to prove or disprove the accuracy of the Venturi tube as a meter for gas and vapors at comparatively low throat velocities. The Pitot tube was used as the instrument for comparison on account of its proven accuracy and its simplicity. The result of the experiment is an apparent close agreement of the theoretical flow of air through a Venturi meter and the flow as derived from a Pitot tube observation.

Tests of an Elevator Plant, by Mr. A. J. Herschmann.

This paper is an account of the tests made on the plunger type elevators forming the equipment of the elevator plant of the Trinity Building, New York City, while in regular operation. Two series of tests are tabulated. In the first a duplex compound pump was used; and in the second, a flywheel pump. It was found that the cost of coal per car-mile was 5.22 cents with the flywheel pump and 8.04 cents with the duplex compound pump.

Test of a Rotary Pump, by Prof. W. B. Gregory.

This is an account of the test of a rotary pump installation consisting of four units of the cycloidal rotary pump erected on the Neches Canal Co.'s property near Beaumont, Texas. The pumps were driven by 18 x 36 x 48-inch tandem compound condensing Corliss engines direct connected. The displacement of each pump is 605 gallons per revolution. The water is elevated 32 feet. It was found that the mechanical efficiency of the two pump units average 83.3 per cent.

Improved Transmission Dynamometer, by Prof. W. F. Durand.

The paper calls attention to a modified form of Tatham dynamometer in which four sprocket wheels are used all in one plane with an automobile or bicycle chain connector instead of leather belt, thus giving a non-slip drive. The load is measured by the turning moment of the beam carrying the two idler wheels, the other two being mounted on stationary bearings.

A Plan to Provide Skilled Workmen, by Mr. M. W. Alexander.

This paper is an account of the work of the General Electric Co., at West Lynn, Mass., in training boys and young men to become practical machinists and patternmakers. The General Electric Co. have established two training rooms, one for machinists and toolmakers, with about 10,000 square feet of floor space and about 105 representative machine tools; and a smaller department for wood and metal patternmaking apprentices, with a floor space of about 1,000 square feet. The paper is coördinate with the article by Mr. Alexander which appeared in the September issue of this journal.

Saw-tooth Skylight in Factory Roof Construction, by Mr Fred S. Hinds.

The saw-tooth roof was developed to meet the needs of the textile industries. When the power cotton loom first came into use, weaving was carried on in the homes of operatives and the natural growth due to the advent of the power loom in these small establishments led to the addition of one-story structures, which, as business increased, were added to, forming what is known as a "weave shed." As these came to cover large areas it was necessary to provide roof lighting and the saw-tooth form of roof skylight was the result. Mr. Hinds' paper is illustrated with drawings showing the construction of various forms of saw-tooth roofs, and is also illustrated with photographs of the B. F. Sturtevant Co.'s plant. This plant was described and illustrated in MACHINERY, October, 1905.

Ferroinclave Construction, by Mr. A. E. Brown.

The ferroinclave roofing is a reinforced concrete structure consisting of No. 24 soft steel sheets with dovetail corrugations filled with cement mortar on both sides, so that the slab is about 1⅜ inch thick. The paper describes the structure of this roofing and gives tests of strength under various loading conditions. For an illustrated description of ferroinclave roofing see MACHINERY for October, 1903.

Saw-tooth Roofs for Factories, by Mr. K. C. Richmond.

The author defines a saw-tooth roof as a general form of skylight, a cross-section of which approximates a 30 x 60-degree draftsman's triangle with the hypothenuse horizontal, the right angle being at the top and the glass in the short leg only. These saw-teeth may be used singly, of any convenient length, and in successive rows or in any desired combination to suit any particular conditions. The object of the saw-teeth is to obtain overhead light and in most cases the windows are faced directly or nearly north. This form of roof lighting has found wide application in many kinds of factory service, including machine shops, textile mills and other plants where a large volume of diffused light is desirable. In the latitude of New York an angle of 17 degrees to 18 degrees may be employed for the glass section and still keep out the sun in the longest summer days, and this angle may be increased from 25 to 30 degrees if a small projecting cornice is built above the window. The paper is illustrated with drawings of various types of wood frame saw-teeth and is accompanied by a general discussion of the various features affecting this form of lighting. It is pointed out that in textile industries a better class of help is attracted by the good lighting afforded by the saw-tooth roof construction.

Our Present Weights and Measures and the Metric System, by Mr. Henry R. Towne.

This scholarly paper is a discussion of the present weights and measures and it advocates an improvement to the end that the system shall be uniform with that of Great Britain. The United States liquid gallon contains 231 cubic inches, while the imperial or British wine gallon contains 277.274 cubic inches. There should be an agreement between the two. Mr. Towne is opposed to the introduction of the metric system and quotes extensively to show that its introduction would mean a revolution in existing conditions which is unthinkable from a practical standpoint. He recommends the creation of a technical commission by Congress which shall study and report on the whole subject of weights and measures.

Mechanical Engineering Index, by Profs. W. W. Bird and A. L. Smith.

This paper is descriptive of the engineering index in the department of mechanical engineering of the Worcester Polytechnic Institute. The paper includes nearly 500 heads, 1,100 sub-heads, and the cross references, all amounting to fifty-six pages of the proceedings. To any one interested in the subject of intelligent and comprehensible indexing of engineering literature the paper is well worth attention.

ON THE ART OF CUTTING METALS.—1.*

FRED. W. TAYLOR.†

Fred. W. Taylor.

The experiments described in this paper were undertaken to obtain a part of the information necessary to establish in a machine shop our (Taylor) system of management, the central idea of which is:

A. To give each workman each day in advance a definite task, with detailed written instructions, and an exact time allowance for each element of the work.

B. To pay extraordinarily high wages to those who perform their tasks in the allotted time, and ordinary wages to those who take more than their time allowance.

There are three questions which must be answered each day in every machine shop by every machinist who is running a metal-cutting machine, such as a lathe, planer, drill press, milling machine, etc., namely:

a. What tool shall I use?

b. What cutting speed shall I use?

c. What feed shall I use?

Our investigations, which were started twenty-six years ago with the definite purpose of finding the true answer to these questions under all the varying conditions of machine shop practice have been carried on up to the present time with this as the main object still in view.

The writer will confine himself almost exclusively to an attempted solution of this problem as it affects "roughing work"; *i.e.*, the preparation of the forgings or casting for the final finishing cut, which is taken only in those cases where great accuracy or high finish is called for. Fine finishing cuts will not be dealt with. Our principal object will be to describe the fundamental laws and principles which will enable us to do "roughing work" in the shortest time, whether the cuts are light or heavy, whether the work is rigid or elastic, and whether the machine tools are light and of small driving power or heavy and rigid with ample driving power.

In other words, our problem is to take the work and machines as we find them in a machine shop, and by properly changing the countershaft speeds, equipping the shop with tools of the best quality and shapes, and then making a slide rule for each machine to enable an intelligent mechanic with the aid of these slide rules to tell each workman how to do each piece of work in the quickest time.

The three great questions, as to shape of tools, speed, and feed, above referred to, are daily answered for all of the men in each shop far better by our one trained mechanic with the aid of his slide rule than they were formerly by the many machinists, each one of whom ran his own machine, etc., to suit his foreman or himself. It may seem strange to say that a slide rule enables a good mechanic to double the output of a machine which has been run, for example, for ten years by a first-class machinist having exceptional knowledge of and experience with his machine, and who has been using his best judgment. Yet, our observation shows that, on the average, this understates the fact.

Twelve Variables Affect the Production of Chips.

To make the reason for this more clear it should be understood that the man with the aid of his slide rule is called upon to determine the effect which each of the twelve elements or variables given below has upon the choice of cutting speed and feed; and it will be evident that the mechanic, or expert or mathematician does not live who, without the aid of a slide rule or its equivalent, can hold in his head these twelve variables and measure their joint effect upon the problem.

These twelve elements or variables are as follows:

a. The quality of the metal which is to be cut;
b. The diameter of the work;
c. The depth of the cut;
d. The thickness of the shaving;
e. The elasticity of the work and of the tool;
f. The shape or contour of the cutting edge of the tool, together with its clearance and lip angles;
g. The chemical composition of the steel from which the tool is made, and the heat treatment of the tool;
h. Whether a copious stream of water, or other cooling medium, is used on the tool;
j. The duration of the cut, *i. e.*, the time which a tool must last under pressure of the shaving without being reground;
k. The pressure of the chip or shaving upon the tool;
l. The changes of speed and feed possible in the lathe;
m. The pulling and feeding power of the lathe.

Broadly speaking, the problem of studying the effect of each of the above variables upon the cutting speed and of making this study practically useful, may be divided into four sections as follows:

A. The determination by a series of experiments of the important facts or laws connected with the art of cutting metals.

B. The finding of mathematical expressions for these laws which are so simple as to be suited to daily use.

C. The investigation of the limitations and possibilities of metal cutting machines.

D. The development of an instrument (a slide rule) which embodies, on the one hand, the laws of cutting metals, and on the other, the possibilities and limitations of the particular lathe or planer, etc., to which it applies and which can be used by a machinist without mathematical training to quickly indicate in each case the speed and feed which will do the work quickest and best.

How the Investigation was Started and how it has been Carried Along.

In the fall of 1880, the machinists in the small machine shop of the Midvale Steel Company, Philadelphia, most of whom were working on piecework in machining locomotive tires, car axles, and miscellaneous forgings, had combined to do only a certain number of pieces per day on each type of work. The writer, who was the newly appointed foreman of the shop, realized that it was possible for the men to do in all cases much more work per day than they were accomplishing. He found, however, that his efforts to get the men to increase their output were blocked by the fact that his knowledge of just what combination of depth of cut, feed and cutting speed would in each case do the work in the shortest time, was much less accurate than that of the machinists who were combined against him. His conviction that the men were not doing half as much as they should do, however, was so strong that he obtained the permission of the management to make a series of experiments to investigate the laws of cutting metals with a view to obtaining a knowledge at least equal to that of the combined machinists who were under him. He expected that these experiments would last not longer than six months. With the exception of a few comparatively short periods, however, these experiments have continued *until the present time*, through a term of about 26 years.

The writer wishes to call attention to the fact that in these first experiments he was far more fortunate than almost all of the experimenters who have investigated the subject since then, in having at his disposal a comparatively large mass of uniform metal to work upon, and a comparatively large and powerful machine to work with, a 66-inch diameter boring mill and large locomotive tires made of hard tire steel of uniform quality having been used. He was also especially fortunate in having over him as president of the company, Mr. William Sellers, who, as is well known, was one of the most patient and broad-minded experimenters of his day. Mr. Sellers, in spite of the protests which were made against the continuation of this work, allowed the experiments to proceed; even, at first, at a very considerable inconvenience and loss to the shop. The extent of this inconvenience will be appreciated when it is understood that we were using a 66-inch diameter vertical boring mill, belt-driven by the usual cone pulleys, and that in order to regulate the exact cutting speed of the tool, it was necessary to slow down the speed of the engine that drove all of the shafting in the shop; a special adjustable engine governor having been bought for this purpose. For over two years the whole shop was incon-

* Abstract of introduction of paper read before the December, 1906, meeting of the American Society of Mechanical Engineers.
† For biographical sketch, see MACHINERY, January, 1906.

venienced in this way, by having the speed of its main line of shafting greatly varied, not only from day to day but from hour to hour. Before the two years had elapsed, however, the writer had obtained such valuable and unexpected results from the experiments as to much more than justify all of the annoyance and expenditure, and soon after that he readily obtained permission to employ a young technical graduate to devote his whole time to the continuation of this work.

Mr. G. M. Sinclair, a graduate of Stevens Institute of Technology, devoted his entire time to this work from 1884 to 1887, when he left the employ of the company.

Mr. H. L. Gantt, also a graduate of Stevens Institute succeeded Mr. Sinclair in July, 1887, and has been interested with us in carrying on these experiments throughout their whole period.

In 1898 Mr. Maunsel White, of Bethlehem, another graduate of Stevens Institute, joined us and has been actively interested in our work up to this time.

Mr. Carl G. Barth, a graduate of the Technical School of Horten, Norway, joined us in 1899, and is still actively working on our investigations.

Our experiments were continued in the works of the Midvale Steel Company until 1889, when the writer left their employ. Since then, these investigations have been carried on in various shops and at the expense of different companies. Among these, we would especially acknowledge our indebtedness to the Cramp's Shipbuilding Company, Messrs. Wm. Sellers & Co., the Link-Belt Engineering Company, Messrs. Dodge & Day, and, more than all, to the Bethlehem Steel Company.

In carrying on this work more than ten machines have been fitted up at various times with special driving apparatus and the other needed appliances, all machines used since 1894 having been equipped with electric drives, so as to obtain any desired cutting speed. The thoroughness with which the work has been done may perhaps be better appreciated when it is understood that we have made between thirty and fifty thousand recorded experiments, and many others of which no record was kept. In studying these laws we have cut up into chips with our experimental tools more than 800,000 pounds of steel and iron. More than sixteen thousand experiments were recorded in the Bethlehem Steel Company. We estimate that up to date between $150,000 and $200,000 have been spent upon this work, and it is a very great satisfaction to feel that those whose generosity has enabled us to carry on the experiments have received ample return for their money through the increased output and the economy in running their shops which have resulted from our experiments.

Throughout the whole 26 years we have succeeded in keeping almost all of these laws secret, and in fact since 1889 this has been our means of obtaining the money needed to carry on the work. We have never sold any information connected with this art for cash, but we have given to one company after another all of the data and conclusions arrived at through our experiments in consideration for the opportunity of still further continuing our work.

Summary of Discoveries.

The writer has no doubt that many of the discoveries and conclusions which mark the progress of this work have been and are well known to other engineers, and we do not record them with any certainty that we were the first to discover or formulate them, but merely to indicate some of the landmarks in the development of our own experiments, which to us were new and of value. The following is a record of some of our more important steps:

A. In 1881, the discovery that a round-nosed tool could be run under given conditions at a much higher cutting speed and therefore turn out much more work than the old-fashioned diamond-pointed tool.

B. In 1881, the demonstration that, broadly speaking, the use of coarse feeds accompanied by their necessarily slow cutting speeds would do more work than fine feeds with their accompanying high speeds.

C. In 1883, the discovery that a heavy stream of water poured directly upon the chip at the point where it is being removed from the steel forging by the tool, would permit an increase in cutting speed, and, therefore, in the amount of work done of from 30 to 40 per cent. In 1884, a new machine shop was built for the Midvale Steel Works, in the construction of which this discovery played a most important part; each machine being set in a wrought-iron pan in which was collected the water (supersaturated with carbonate of soda to prevent rusting), which was thrown in a heavy stream upon the tool for the purpose of cooling it. The water from each of these pans was carried through suitable drain pipes beneath the floor to a central well from which it was pumped to an overhead tank from which a system of supply pipes led to each machine. Up to that time, so far as the writer knows, the use of water for cooling tools was confined to small cans or tanks from which only a minute stream was allowed to trickle upon the tool and the work, more for the purpose of obtaining a water finish on the work than with the object of cooling the tool; and, in fact, these small streams of water are utterly inadequate for the latter purpose. So far as the writer knows, in spite of the fact that the shops of the Midvale Steel Works until recently have been open to the public since 1884 no other shop in this country was similarly fitted up until that of the Bethlehem Steel Company in 1899, with the one exception of a small steel works which was an offshoot in personnel from the Midvale Steel Company.

D. In 1883, the completion of a set of experiments with round-nosed tools; first, with varying thicknesses of feed when the depth of the cut was maintained constant; and, second, with varying depths of cut while the feed remained constant, to determine the effect of these two elements on the cutting speed.

E. In 1883, the demonstration of the fact that the longer a tool is called upon to work continuously under pressure of a shaving, the slower must be the cutting speed, and the exact determination of the effect of the duration of the cut upon the cutting speed.

F. In 1883, the development of formulas which gave mathematical expression to the two broad laws above referred to. Fortunately these formulas were of the type capable of logarithmic expression and therefore suited to the gradual mathematical development extending through a long period of years, which resulted in making our slide rules, and solved the whole problem in 1901.

G. In 1883, the experimental determination of the pressure upon the tool required on steel tires to remove cuts on varying depths and thickness of shaving.

H. In 1883, the starting of a set of experiments on belting described in a paper published in the Transactions, A. S. M. E., Vol. 15 (1894).

J. In 1883, the measurement of the power required to feed a round-nosed tool with varying depths of cut and thickness of shaving when cutting a steel tire. This experiment showed that a *very dull tool* required as much pressure to feed it as to drive the cut. This was one of the most important discoveries made by us, and as a result all steel cutting machines purchased since that time by the Midvale Steel Company have been supplied with feeding power equal to their driving power and very greatly in excess of that used on standard machine tools.

K. In 1884, the design of an automatic grinder for grinding tools in lots and the construction of a tool room for storing and issuing tools ready ground to the men.

L. From 1885 to 1889, the making of a series of practical tables for a number of machines in the shops of the Midvale Steel Company, by the aid of which it was possible to give definite tasks each day to the machinists who were running machines, and which resulted in a great increase in their output.

M. In 1886, the demonstration that the thickness of the chip or layer of metal removed by the tool has a much greater effect upon the cutting speed than any other element, and the practical use of this knowledge in making and putting into everyday use in our shops a series of broad-nosed cutting tools which enabled us to run with a coarse feed at as high a speed as had been before attained with round-nosed tools when using a fine feed, thus sustituting, for a considerable portion of the work, *coarse feeds and high speeds* for our old maxim of *coarse feeds and slow speeds.*

N. In 1894 and 1895, the discovery that a greater proportional gain could be made in cutting soft metals through the use of tools made from self-hardening steels than in cutting hard metals, the gain made by the use of self-hardening tools over tempered tools in cutting soft cast-iron being almost 90 per cent, whereas the gain in cutting hard steels or hard cast iron was only about 45 per cent. Up to this time, the use of Mushet and other self-hardening tools had been almost exclusively confined to cutting hard metals, a few tools made of Mushet steel being kept on hand in every shop for special use on hard castings or forgings which could not be cut by the tempered tools. This experiment resulted in substituting self-hardening tools for tempered tools for all "roughing work" throughout the machine shop.

P. In 1894 and 1895, the discovery that in cutting wrought iron or steel a heavy stream of water thrown upon the shaving at the nose of the tool produced a gain in cutting speed of *self-hardening tools* of about 33 per cent. Up to this time the

makers of self-hardening steel had warned users never to use water on the tools.

Q. From 1898 to 1900, the discovery and development of the Taylor-White process of treating tools; namely, the discovery that tools made from chromium-tungsten steels when heated to the melting point would do from two to four times as much work as other tools.

R. In 1899-1902, the development of our slide rules, which are so simple that they enable an ordinary workman to make practical and rapid everyday use in the shop of all the laws and formulas deduced from our experiments.

S. In 1906, the discovery that a heavy stream of water poured directly upon the chip at the point where it is being removed from *cast iron* by the tool would permit an increase in cutting speed, and therefore, in the amount of work done, of 16 per cent.

T. In 1906, the discovery that by adding a small quantity of vanadium to tool steel to be used for making modern high speed chromium-tungsten tools heated to near the melting point, the hardness and endurance of tools, as well as their cutting speeds, are materially improved.

Chief Practical Value of Discoveries Embodied in the Slide Rule.

While many of the results of these experiments are both interesting and valuable, we regard as of by far the greatest value that portion of our experiments and of our mathematical work which has resulted in the development of the slide rules; *i. e.*, the patient investigation and mathematical expression of the exact effect upon the cutting speed of such elements as the shape of the cutting edge of the tool, the thickness of the shaving, the depth of the cut, the quality of the metal being cut and the duration of the cut, etc. This work enables us to fix a daily task with a definite time allowance for each workman who is running a machine tool, and to pay the men a bonus for rapid work.

The gain from these slide rules is far greater than that of all the other improvements combined, because it accomplishes the original object, for which in 1880 the experiments were started; *i. e.*, that of taking the control of the machine shop out of the hands of the many workmen, and placing it completely in the hands of the management, thus superseding "rule of thumb" by scientific control.

Mistakes of Not Originally Determining Each Variable Separately—Standard of Twenty Minutes for Each Test.

Almost the whole course of our experiments is marked by imperfections in our methods, which, as we have realized them, have led us to go again more carefully over the ground previously traveled. These errors may be divided into three principal classes:

A. The adoption of wrong or inadequate standards for measuring the effect of each of the variables upon the cutting speed.

B. Failure on our part from various causes to hold all of the variables constant except the one which was being systematically changed in order to study the effect of these changes upon the cutting speed.

C. The omission either through oversight or carelessness on our part of some one of the precautions which should be taken to insure accuracy, or failure to record some of the phenomena considered unimportant at the time, but which afterward proved to be essential to a complete understanding of the facts.

The effect of each variable upon the problem is best determined by finding the exact rate of cutting speed (say, in feet per minute) which shall cause the tool to be completely ruined after having been run for 20 minutes under uniform conditions. For example, if we wish to investigate the effect which a change in the thickness of the feed has upon the cutting speed, it is necessary to make a number of tools which are in all respects uniform, as to the exact shape of their cutting edge, their clearance and lip angles, their chemical composition and their heat treatment. These tools must then be run one after another, each for a period of 20 minutes, throughout which time the cutting speed is maintained exactly uniform. Each tool should be run at a little faster cutting speed than its predecessor, until that cutting speed has been found which will cause the tool to be completely ruined at the end of 20 minutes (with an allowance of a minute or two each side of the 20-minute mark). In this way that cutting speed is found which corresponds to the particular thickness of shaving which is under investigation.

A change is then made in the thickness of the shaving, and another set of 20-minute runs is made, with a series of similar uniform tools, until the cutting speed corresponding to the new thickness of feed has been determined; and by continuing in this way all of the cutting speeds are found which correspond to the various changes of feed. In the meantime, every precaution must be taken to maintain uniform all the other elements or variables which affect the cutting speed, such as the depth of the cut and the quality of the metal being cut; and the rate of the cutting speed must be frequently tested during each 20-minute run to be sure that it is uniform.

The cutting speeds corresponding to varying feeds are then plotted as points upon a curve, and a mathematical expression is found which represents the law of the effect of feed upon cutting speed. We believe that this standard or method of procedure constitutes the very foundation of successful investigation in this art. It was only after about 14 years' work that we found that the best measure for the value of a tool lay in the exact cutting speed at which it was completely ruined at the end of 20 minutes.

Pressure and Rubbing of Chip what Breaks Down Tool.

The ultimate cause for a tool giving out when cutting metal is the dullness or wear of the tool produced by the rubbing or pressure of the chip upon the lip surface of the tool, and the chief element causing this wear, particularly at the high speeds at which tools should be run to do their best work, is the softening of the tool due to the heat produced by the friction of the chip upon its lip surface. Now, it seems perfectly evident that this heat will be increased directly in proportion to three elements:

a. The pounds of pressure of the chip upon the tool;

b. The speed with which the chip slides across the nose of the tool;

c. The coefficient of friction between the chip and the surface of the tool.

And yet, paradoxical as it may seem, the writer asserts that *there is no traceable relation between the pressure of the chip upon the tool and the cutting speed.*

Discovery of Taylor-White Process.

It is a noteworthy fact that when thorough investigations are attempted by earnest men in new fields, while frequently the object aimed at is not attained, yet quite often discoveries are made which are entirely foreign to the purpose for which the investigation was undertaken. And it may be said that the indirect results of careful scientific work are, generally speaking, fully as valuable as the direct. Two interesting illustrations of this fact have been furnished by our experiments.

The discovery of the Taylor-White process of treating tools by heating them almost to the melting point, or, in other words, the introduction of modern high speed tools the world over, was the indirect result of one of our lines of investigation.

The demonstration of the fact that the rules for using belting in common practice furnished belts which were entirely too light for economy was also one of the indirect results of our experiments.

The manner of making these discoveries was each time in a way so typical of what may be expected in similar cases that it would seem worth while to describe it in some detail.

During the winter of 1894-1895, the writer conducted an investigation in the shop of Wm. Sellers & Co., at the joint expense of Messrs. William Cramp & Sons, shipbuilders, and Messrs. Wm. Sellers & Co., to determine which make of self-hardening tool steel was, on the whole, the best to adopt as standard for all of the roughing tools of these two shops.

As a result of this work, the choice was narrowed down at that time to two makes of tool steel: (1) the celebrated Mushet self-hardening steel, the chemical composition of the particular bar analyzed at this time being as follows:

Tungsten, (per cent) 5.441; chromium, 0.398; carbon, 2.150; manganese, 1.578; silicon, 1.044.

(2) A self-hardening steel made by the Midvale Steel Company of the following chemical composition:

Tungsten, (per cent) 7.723; chromium, 1.830; carbon, 1.143; manganese, 0.180; silicon, 0.246; phosphorus, 0.023; sulphur, 0.008.

Of these two steels, the tools made from the Midvale steel were shown to be capable of running at rather higher cutting

speeds. The writer himself heated hundreds of tools of these makes in the course of his experiments in order to accurately determine the best temperatures for forging and heating them prior to grinding so as to get the best cutting speeds. In these experiments he found that the Mushet steel if overheated crumbled badly when struck even a light blow on the anvil, while the Midvale steel if overheated showed no tendency to crumble, but, on the other hand, was apparently permanently injured. In fact, heating these tools slightly beyond a bright cherry red caused them to permanently fall down in their cutting speeds; and the writer was unable at that time to find any subsequent heat treatment which would restore a tool broken down in this way to its original good condition. This defect in the Midvale tools left us in doubt as to whether the Mushet or the Midvale was, on the whole, the better to adopt as a shop standard.

In the summer of 1898, soon after undertaking the reorganization of the management of the Bethlehem Steel Company, the writer decided to continue the experiments just referred to with a view to ascertaining whether in the meanwhile some better tool steel had not been developed. After testing several additional makes of tools, our experiments indicated that the Midvale self-hardening tools could be run if properly heated at slightly higher speeds than those of any other make.

Upon deciding to adopt this steel as our standard the writer had a number of tools of each make of steel carefully dressed and ground to exactly the same shape. He then called the foremen and superintendents of the machine shops of the Bethlehem Steel Company to the experimental lathe so that they could be convinced by seeing an actual trial of all of the tools that the Midvale steel was, on the whole, the best. In this test, however, the Midvale tools proved to be worse than those of any other make; *i. e.*, they ran at slower cutting speeds. This result was rather humiliating to us as experimenters who had spent several weeks in the investigation.

It was of course the first impression of the writer that these tools had been overheated in the smith shop. Upon careful inquiry among the smiths, however, it seemed as though they had taken special pains to dress them at a low heat, although the matter was left in much doubt. The writer, therefore, determined to make a thorough investigation before finally adopting the Midvale steel as our shop standard to discover, if possible, some heat treatment which would restore Midvale tools injured in their heating (whether they had been underheated or overheated) to their original good condition.

For this purpose Mr. White and the writer started a carefully laid out series of experiments, in which tools were to be heated at temperatures increasing, say, by about 50 degrees all the way from a black heat to the melting point. These tools were then to be ground and run in the experimental lathe upon a uniform forging, so as to find:

a. That heat at which the highest cutting speed could be attained (which our previous experiments had shown to be a cherry red).

b. To accurately determine the exact danger point at which if over or underheated these tools were seriously injured.

c. To find some heat treatment by which injured tools could be restored to their former high cutting speeds.

These experiments corroborated our Cramp-Sellers experiments, showing that the tools were seriously broken down or injured by overheating, say, somewhere between 1,550 degrees F. and 1,700 degrees F.; but to our great surprise, tools heated up to or above the high heat of 1,725 degrees F. proved better than any of those heated to the best previous temperature, namely, a bright cherry red; and from 1,725 degrees F. up to the incipient point of fusion of the tools, the higher they were heated, the higher the cutting speeds at which they would run.

Thus, the discovery that phenomenal results could be obtained by heating tools close to the melting point, which was so completely revolutionary and directly the opposite of all previous heat treatment of tools, was the indirect result of an accurate scientific effort to investigate as to which brand of tool steel was, on the whole, the best to adopt as a shop standard; neither Mr. White nor the writer having the slightest idea that overheating beyond the bright cherry red would do anything except injure the tool more and more the higher it was heated.

Ordinary Belting Too Light.

During our early Midvale Steel Company experiments, extending from 1880 to 1883, the writer had so much trouble in maintaining the tension of the belt used in driving the boring mill upon which he was experimenting that he concluded: (1) that belting rules in common use furnished belts entirely too light for economy; and (2) that the proper way to take care of belting was to have each belt in a shop tightened at regular intervals with belt clamps especially fitted with spring balances, with which the tension of the belt was accurately weighed every time it was tightened, each belt being retightened each time to exactly the same tension.

In 1884, the writer designed and superintended the erection of a new machine shop for the Midvale Steel Company, and this gave him the opportunity to put these conclusions to a practical test. About half the belts in the shop were designed according to the ordinary rules and the other half were made about three times as heavy as the usual standard. This shop ran day and night. The belts were in all cases cared for and retightened only upon written orders sent from the shop office; and an accurate record was kept through nine years of all items of interest concerning each belt, namely: the number of hours lost through interruption to manufacture; the number of times each belt interrupted manufacture; the original cost of each belt; the detail costs of tightening, cleaning and repairing each belt; the fall in the tension before requiring retightening; and the time each belt would run without being retightened. Thus at the end of nine years these belts furnished a record which demonstrated beyond question many important facts connected with the use of belting, the principal of these being that the ordinary rules gave belts only about one-half as heavy as should be used for economy. This belting experiment illustrates again the good that often comes indirectly from experiments undertaken in an entirely different field.

Need of Standardization.

Too much emphasis cannot be laid upon the fact that standardization really means simplification. It is far simpler to have in a standardized shop two makes of tool steel than to have 20 makes of tool steel, as will be found in shops under the old style of management. It is far simpler to have all of the tools in a standardized shop ground by one man to a few simple but rigidly maintained shapes than to have, as is usual in the old-style shop, each machinist spend a portion of each day at the grindstone, grinding his tools with radically wrong curves and cutting angles, merely because bad shapes are easier to grind than good. Hundreds of similar illustrations could be given showing the true simplicity (not complication) which accompanies the new type of management.

No one doubts for one minute that it is far simpler to run a shop with a boiler, steam engine, shafting, pulleys and belts than it would be to run the same shop with the old-fashioned foot power, yet the boiler, steam engine, shafting, pulleys and belts require, as supernumeraries or non-producers on the payroll, a fireman, an engineer, an oiler, and often a man to look after belts. The old style manager, however, who judges of complication only by comparing the number of non-producers with that of the producers, would find the steam engine merely a complication in management. The same man, to be logical, would find the whole drafting force of an engineering establishment merely a complication, whereas in fact it is a great simplification over the old method.

Individual Motor Drive Not Recommended.

There is one recommendation, however, in modern machine shop practice in making which the writer will probably be accused of being old-fashioned or ultra-conservative. Of late years there has been what may be almost termed a blind rush on the part of those who have wished to increase the efficiency of their shops toward driving each individual machine with an independent motor. The writer is firmly convinced through large personal observation in many shops and through having himself systematized two electrical works that in perhaps three cases out of four a properly designed belt drive is preferable to the individual motor drive for machine tools. There is no question that through a term of years the total cost, on the one hand, of individual motors and electrical wiring, cou-

pled with the maintenance and repairs, of this system will far exceed the first cost of properly designed shafting and belting plus maintenance and repairs (in most shops entirely too light belts and countershafts of inferior design are used, and the belts are not systematically cared for by one trained man, and this involves a heavy cost for maintenance). There is no question, therefore, that in many cases the motor drive means in the end additional complication and expense rather than simplicity and economy.

* * *

FORMULAS FOR DETERMINING THE PROPORTIONS OF TAPS.

ERIK OBERG.

It has been a very common thing among manufacturers of taps, and still more among persons who only occasionally have been called upon to make these tools, to produce taps without following any definite rule as to the proportions of the various details. Little attention has been given to the possibility of expressing the relation between the diameter and the total length, for instance, by a simple formula. For this reason it is very common to find that the dimensions of taps, or of any other tools of a similar character which are made in a great number of sizes, do not follow any definite rule in their proportions, except the one that a larger size has most of its dimensions a trifle larger than those of the preceding one; even this, however, is not always the case as persons familiar with small tools cannot have helped but notice. Various manufacturers also differ widely as to the proportions of their tools. For this reason the writer has made an attempt to express the rules according to which taps of proper proportions could be made in simple formulas. These formulas are all worked out so that all the dimensions of the tap stand in a certain relation to the diameter of the tap. This insures a tap which will be well proportioned and at the same time it will be well adapted for its work, even if the pitch of the thread should vary for the same diameter. The formulas are worked out with particular regard to taps with standard threads, either United States standard or sharp V-thread, but will be equally serviceable for finer pitches.

Hand Taps.

If we first consider the case of ordinary hand taps, we will find that it is not possible to get a set of formulas which will be suitable for all sizes from the very smallest to the very largest. For this reason we must work out one set of formulas which will be adapted for sizes up to and including one inch in diameter, and one set for larger sizes. In the formulas:

A = the total length of the tap,
B = the length of the thread,
C = the length of the shank,
D = the diameter of the tap,
E = the diameter of the shank,
F = the size of the square,
G = the length of the square.

For sizes up to and including one inch in diameter our formulas are:

$A = 3.5D + 1\frac{5}{8}$ inch,
$B = 2D + \frac{1}{2}$ inch,
$C = 1.5D + 1\frac{1}{8}$ inch,
E = root diameter of thread — 0.01 inch,
$F = 0.75E$,
$G = 0.75D + 1/16$ inch.

For sizes one inch and larger our formulas will be:

$A = 2.25D + 2\frac{7}{8}$ inches,
$B = D + 1\frac{1}{2}$ inch,
$C = 1.25D + 1\frac{3}{8}$ inch,
E = root diameter of thread — 0.02 inch,
$F = 0.75E$,
$G = 0.33D + \frac{1}{2}$ inch.

The supplement contains tables for the dimensions of hand taps with standard threads based on these formulas. Of course, where no necessity for close fractional dimensions exists, the dimensions are only approximately those obtained from the formulas, and are given as practical working dimensions. As seen in the table the shanks for the 3/16 inch and the ¼ inch diameter taps are made equal to the diameter of the tap, according to the usual custom in manufacturing these taps.

Machine Screw Taps.

We will next give formulas for taps used for tapping the holes for regular machine screws, these taps being termed machine screw taps. In fact these taps are nothing but hand taps, but it has become customary to make them in a somewhat different way from ordinary hand taps. The shank on the smaller sizes is larger than the diameter of the tap itself, and on the larger sizes equal to the diameter of the tap. On the larger sizes there is a neck between the threaded portion and the shank, but on the smaller the thread runs directly into the shank part. In the formulas for machine screw taps:

A = the total length of the tap,
B = the length of the thread,
C = the length of the neck,
D = the diameter of the tap,
E = the length of the shank,
F = the diameter of the shank,
G = the size of the square,
H = the length of the square.

The following formulas will apply to all sizes of machine screw taps:

$A = 5D + 1\ 5/16$ inch,
$B = 3D + \frac{3}{8}$ inch,
$G = 0.75F$,
$H = 0.67D + \frac{1}{8}$ inch.

F, the diameter of the shank, is 0.125 inch up to and including No. 5 machine screw tap, and equal to D for larger sizes. Up to and including No. 7 machine screw tap there is no neck between the shank and the thread. For larger sizes

$C = 0.75D$.

For sizes up to and including No. 7

$E = 2D + 15/16$ inch.

For larger sizes

$E = 1.25D + 15/16$ inch.

The supplements contain a table based upon these formulas.

Tapper Taps.

For tapper taps we may also make up a set of empirical formulas. In these

A = the length of the thread,
B = the parallel part of the thread,
C = the chamfered part of the thread,
D = the diameter of the tap,
E = the diameter of the shank,
F = the diameter at the point of the thread.

The formulas for tapper taps up to and including 9-16 inch are as follows:

$A = 4.5D + 5/16$ inch,
$B = 2.75D + 3/16$ inch,
$C = 1.75D + \frac{1}{8}$ inch,
E = root diameter of thread — 0.01 inch,
F = root diameter of thread — $(0.005D + 0.005$ inch).

For sizes from ⅝ inch diameter to 2 inches inclusive the formulas are:

$A = 2D + 1\frac{3}{4}$ inch,
$B = 1.25D + 1$ inch,
$C = 0.75D + \frac{3}{4}$ inch,
E = root diameter of thread — 0.02 inch,
F = root diameter of thread — $(0.005D + 0.005$ inch).

By means of the formulas given, the dimensions for any intermediate size between those tabulated in the supplement may easily be determined. It is understood, of course, that the formulas have a great degree of flexibility, and that they are proposed only in order to facilitate the work of the toolmaker or draftsman to whom it is often left to settle upon the dimensions for these tools. The tables (see supplement) are worked out in order to save figuring in each individual case, but, as stated previously, give the approximate working dimensions, and do not give the close theoretical values figured from the formulas, excepting when essential.

The total railway mileage under contract for construction or in immediate prospect in the United States and Canada is over 25,000 miles.

THE PLANER VS. THE MILLING MACHINE.

H. P. FAIRFIELD.

It did not occur to me when presenting the photographs of a simple planer job in the September, 1906, issue that the editorial comment would bring out an opinion regarding the relative value, as a cost reducer, of planing and milling. The remarks as I read them, are of a general nature, and were meant to apply to grouped or strung work as it is usually done on the planer, and the particular piece shown was merely used to give point to the words.

The question of planing *versus* milling is to me an interesting one, and Mr. Edgar's presentation of his views in the November issue has interested me to the extent of showing a few more photographs, illustrating the manner in which work is being done by several of our New England firms of high standing, who have given time and thought to the subject of costs in the shop.

It may be well to mention that the object of the original illustrations was to show a simple job of planer work and the way in which it could be systematically done in a planer where only the regular equipment of the machine was available, that is to say, the usual stops, straps, bolts, leveling strips, backing strips and chucks. The piece shown is regularly done in our shops, using special fixtures, but as these might vary in different shops they were not pertinent to the purposes which were sought in the original paper.

Fig. 1 of the present paper illustrates the fixture we use

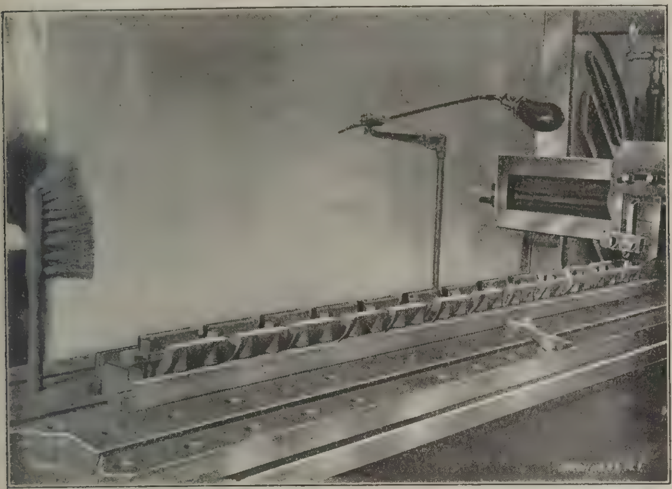

Fig. 1. Fixture for Holding Caps for Bearings while Planing.

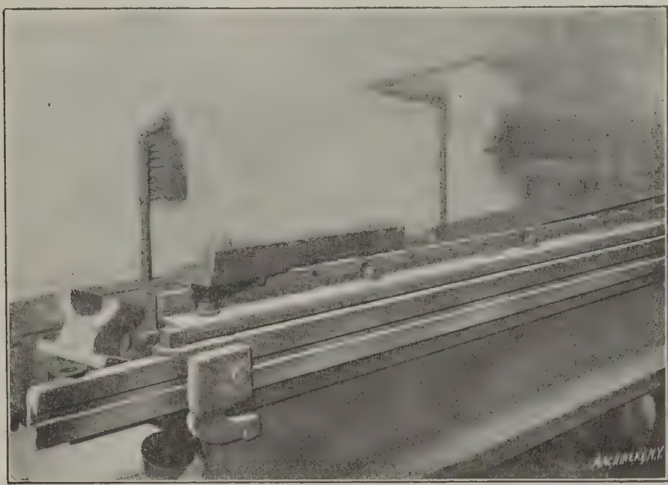

Fig. 2. Fixture for Holding Base of Bearings while Planing.

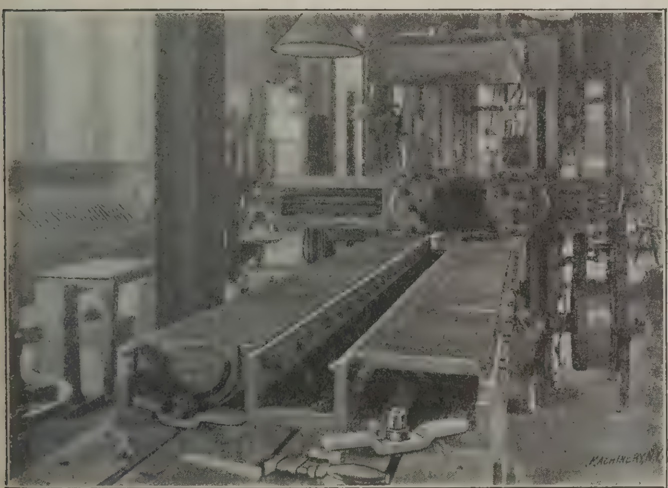

Fig. 3. Fixture for Planing Castings shown in Fig. 4.

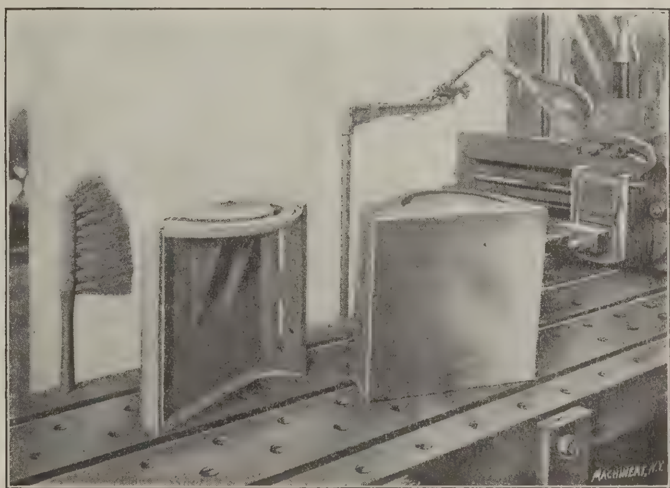

Fig. 4. Castings Planed in Manner shown in Fig. 3.

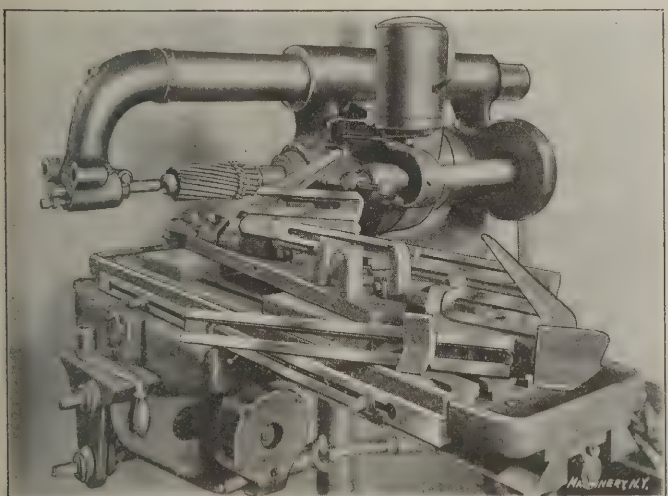

Fig. 5. Work on which the Milling Machine is Superior to the Planer.

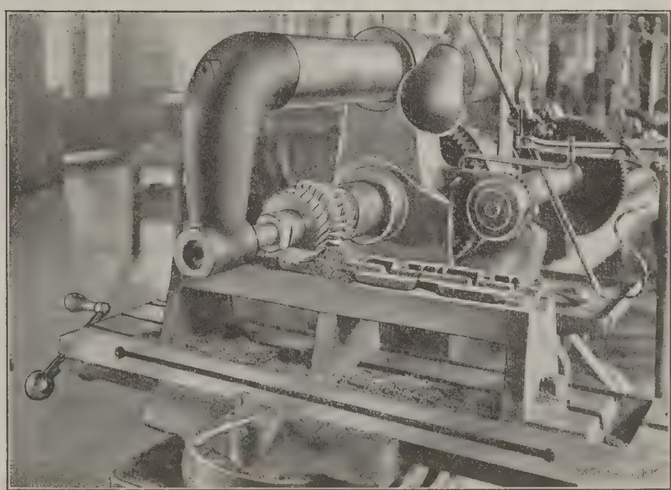

Fig. 6. Using Gang of Cutters for Rapid Finishing by Milling.

for holding the caps, and it appears to me as being much simpler than the one Mr. Edgar suggests as there are no pins or setscrews, a simple casting fitted to the planer bed comprising all there is to it.

Fig. 2 shows the fixtures used in holding the base portion of the bracket, and they will be seen to consist of a simple backing strip, undercut at the lower edge to lock the edge of the casting, and a similar strip for the front side of the

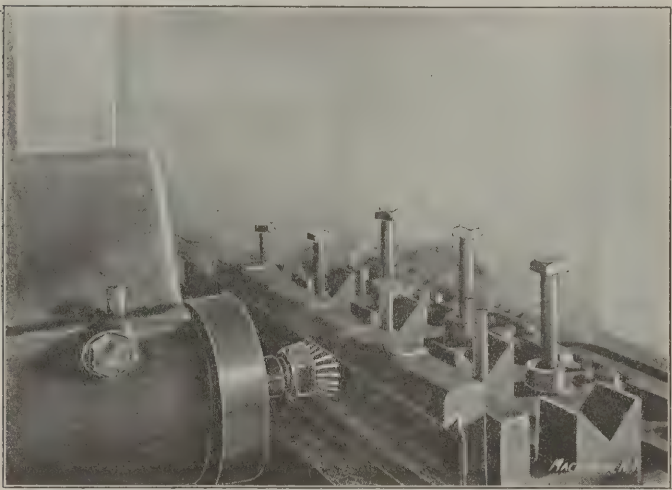

Fig. 7. Finishing Slides by Angular Cutter on the Milling Machine.

planer, fitted with setscrews at an angle suitable for forcing the casting to be held against the backing strip and down firmly to the planer platen. For ease of handling, these strips are made in short sections, but when in use they form a continuous fixture and can be used in sets, if there is more than one head mounted upon the cross-rail. This fixture, while similar to the one shown by Mr. Edgar is to my mind simpler, as no setscrews are used, or needed, in the backing. His jig or fixture for holding the piece when milling with a face cutter *might* hold the work when a light cut was being taken, but could hardly be said to be a good device as it appears trappy and locates by the wrong surfaces to insure steadiness.

Fig. 3 shows a set of fixtures designed to hold the casting shown in Fig. 4 while it is being planed. As the planer used for this work has two heads upon the cross-rail the castings are strung in two groups covering practically the whole surface of the platen.

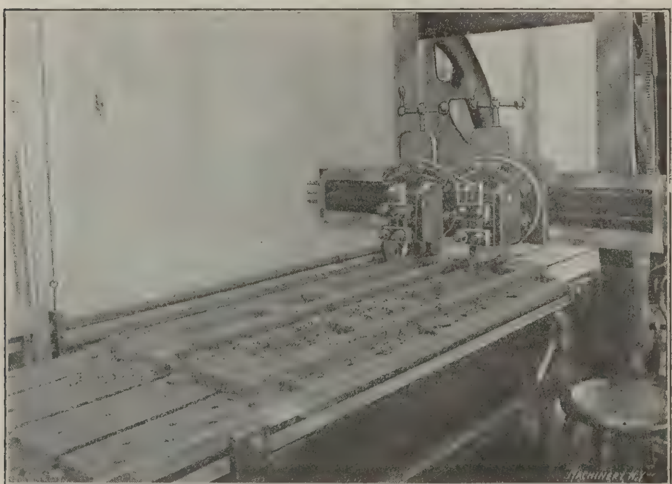

Fig. 8. A Case where Accuracy is Easier Procured by using the Planer.

A decision as to whether a piece of work shall be done upon a milling machine or in a planer often depends upon the available machine, but in our shop much experimenting has been and is being done in an honest attempt to learn which method will give the lowest piece cost. The mere question of removing stock is only a portion of the problem; the relative expense of equipment enters to some extent, but the main question in determining the method of machining is that condition of the work when leaving the different machines which calls for the least hand work to insure both accuracy and finish. An ability to chew cast iron does not mean much after all in machine construction unless other qualifications are present.

The result of experiment has led to milling some work that was formerly planed, but so far as our results show there is not much comparison between the two methods for the work shown, when time, accuracy, and low initial cost are considered. An attempt has also been made to add others' experiences to our stock of data, and considerable time has been spent in viewing what the other fellow has done. The results of all this lead us to conclude that for simple plane surfaces, the planer properly equipped with fixtures and tools by which to do the work is in the game to stay.

When such work as that shown in Fig. 5 has to be done in any considerable quantities, the milling machine will naturally be the method chosen. Fig. 6 shows another job that can be done upon an ordinary milling machine, and much quicker than on the planer. In Fig. 7 experiment has led to milling the angled side of the piece, but the reverse, which is a simple plane surface, is done upon a planer, stringing as many as convenient at a time. Figs. 8 and 9 are views that show ordinary practice, and when accuracy and piece cost is an item, in my opinion the *best* practice.

To sum up, then, my belief is that where the simpler plane surfaces that naturally lend themselves to grouping, are to be produced, the planer with a proper equipment is the natural machine to use, and will be found to give the lowest piece

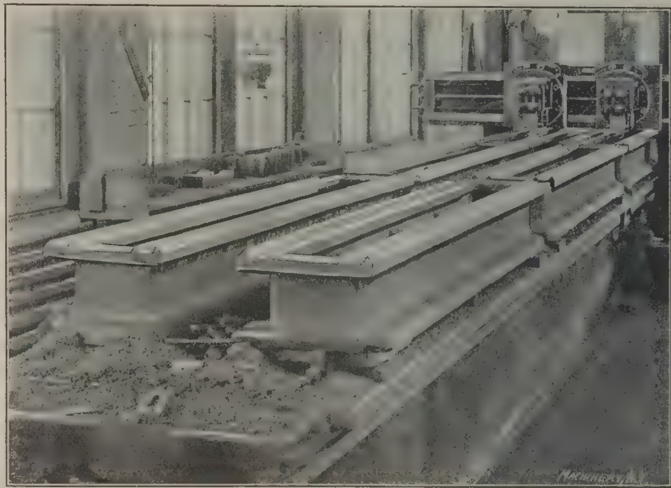

Fig. 9. Planing the Ways of Lathe Beds.

cost. It is understood, of course, that the piece cost when figured includes its proportionate share of fixed costs as it always should.

* * *

THE SIXTIETH BIRTHDAY OF BUGHOUSE BANNISTER.

THE HIRED MAN.

Bughouse Bannister was a millwright; if he had been twenty-five or thirty years old, instead of sixty, he would have been a mechanical engineer or a mechanical superintendent, or a master mechanic or a mechanical expert, but being sixty, he refused to call himself any new-fangled name.

The ambition of his life had been to bring forth a new steam engine, one that would astonish his friends, and now on his sixtieth birthday the engine was done and ready to try, and Bughouse invited his friends in to be astonished, and they certainly were astonished good and plenty! * * *

Just as firmly as Bughouse stuck to his title of millwright, he also stuck to some ideas of millwright vintage; he could not realize that mechanical art had improved to the extent that it was possible to make gears good enough so that a rack and pinion feed could be used in a machine without "the teeth showing the work," or that bevel gears could be made to run as well and be as good every way as spur gears, and so he naturally clung also to the old idea of millwright days, that one gear of a pair must have a "hunting tooth." Thus do some people refuse to be "dragged from the altars

of their forefathers," and thus was Bughouse put in a position to astonish his friends. * * * * *

It never was quite clear to me why Bughouse clung so tenaciously to the old exploded ideas, but it may be because he was over "fifty." I was told not long ago by a gentleman who is an eminent authority on *some* subjects, from which *some* people, including Bughouse, would argue that he must necessarily be also an eminent authority on *all other* subjects, that "men over fifty do not progress," but here is what is puzzling me: this eminent authority is himself "over fifty," and if he is right, men "over fifty" do *not* progress, and if they don't, *he*, being "over fifty" must be *wrong*: therefore men over fifty *do* progress, and it follows that—well, anyhow, it is evident that it is a perplexing subject, and the more you study it the more you don't find out, but all this is neither yonder nor here, as Bughouse used to call the New York & New Haven Railroad. * * * *

Bughouse started up his engine. She turned over nicely a few times, and then began to hesitate a little going by the quarter. Then instead of going by she stopped just before she got there, and came back the other way almost to the quarter, then back again, but not so near to the quarter this time, and so on, less and less, until she reversed the whole thing and started up the other way and finally made a few turns backwards.

Bughouse always said that when he made his engine he would drive the valve by gears, *because gears had more power*

"You must have a hunting tooth."

than anything else (and I have heard truly mechanical engineers say the same about gears)—so he did as he always said he would do, *and had put a "hunting tooth" in one of the gears.* * * * * * *

These peculiar motions, while they might be all right for a washing machine or a cock grinder, were no good for an engine; and this is about the way some things are "invented." A man tries to invent a peanut roaster, and when he gets it done finds it will make a much better ice cream freezer, and so calls the world to witness what a great ice cream freezer inventor he is!

I know, because I am an inventor myself.

* * * * * *

This is the first story I have ever written where the moral could not easily be seen without the aid of X-rays, but the moral of this one does not seem to be clear, probably because I am myself "over fifty," so I will need to add the only moral I can think of: *Don't have any birthdays after you are forty-nine.*"

* * *

About 35,000 American automobiles were manufactured in 1906 and it is expected that this number will be greatly exceeded in 1907, it being estimated that 45,000 cars will be manufactured to supply the enormous demand.

PERSPECTIVE VS. OBLIQUE PROJECTIONS.

FREDERIC R. HONEY.

Frederic R. Honey.

When the study of linear perspective is omitted in a course of instruction in industrial drawing, it is for the reason that it is dispensable in practical work. A knowledge of perspective is essential to the artist, however, because his work always includes the representation of objects as they appear, as distinguished from their representation in their true dimensions, which is specifically the province of the mechanical draftsman. Then, again, a knowledge of perspective is regarded as involving a considerable familiarity with complicated constructions which have no direct bearing on the work of the draftsman.

As a consequence, when it becomes necessary to represent an object pictorially, to convey to the ordinary observer a knowledge of its general form and proportions, one of the systems of oblique or of isometric projection is employed. This kind of projection is frequently introduced in drawings accompanying the specifications of patents but gives a more or less distorted view of the object.

The principle of the oblique projection is illustrated in Fig. 1. Let *abcd* represent a plane or a sheet of drawing paper. Let EF be a perpendicular line piercing the plane at F. If any oblique line be drawn from E to this plane, piercing it at e, e_1, e_2 or e_3, and this point be joined with F, any one of the lines Fe, Fe_1, Fe_2 or Fe_3 is an oblique projection of EF. The line Ee, Ee_1, Ee_2 or Ee_3 may be situated in any direction, and may form any assigned angle with the plane. That is, a perpendicular line may be represented in any direction, and may be made as long or as short as we please.

A very convenient system, and the one which the writer usually adopts, is the following: From Fig. 1 we see that all lines situated in the plane of the paper are shown in their true length and relative positions. The same is true of all lines in any plane parallel to the plane of the paper.

If we draw all lines which are perpendicular to the paper, at an angle of 45 degrees, and make them one-half of their length in space, we obtain a very simple and easily recognized representation of the object.

Let the square *abcd*, Fig. 2, represent a face of a cube in coincidence with the plane of the paper. Draw the 45-degree lines, *ae*, *bf*, *cg* and *dh*, each equal to one-half the edge of the cube, and complete the square *efgh*. The face of the cube which coincides with, and the one which is parallel to the plane of the paper, are shown in their true value.

The same will evidently be true of the cylinder, Fig. 3, as one base coincides with the paper. The 45-degree line *ab* drawn from the center *a* making *ab* equal to one-half the length of the cylinder, determines the center of the base parallel to the paper; and the figure is completed by the 45-degree lines tangent to the circles.

If we wish to represent a hollow cylinder or tube, the thickness of the material is shown in its true dimensions, and the circles described from *a* and *b* as centers complete the projection. If these figures be drawn on a large scale, the distortion would be very marked and the superiority of the perspective drawings, Figs. 4 and 5, is apparent.

Let the square *abcd*, Fig. 4, represent one face of the cube. Assume S any convenient point above the cube, and draw SD parallel to *ab*, making it equal to the distance from the eye of the observer to the paper. This measurement will fall beyond the limits of the paper as indicated by the arrow. We assume for the moment that it is accessible.

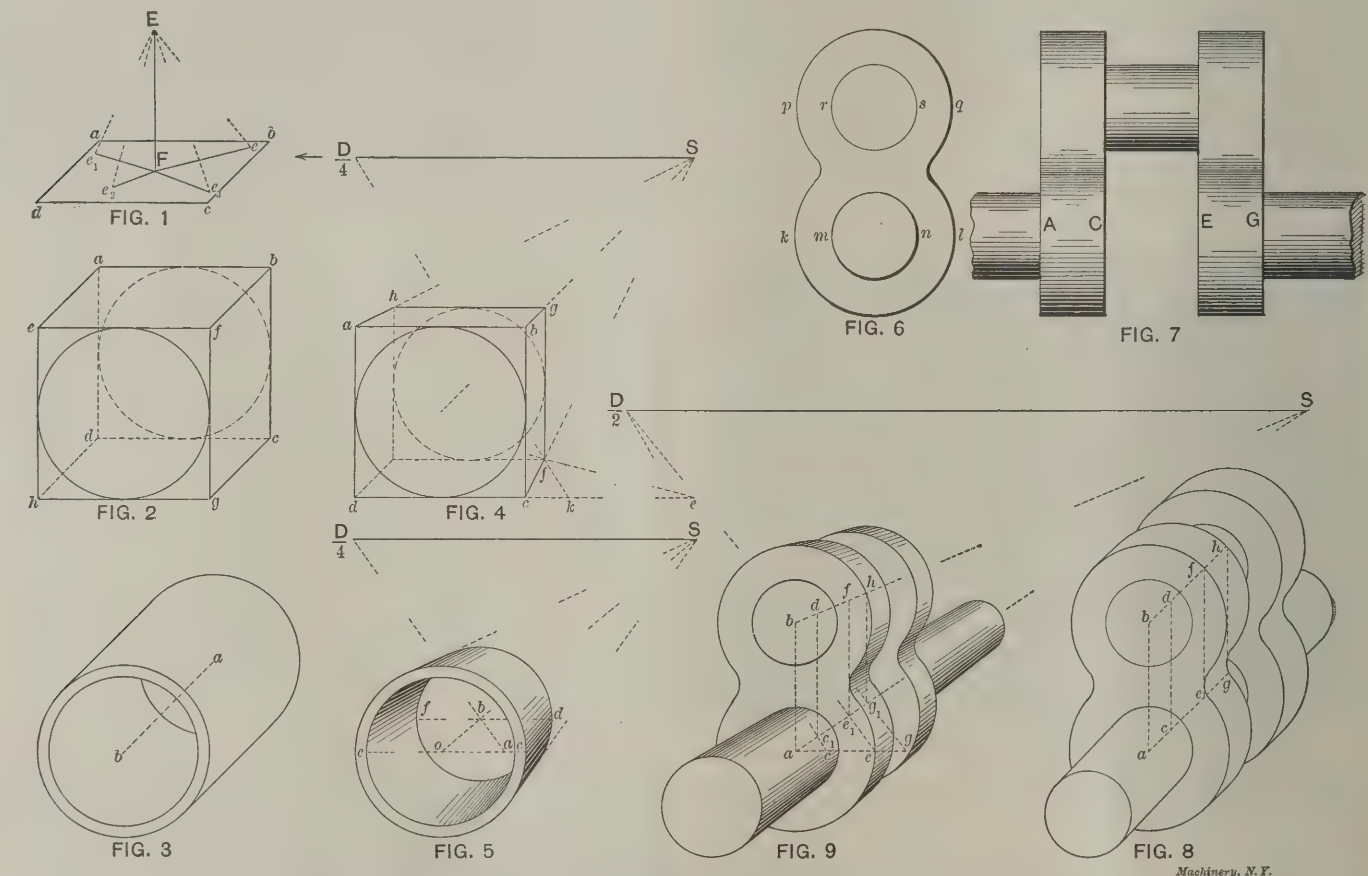
FREDERICK R. HONEY was born in London, England. He was a student at the school of Science and Art, South Kensington, London, and served an apprenticeship with Ravenhill & Co., marine engineers, London. At one time he had a position under the British Government at the Bombay Dock Yard, East Indies, and was afterward chief engineer of a steamer owned by a Parsee firm plying on the west coast of India. He is an instructor in the Sheffield Scientific School, and lecturer in the Yale School of Fine Arts and in the Art School, Smith College. Mr. Honey has been a well-known contributor to various technical publications for many years.

From a, b, c and d draw lines to S. Produce dc to e making $ce = cd$. From e draw a line to D (off the paper), intersecting cS at f. Draw the perpendicular fg and the horizontal gh, completing the perspective of the solid which is a correct perspective drawing, and which will satisfy the eye if it be placed at a distance from the paper equal to the measurement SD.

In order to bring the construction wholly within the limits of the drawing, we may mark on the line drawn from S any fractional part of the distance to D, as for example, one-fourth to $\frac{D}{4}$. If we lay off ck one-fourth of dc and draw a line from k to $\frac{D}{4}$ we obtain f, the same intersection as before. Any fraction of the distance may be laid off on SD provided the same fraction is employed on dc produced.

The height of the horizon or the level of the eye is assumed by the draftsman. S represents the point opposite the eye, or of representing an object as compared with oblique projection, we take as an example a portion of a built-up crankshaft such as is used in the most powerful reciprocating engines of our large steamships. The proportions in Figs. 6 and 7 showing two views of the crankshaft are in accordance with the best practice, and are taken from "Machine Design," by Low and Bevis. Fig. 8 is an oblique projection reduced to an assigned scale. The distance between the axes of the shaft and pin are laid off on a perpendicular from a to b. From each of these points 45-degree lines are drawn on which are laid off one-half of the measurement corresponding to those which are found in Fig. 7.

Thus $ac = bd =$ one-half of AC; $ce = df =$ one-half of CE; and $eg = fh =$ one-half of EG. From each of the centers a, c, e and g, draw two circles whose diameters are equal to kl and mn, Fig. 6. From each of the centers b, d, f and h, draw two circles whose diameters are equal to pq and rs. Connect the eye of the crankpin with that of the shaft by arcs which correspond with those of Fig. 6. The outline of Fig. 6 is repeated four times, and then 45-degree tangents showing visible lines, are drawn completing the oblique projection.



Principles and Practice of Perspective Drawing. Note the Distortion in Oblique Projections.

its projection on the paper. Its distance on the right or the left of the object is also assumed. These measurements evidently affect the apparent outline of the figure. They are selected at distances calculated to produce a satisfactory perspective drawing, *i. e.*, one which will exhibit the required details clearly. The draftsman should be careful not to make the distance from S to D too short, which would result in "steep perspective."

The application of the construction in drawing a cylinder, Fig. 5, is very simple. From o, the center of the circle, draw the horizontal line oa equal to one-fourth of the length of the cylinder.

A line drawn from a to $\frac{D}{4}$ intersects oS at b, the center of the other base. Draw bd parallel to oa. A line drawn from c to S intersects bd at d. With the radius bd draw the circle representing the other base. Tangents to the two circles drawn to S complete the outline of the figure. The drawing is completed by the circles representing the hole, the radii of which are, respectively, oe and bf.

To illustrate the use to which perspective may be put in practical work, and to indicate the superiority of this method

The perspective, Fig. 9, is drawn as follows: Draw the perpendicular ab equal to the distance between the centers of the circles, Fig. 6, and copy the end view. Assume a horizontal line $S\frac{D}{2}$ equal to one-half the distance from the eye to the paper, at any convenient distance above the figure. From a and b draw lines to S. From a draw the horizontal line ag, and lay off $ac = \frac{AC}{2}$ (Fig. 7); $ce = \frac{CE}{2}$, and $eg = \frac{EG}{2}$. From the points c, e and g draw lines to $\frac{D}{2}$, intersecting aS at c_1, e_1 and g_1. From these points draw perpendiculars intersecting bS at d, f and h. From S draw tangents to the circles representing the eyes of the pin and shaft. Perpendiculars from d, f and h drawn to one tangent; and perpendiculars from c_1, e_1 and g_1 to the other tangent, will give the radii of the remaining circles, and the draftsman will readily complete the perspective.

LETTERS UPON PRACTICAL SUBJECTS.

ANCHOR PLATES FOR FOUNDATION BOLTS.

I show herewith sketches of two styles of anchor plates. At the shop where I am employed we had been using the anchor plate shown in Fig. 1 with a square head bolt. We had to rearrange our machinery, placing much of it upon new foundations, and rather than dig out the old plates and bolts we sawed the bolts off with a hack-saw even with the floor line.

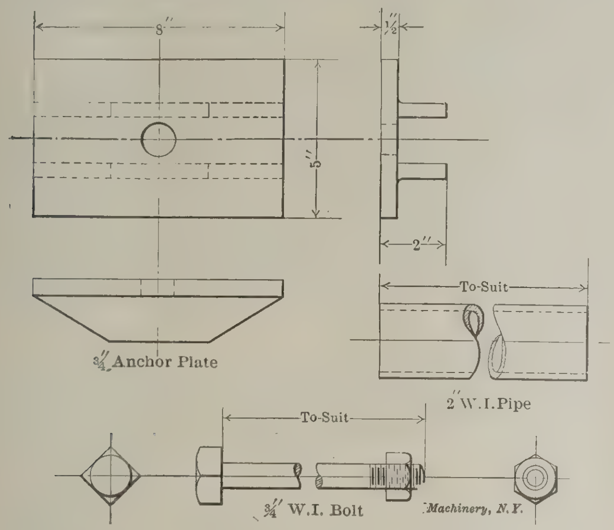


Fig. 1. Old Style Anchor Plate for Square Head Bolt.

In setting up the new foundations the bolts would in some cases be too long and in places too short after the floor was leveled. To overcome this difficulty the bolt and plate shown in Fig. 2 were designed. With this bolt a square nut is set on the little shelf, shown by the section lining, where the projecting ledge at each side holds it in place. A straight rod threaded on both ends is screwed into it. The ring on top of the plate keeps the pipe centered around the bolt while the cement or grouting is being poured. When the bolt is short all that is necessary to do is to cut off a new rod of the required length, thread it, and place it in the pipe, where it may be screwed into the nut, which is so securely enclosed that it cannot be lost. When the machinery is moved the bolt can be taken out and used in the new foundation. E. C. F.

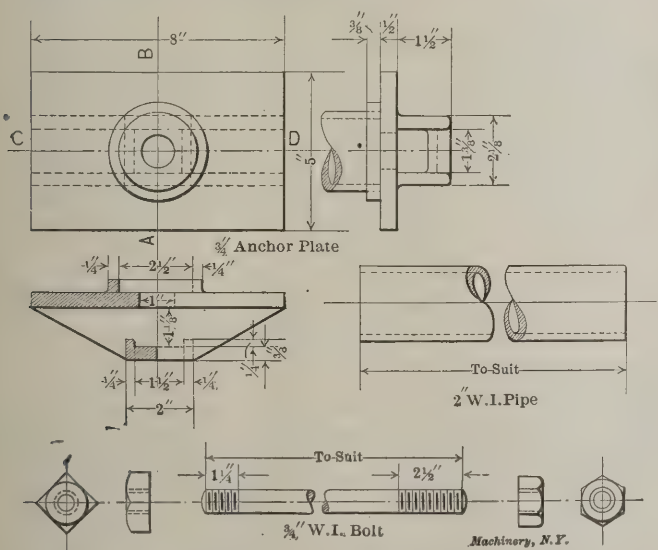

Fig. 2. Improved Anchor Plate for Square Nut and Threaded Rod.

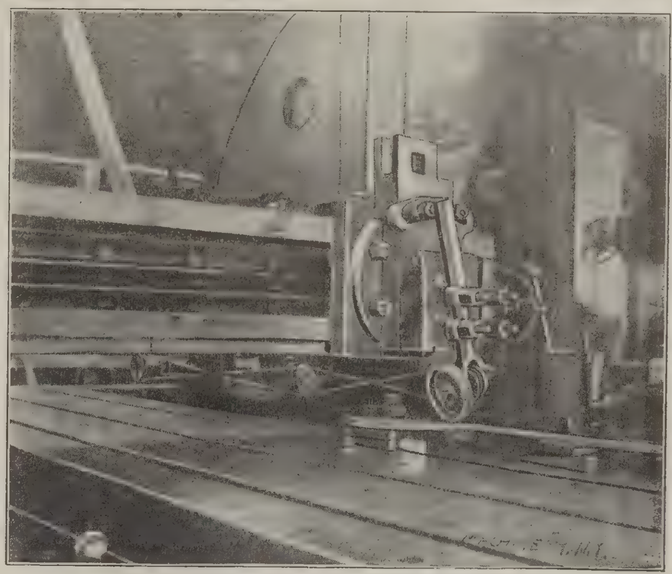
THE PROPER METHOD OF MAKING SURFACE PLATES.

In order to have straight and true beds and platens on the machine tools manufactured to-day, it is essential to have good surface plates to scrape them in by. There has long existed an erroneous idea as to how to make a good surface plate. Some contend that a good proof staff or surface plate can be made by scraping in two plates together, until they show a good bearing. This is not right. A proof staff made after such a fashion is not necessarily true. Inaccuracies in the one plate will often be concealed by corresponding inaccuracies in the other. The proper way to obtain a good surface plate or proof staff is to have three plates carefully planed up and then worked with as follows, numbering the plates one, two and three. First, fit No. 3 and No. 2 to No. 1; you have now No. 2 and No. 3 alike; second, fit No. 2 and No. 3 by scraping as much on one plate as the other; third, fit again No. 1 to No. 2; fourth, fit again No. 3 to No. 1; fifth, fit No. 2 to No. 3 together by scraping as much on one plate as the other. Continue this procedure carefully until No. 1 will fit No. 2 and No. 3, and No. 2 will fit No. 1 and No. 3. You have now three plates that are accurate and which can be relied upon. Having three good plates, one can be laid aside as a guide to be used only for testing the other plates at frequent intervals, while the other plates can be used in active service. J. J. JENKINS.

SURFACE GRINDING ON THE PLANER.

The accompanying cut shows a surface-grinding job done on the planer. The work seen strapped on the bed is one jaw of the guide for an endless steel knife, which runs over pulleys exactly as does a band saw, and is kept perfectly straight on the tangents by these guides. The latter are made of cast iron, faced with hardened steel, and have to be trued up every few months because of the constant motion of the knife. To do this with a tool was out of the question, so our foreman, Mr. S. F. Cronk, solved the problem with the outfit shown, constructed entirely from odds and ends. In the toolpost of the planer is secured the shank of the holder for a small grinding wheel spindle and on the rear of the housing is clamped a jack-shaft having a grooved pulley at one end and a flanged pulley at the other. This shaft is driven by a one-inch belt, which can be seen inside the reverse belt and which passes over the large pulley on the countershaft. The round belt shown under the cross-rail drives the grinding wheel spindle from the jack-shaft. The cutting is done by the body of the cup-shaped wheels which have served their usefulness on the cutter grinder. As can be seen, the photograph was taken about on the level of the planer bed, the machine itself being a 15-foot New Haven planer with clutch drive.



Surface Grinding on the Planer.

Middletown, N. Y. DONALD A. HAMPSON.

ANOTHER MATHEMATICAL "PROOF."

Having realized that my attempt to disprove Euclid was met with stern opposition, and that the readers of MACHINERY bestowed upon me ridicule rather than compassion, which lat-

ter would probably have been a more properly selected sentiment in the case, I have promised myself not to try to aspire to scientific honors in the realms of geometry; this, however, does not say that I am going to "give up," but simply that I intend to switch over to a more congenial territory. The laws of geometry are evidently a little too rigid to be tampered with; but by means of algebra one can prove almost anything. While the readers of MACHINERY did not favorably accept of my "proof" that a right angle equals one that is larger than a right angle, there may be some difference of opinion as to the fundamental principles of algebra if I can prove that 1 equals 2 by the use of simple algebraic operations. Assume that

$$a = b.$$

Multiply both terms with a, in which case

$$a^2 = ab.$$

Subtract from both terms b^2. The remainders are then equal:

$$a^2 - b^2 = ab - b^2.$$

This expression can be written in the form

$$(a + b)\ (a - b) = b(a - b).$$

Divide both members with $a - b$; the quotients are then equal:

$$\frac{(a + b)\ (a - b)}{a - b} = \frac{b(a - b)}{a - b}.$$

Carrying out the division we have

$$a + b = b.$$

But a is assumed equal to b. Thus

$$b + b = b, \text{ or } 2b = b.$$

Divide both terms with b and we have

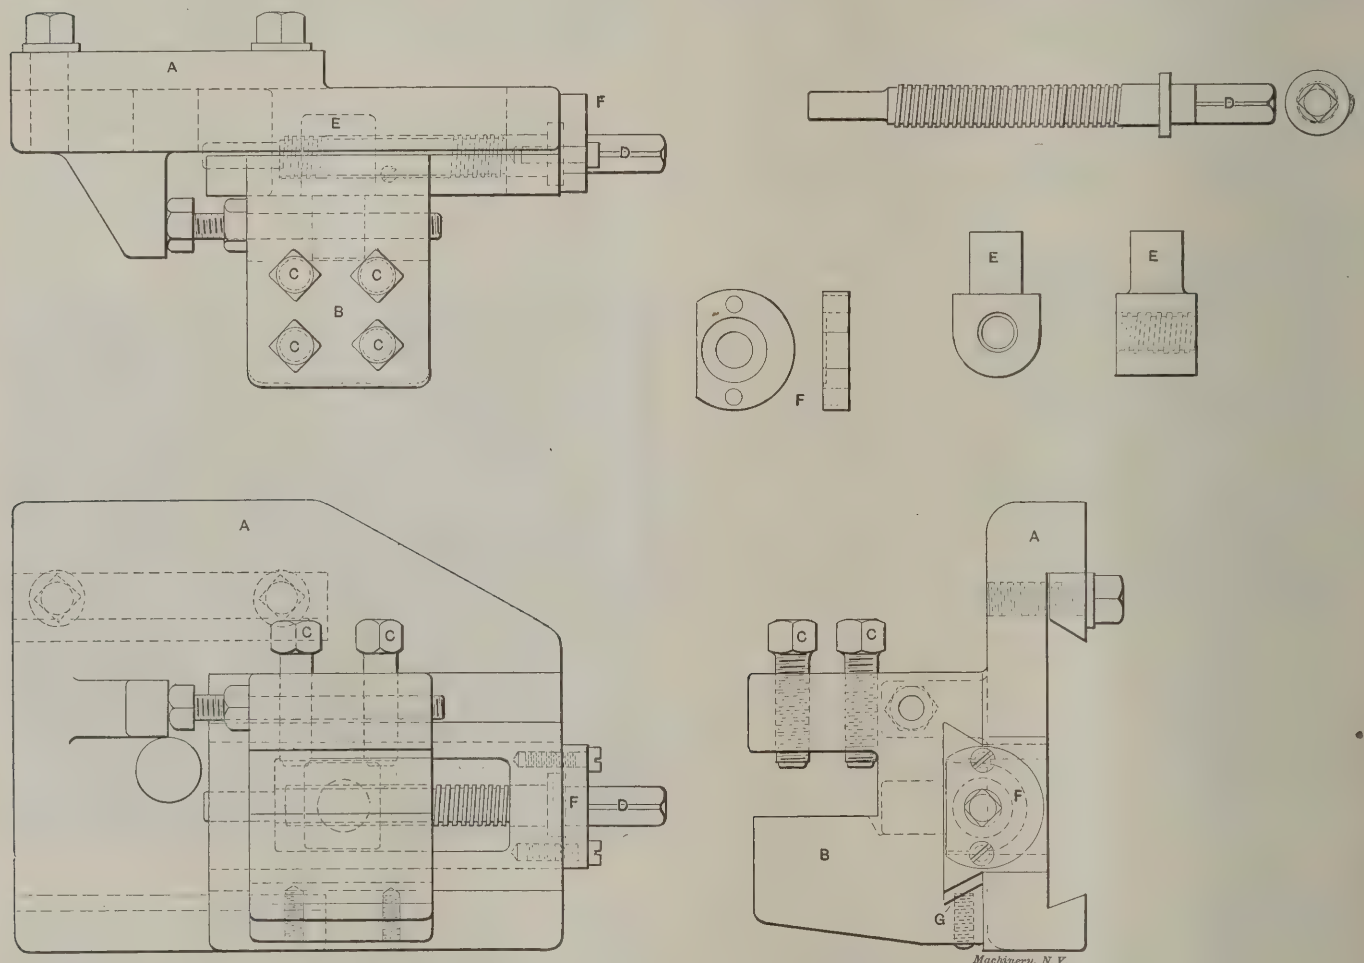
$$2 = 1.$$

Whoever invented the algebraic operations made use of is not known, but the honor is supposed to belong to an Arab whose name is not preserved to posterity. Perhaps that makes it safer to question his methods than in the case of Euclid. I promise I shall never attack his conclusions any more. But, by the way, I have a scheme of perpetual motion which is not yet patented. Any person with sufficient capital for exploitation may have it for the asking. R. S.

TOOL-HOLDER FOR CHUCKING IN THE SCREW MACHINE.

The accompanying cut shows a tool used in connection with chucking work on a 2-inch screw machine designed for machining round bar stock only. On this machine, when it was necessary to use a chuck to hold pieces, the cross-slide of the machine was thrown out of service, both on account of the large swing of the chuck body and the short length of the longitudinal feed screw of the machine. Moreover, the capacity of the regular box tools in the turret was but 2¼ inches. For these reasons the following fixture was designed.

Referring to the cut, *A* represents a steel casting which fits on the turret of the machine. The tool carrier, *B*, which is a steel forging, finished all over, is provided with four set-screws, *C*, and receives its feed from the square-threaded screw *D*, which in turn is operated by an ordinary crank. By using four clamping screws for holding the tools, it becomes possible to do both end and side forming, facing and turning. The feed screw *D* is a running fit in the bronze nut *E*, allow-



Tool-Holder for Chucking in the Screw Machine.

ing the feed screw to bear on the ends alone, thereby preventing binding or locking. The end thrust of the screw is taken up by the collar *F*, which is held by two fillister head screws. By placing the adjustable gib *G* on the under side, an easy travel is secured for the tool carrier when in operation. The work performed consists mostly of small special castings varying in diameter from one to seven inches. In this manner the fixture becomes universal to a great extent, and is rendered particularly valuable on account of the shop lacking a turret lathe designed for chucking rather than for plain screw machine work. W. T. M.

"URGE ORDER" SYSTEM.

The cut herewith shows a card of an "Urge Order" system used by The R. K. Le Blond Machine Tool Co. for getting out rush parts, or pieces that are urgently needed for completing a lot of machines. This is not an integral part of the regular shop system but is supplementary to it, and used only for those pieces which have preference over all other work com-

ing through the shop, and for this purpose it has proved very effective. It is the custom to gather all the machine parts, screws, etc., needed to erect a lot of machines several weeks before they are to be erected upon trucks in the stock room to be delivered into the shop when needed. It frequently occurs that some parts that are wanted are not on hand in the stock room at this time, and the object of the system is to get

Cause of Delay?

C Johnson Foreman

"Urge" Orders of the R. K. Le Blond Machine Tool Company.

these through at once. On these parts work is usually already commenced in the shops, and they are in some partial state of completion.

The number of parts needed is stated on the urge order with the name or mark of the pieces. The order or card is taken to the foreman in whose department the work is. The foreman fills in the date when he will deliver same to the next department and signs his name. If for some cause he cannot promise a delivery owing to the lack of some tool, jig, etc., that he might be waiting for, he indicates this reason on the card. The card is then returned to the superintendent's office, inspected and filed in a dated card index. This index is the usual kind used for similar purposes and has tab cards numbered from 1 to 31. The cards are received daily, and on the day marked on the card it is checked and taken with the work to the next department, to be again dated and signed by the foreman. This is continued until the work is delivered to the stock room. As will be seen, this forms a record of all promises made by the foreman and keeps a constant check on the work until it is finished. W. G.

JIG FOR PLANING CONNECTING-ROD BRASSES.

Having at different times derived ideas from other jig and tool designers, I hereby submit drawings and description of a jig designed this last summer with the hope that someone may derive an idea from it. The pieces to be milled were connecting rod brasses for Corliss engines from 30 x 36 inches down to 10 x 12 inches; two different sizes of this jig were sufficient for all.

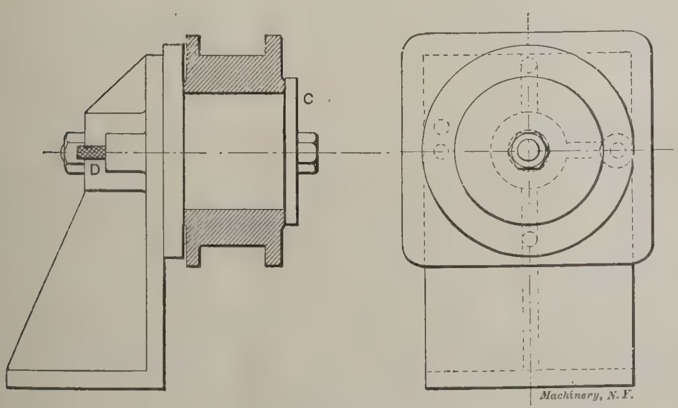

Fig. 1. Jig with Work in Place.

The jig consists mainly of two pieces, as shown in Fig. 2, the angle plate and the revolving faceplate. The jig is so arranged that all four sides, one of which is planed for a wedge, could be milled at one setting by simply turning the faceplate until the index pin engaged in the proper hole. The hole off center is for locating the proper angle when milling the wedged side. The angle plate *A* is made quite stiff, because it has to take the entire cutting strain, without springing to any extent. The faceplate *B* is finished all over. The hole in the center for the studs for holding faceplate and work in position was drilled in the lathe to insure accuracy. It had been our great trouble in the past that we could not with the cheap labor we use, get our work milled square with the bore, which necessitated a lot of filing and chipping. The washer *C*, Fig. 1, is used for locking plate after swinging

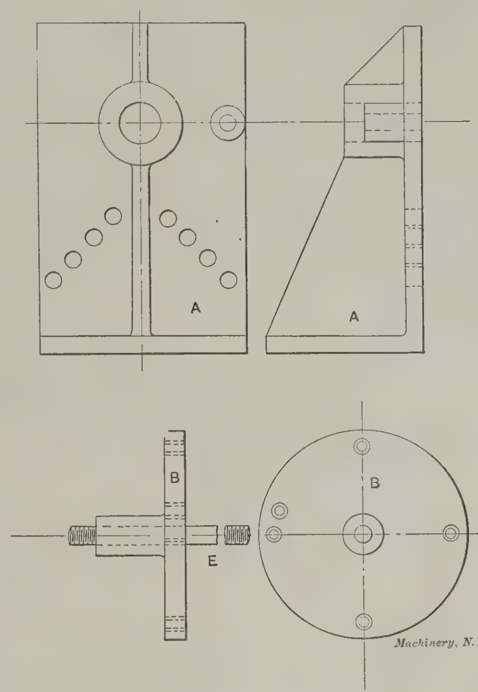

Fig. 2. Details of Jig.,

into position and engaging index pin *D*. The holes into which the index pin engages are bushed with taper bushings, made of tool steel and hardened and lapped to fit. The work is centered on bushings the same size as the pin on which the brasses are to run. This enables the operator, by squaring one side, to chuck his work accurately, and all work done is interchangeable. The eight holes drilled diagonal in the angle plate are for the purpose of putting stops to hold the work after it is clamped in position as an additional precaution against slipping. Of course this jig can be improved upon, but at present it is doing the work for which it was designed, doing it better and in one-third of the time of the old way, *i. e.*, using special parallels. R. G. D.

THE STRENGTH OF A MOUTHPIECE RING AND COVER.

In relation to the above article in the November issue (Engineering Edition, page 119) I wish to call attention to a part of a mouthpiece ring which sometimes has proven out to be designed too weak, referring to the danger of failure of the flange at the corner of the gasket groove. I notice, in the article referred to, the words: "The possibility of this would be a rather difficult thing to calculate with assurance, but good judgment would seem to indicate that the casting is none too strong at this point." I think the manner of figuring the strength at this point, which I present, will be of value to those interested in the design of such vessels.

At the left of the cut is shown the ring as suggested. The load ($L + N\ E$, see the article) is acting with a certain bending moment on the flange of the bolt circle, and trying to break it in the cylindrical area whose height is h and whose length is $2\ \pi\ r$, as shown in the right-hand figure, which is a plane development of the circumference of the ring. Considering the action as being that of a cantilever whose length l is 2 inches, breadth $b = 2\ \pi\ r = 166.5$ inches, and whose depth $= h = 1\frac{1}{2}$ inch. We may obtain the extreme fiber stress as follows:

$$\text{Bending moment} = (L + N\,E)\,l$$

$$\text{Resisting moment} = S\,Z = \frac{S\,b\,h^2}{6}$$

$$(L + N E)\, l = \frac{S\, b\, h^2}{6}$$

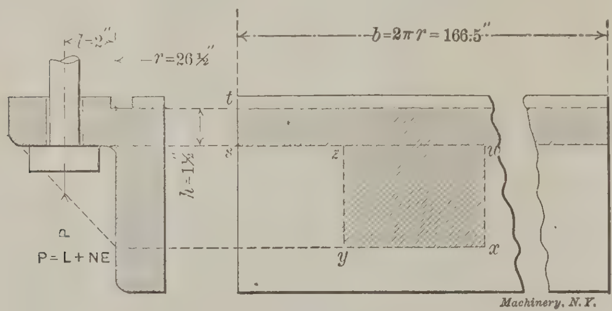
$$S = \frac{6\, l\, (L + N E)}{b\, h^2}$$

$$S = \frac{12\,(126{,}000 + 24 \times 1{,}200)}{166.5 \times 1.5^2} = 4{,}950 \text{ pounds per square in.}$$

The result of this calculation shows that the factor of safety for the flange is smaller than 5, so that it would be advisable to increase the thickness of the flange to give sufficient strength. An increase of thickness to 2¼ inches gives a unit stress of 3,640 pounds, an amount well within reasonable limits. Instead of increasing the thickness, however, flange ribs, as shown in the dotted lines in the cut, could be provided for getting a higher strength. The development in this case will give two rectangles, the upper one, $s\ t\ u\ v$, being as before, while the lower one, $w\ x\ y\ z$, has a length $y\ x$ equivalent to the total thickness of all the ribs used. Obtaining the moment of resistance of figure $s\ t\ u\ v\ w\ x\ y\ z$, the unit stress will easily be found. HERMAN GUMPEL.

Belleview, Pa.

[In calculating the strength of the flange in this manner the stress would be slightly higher even than is indicated by our contributor's figures, since he uses too small a load $(L + NE)$, as N should be 36 instead of 24. We made, at the time the article was written, a rough calculation after the manner suggested, carrying it far enough to show that the original design was weak in this respect. We believe,



Finding the Strength of a Flange.

however, that the actual stresses would be somewhat less than would be indicated by a simple solution of this kind. The tendency to bend is resisted, not only by the deformation of the fiber when the section is considered as a beam, but also by the compression of the outer fibers of the flange the moment any bending takes place. We agree with our contributor, however, that the construction is none too strong at the point in question and it could be improved by thickening the flange or by adding ribs. The value of ribbing in a casting of this sort, on general principles, is shown in Prof. Benjamin's article on the bursting strength of cast-iron cylinders in MACHINERY, Engineering Edition, November, 1905.—EDITOR.]

THREADING TOOLS AND THREAD GAGES.

E. A. Johnson.

Of all tool-makers who are employed in the manufacture of taps and dies, there are but few outside of the shops where standard thread plugs and templets are made for the trade who understand how to produce an accurate thread. By an accurate thread I do not mean a precision screw, but a thread which, while a commercial possibility, will measure within a fraction of a thousandth inch of being theoretically correct. It is probably cheaper in a majority of cases to buy gages rather than to make them, but many shops prefer to make their own, especially where the pitch is not standard. In such shops, when a new gage is to be made, the work is usually intrusted to a man who has the reputation of being a "crack-a-jack" at thread cutting, though he may not have the first idea as to what his gage really measures when finished. For such cases the following is intended as a guidance.

The chief requisites for cutting a correct thread are correct threading tools, a correct setting of the tool, and a lathe with a reasonably accurate leadscrew. In making the thread tool a correct 60 degree angle gage is necessary. To produce such a gage first plane up a piece of steel in the shape of an

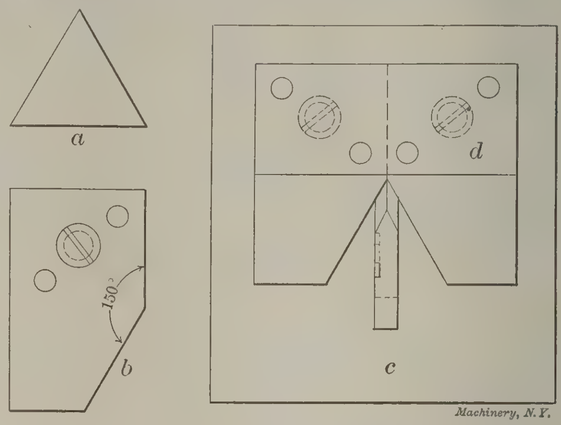


Fig. 1. Gages for making Threading Tools.

equilateral triangle as shown at a in Fig. 1. After hardening this triangle, grind and lap the edges until the three corner angles prove to be exactly alike when measured with a protractor. This is now the master gage. To produce the female gage make two pieces, one right hand and one left, like that shown at b in Fig. 1; harden them and lap the edges that form the 150 degree angle so that they are straight, and square with both sides. When this is done the two pieces should be screwed, and doweled to a backing plate d as shown in Fig. 1, using the master triangle to locate them, thus producing a practically perfect female gage.

In making up the tool some form of cutter to be used in a holder should be chosen in preference to a forged tool on account of convenience in handling and measuring and the feasibility with which it may be re-ground without destroying

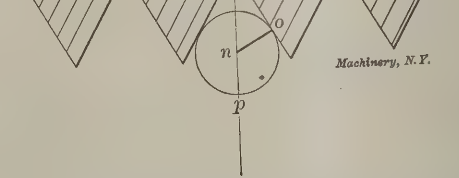

Fig. 2. Measuring the Angle Diameter of a Thread.

the shape. The tool should be made so that the top will stand level when in the holder and the clearance should be about 15 degrees, which is ample for a single thread unless the pitch is very coarse. With that amount of clearance the included angle between the sides of the tool in a plane perpendicular to the front edge is approximately 61° 44′. The tool should be planed to that angle as nearly as is possible by measuring with a protractor, then, to test its accuracy, it should be placed top down on a flat piece of glass c and tried with the 60 degree gage as shown in Fig. 1. After lapping the tool until it shuts out the light when tried in this manner, the angle may be considered as nearly correct as is possible to obtain with ordinary means. To adapt the V-thread tool thus made to cut the United States standard form of thread, it is only necessary to grind off the sharp edge an

EUGENE A. JOHNSON was born in Michigan, 1872. He served his apprenticeship with A. F. Bartlett & Co., Saginaw, Mich., and afterward worked for the P. M. R. R., Mitts & Merrill, Veeder Mfg. Co., A. B. Dick & Co., Illinois Sewing Machine Co. and others. At present he is assistant foreman in the screw machine equipment department of the Pratt & Whitney Co.

amount equal to one-eighth of the depth of a V-thread of the required pitch, or for 20 threads per inch $\frac{0.866}{20} \times \frac{1}{8} = 0.0054$ inch. To test the accuracy of this grinding a piece of steel should be turned up to the correct outside diameter and a short shoulder turned down at the end to the correct diameter of the bottom of the thread; then the piece is threaded and the tool fed in until the flat of the tool just tangents the shoulder. Then cut a nick in the edge of a piece of sheet steel with the threading tool. This sheet steel piece is now applied like a gage to the threaded cylindrical piece. If the nick in the sheet steel fits the thread so that it shuts out the light the flat of the tool is correct.

In preparing a plug gage for threading it should be made the same as the cylindrical test piece above with a part turned down to the root diameter of the thread except that for V-thread it is customary to leave the shoulder 0.005 inch large on account of the impossibility of producing a perfectly sharp point on the tool. The thread tool should be set level, with the top at the same height as the center line of the spindle of the lathe, otherwise the correct angle will not be reproduced. After a master plug has once been produced, it is not necessary to turn down a portion to the root diameter of the thread as the work can be compared with the master plug by means of a micrometer fitted with either ball or V points for measuring in the angle of the thread.

It occasionally happens that a tap is to be threaded, or other external threading is to be done, of an odd size or pitch where it is desired to originate a master plug. In such cases the writer uses three wires for measuring the angle of the thread, placing one wire in the angle of the thread on one side of the piece and the other two on the opposite side, one on each side of the corresponding thread, measuring over the whole with a micrometer. The formula for the micrometer reading is obtained as follows: In Fig. 2 assume that m is the bottom of a V-thread, the circle showing one wire in place. Then angle $a = 30$ degrees; sin 30 deg. $= 0.5$; $\frac{no}{0.5} = mn$ or $2no = mn$. As no and np are radii of the same circle, it follows that $mp = 3no = 1\frac{1}{2} \times$ diameter of wire. Multiplying by two to add a length mp for the opposite side gives $2mp = 3 \times$ diameter of wire. Hence for V-thread,

$$\text{Dia. of screw} - \frac{1{,}732}{\text{No. thds. per in.}} + (3 \times \text{dia. of wire used})$$

$=$ micrometer reading.

For U. S. form we have to take into account the flat at the bottom of the thread, so instead of using the U. S. constant 1.299 we add to it $\frac{1}{8}$ of 1.732 or 0.2165 giving as a constant 1.5155, making the formula:

$$\text{Dia. of screw} - \frac{1.5155}{\text{No. thds. per in.}} + (3 \times \text{dia. of wire used})$$

$=$ micrometer reading.

E. A. Johnson.

Hartford, Conn.

[The subject of measuring threads with the wire system was treated at length in Machinery, January, 1904, in an article by Joseph M. Stabel entitled "Measuring External Thread Diameters."—Editor.]

DRAWING TABLE FOR A TECHNICAL SCHOOL DRAFTING ROOM.

F. H. Sibley.

Following is a description of a drafting table that is giving first-rate satisfaction for college drawing room work. Its advantages are strength, compactness and the utilization of what would otherwise be wasted space beneath the tables. The table was designed for the drafting room of the mechanical department at the Case School of Applied Science, and has been in use for about two years. Conditions here made it necessary to construct a cabinet table containing drawers for instruments and lockers for boards and T squares. As several squads of men have to be accommodated at different periods, at the same set of tables, these tables had to be designed so as to discourage the tendency on the part of some students to "swipe" their neighbors' instruments and drawings, and at the same time allow a number of men to use the same desk.

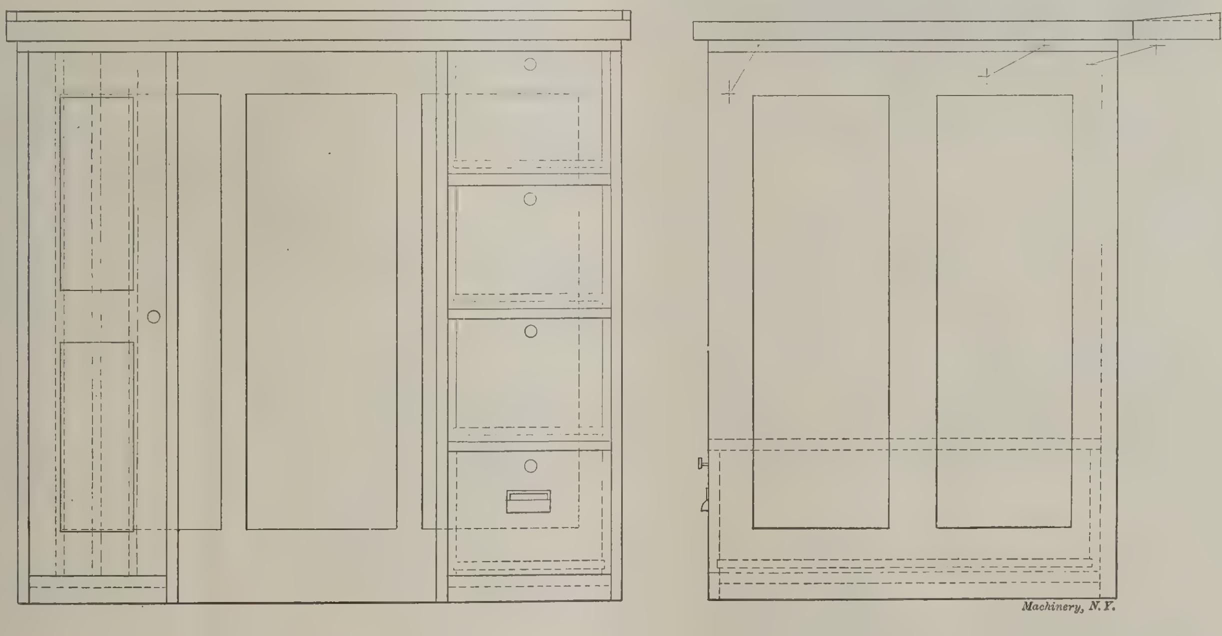

Fig. 1. Front and Side Elevation of Student's Drawing Cabinet Table.

The halftone, Fig. 2, shows the cabinet which has four instrument drawers on the right-hand, and a cupboard on the left-hand side, the latter containing four spaces for boards and T squares. The drawers and cupboard are fitted with combination locks, so that each student has access to one instrument drawer and four boards. Two views of the table are shown in Fig. 1. Its dimensions are 3 feet 5 inches long by 2 feet 3 inches wide and 3 feet 3 inches high to the top of the board when in the horizontal position. The material in the cabinet part is $\frac{7}{8}$ inch oak lumber stained a dark color and varnished. The panels in the back and at the ends are $\frac{1}{2}$ inch oak.

F. H. Sibley was born in North Oxford, Mass., 1872. He was educated in Brown University and Case School of Applied Science. He served a shop apprenticeship in Worcester, Mass., and has worked for the city of Providence, Geo. Lawley & Son Corporation, Westinghouse Switch & Signal Co., West Shore & Michigan Southern R. R. in the capacity of assistant engineer, draftsman, calculator, etc. He is at present instructor in machine design in the Case School of Applied Science, Cleveland, Ohio.

The instrument drawers are 7 inches deep, 10 inches wide and 2 feet 1 inch long. They are made of soft wood ½ inch thick, except the front, which is of ⅞ inch oak. Besides the lock already mentioned each drawer has a pull with a slot in it for the occupant's name. A stop is fastened to the bottom so that the drawer cannot be entirely removed from its place. This prevents any one from getting at the instruments in the drawer underneath. The board locker is 10 inches wide and extends nearly the whole height of the table. The four board spaces are each 2 inches wide, separated by ½-inch vertical slats. The door is of ⅞-inch oak with ½-inch panels and is hinged on the left-hand side so that it swings clear of the worker's knees. The space between the locker and the tier of drawers is 17 inches wide, allowing ample

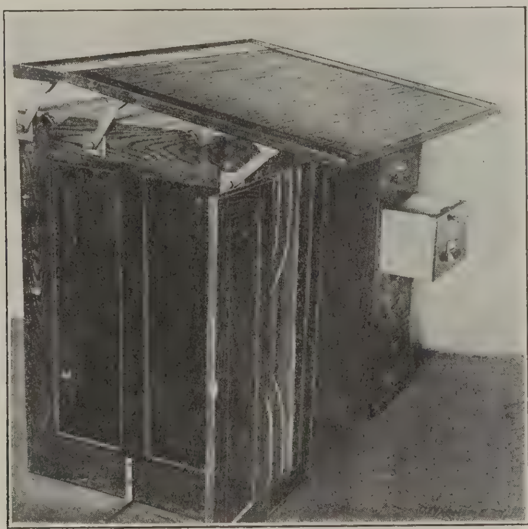

Fig. 2. Drawing Table used in Case School of Applied Science, Cleveland, Ohio.

room to work sitting at the table. A foot rest made of 1-inch gas pipe is to be placed across this space about 6 inches above the floor.

The cabinet is fastened to the floor with two malleable iron brackets and screws. Its top is of soft wood ⅞ inch thick and above it is an adjustable drawing board mounted on iron links. This board is made of butternut wood 1 inch thick. Its dimensions are 3 feet 8 inches by 2 feet 6 inches, and it has strips 3 inches wide jointed to each end to prevent warping. Fastened to the back of the board with 4-inch strap hinges is a leaf with a flange around it for holding instruments and ink bottles. The leaf is attached to the cabinet by links in such a way that when the board is thrown forward to the inclined position the leaf is lifted, but remains horizontal.

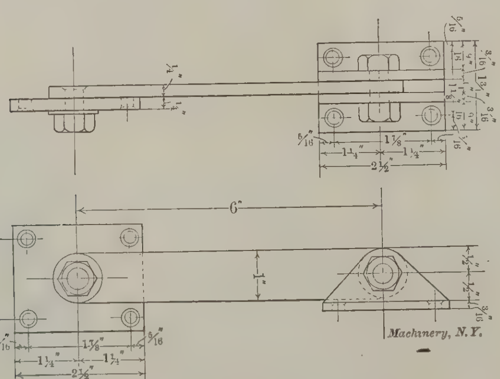

Fig. 3. Details of Link Arrangement.

A detail of the link and its fastenings is shown by Fig. 3 and the arrangement of the links on the board and cabinet in the two extreme positions is illustrated by Fig. 4. The lower end of the link is fastened to a malleable iron plate with a ½-inch bolt, the plate being counter sunk on the side next to the cabinet and the bolts riveted down flush. The plate is then screwed to the cabinet. The upper end of the link is fastened in a small brass or malleable iron bracket with a ½-inch bolt having a nut and washer on each end; in place of the bolt a ½-inch pin having a split cotter at each end has been used. The bracket is screwed to the under surface of the table.

The links are all made the same length, but it is evident that by varying their length and position, the adjustment of the board can be varied to suit the user. In the table here

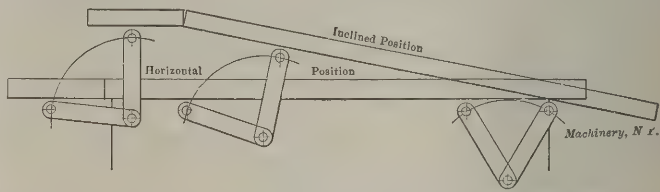

Fig. 4. Diagram showing Extreme Positions of Links and Board.

described the board is thrown forward 7 inches and raised 3 inches at the back, giving it a slope of about 12 degrees. For maximum strength and stiffness the links under the leaf at the back ought to be in nearly a vertical position when the board is thrown forward. The board should also, when in this position, have a solid bearing on the front edge of the cabinet for if supported by the links alone it will not be steady.

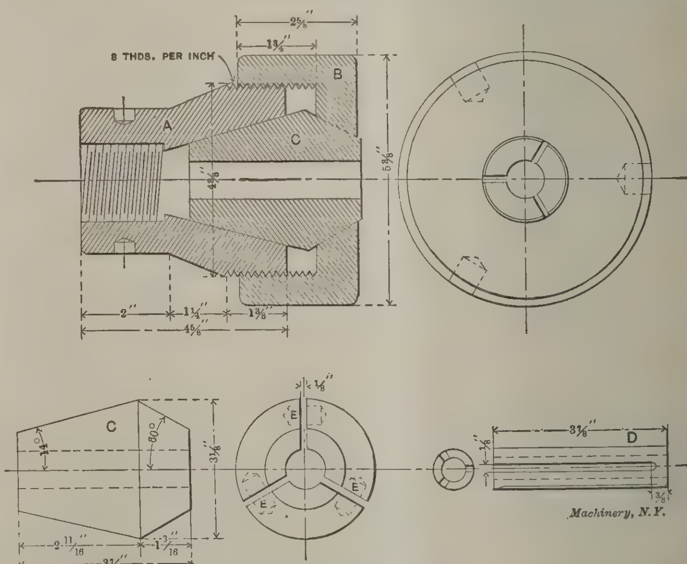
These tables were built by contract for $14.50 each, exclusive of the iron work. The cost of locks and fittings, links, hinges, etc., with labor for putting on same amounted to about $4.00 each, making the total cost of each table about $18.50.

In operation, four men, working at different periods, are assigned to a table, a book list of the lock combinations is kept, with the user's name opposite the combination. The scheme makes it possible to accommodate a varying number of students, without filling up the drafting room with lockers which are in use only a small part of the time. By locking together the drawing boards in groups of four, space is greatly economized at the same time as drawings may be left on them over night without much danger of loss.

Cleveland, O. F. H. Sibley.

COLLET CHUCK.

The chuck shown in the accompanying cut consists of three parts, the sleeve *A*, the knurled nut *B*, and the split collet *C*. The sleeve *A* is threaded to fit the spindle of the lathe and



Collet Chuck for use in Lathe.

bored to receive one end of collet *C*. The nut *B* is bored to receive the opposite end of the collet *C* and has three holes drilled in the outside for the spanner wrench. The tightening of this nut forces *C* against the taper in *A*, thus gripping the work. Several collets of different bores should be made for different sizes of stock. Sizes under ⅞ inch can be conveniently held by making steel sleeves as shown at *D* in the cut. The collet *C* is split in three parts and drilled, as shown at *E* in the detail of the collet, for coiled springs, which force the jaws apart when the nut *B* is loosened, thus allowing the work to be removed easily. H. H. Wilkinson.

Salem, Ohio.

SHOP KINKS.

A DEPARTMENT OF PRACTICAL IDEAS FOR THE SHOP.

Contributions of kinks, devices and methods of doing work are solicited for this column. Write on one side of the paper only and send sketches when necessary.

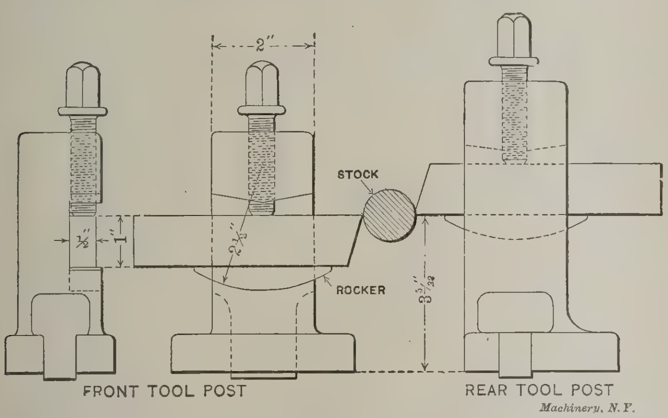
CLEANING TOOLS WITH AN INK ERASER.

A very convenient way of removing rust and brightening surfaces of tools, such as steel scales or brass and German silver protractors, is to rub the surface with a common ink eraser. It does not scratch the surface as emery cloth does; it is always at hand for a draftsman and would also be appreciated by a machinist. WM. H. KELLOGG.

Chicago, Ill.

IMPROVED TOOLPOST FOR THE SCREW MACHINE.

The toolposts on the Garvin screw machine cross slide were giving me a great deal of trouble both in regard to failing to hold the tool rigidly, and on account of the breaking off of

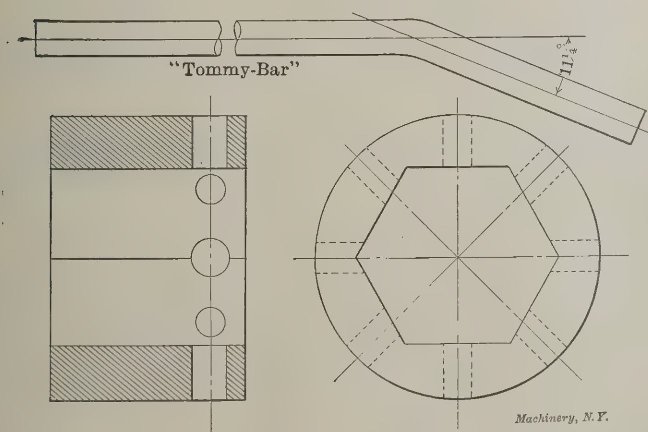


the part which fits in the T-slot, due to the pressure sidewise. I therefore decided to design a toolpost which would stand up under all conditions with the result shown in the accompanying cut. C. W. PUTNAM.

New York City.

SIMPLE SOCKET WRENCH.

I had occasion to tighten a ¾-inch nut in a position where an ordinary wrench could not be used. The socket shown in the cut was made, having a hexagon hole for the nut. Through the top of the socket eight holes were drilled 45 degrees apart for a steel rod which was used as a handle or "tommy-bar." This pin, being bent at an angle of 11¼ degrees, enabled the



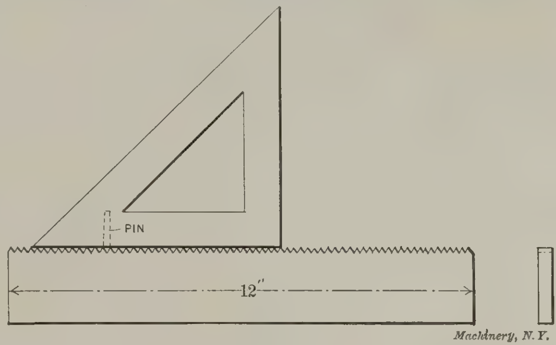
nut to be turned one-sixteenth of a turn for each position of the pin, and thus permitted the nut to be tightened with a very short angular movement of the handle.

Auburn, N. Y. JOSEPH ROACH.

[This scheme is a good one for the purpose described. We recently saw it in use in the Schenectady plant of the General Electric Co. on 3-inch nuts, these being located in a generator frame where an ordinary wrench could not be employed. The simplicity of construction, ease of operation and effectiveness will commend this form of wrench to all who have use for such a tool.—EDITOR.]

SECTION LINER.

The accompanying cut shows the principle of a section liner which, although simple, answers the purpose fully as well as some of the more complicated and expensive arrangements. It consists of a piece of brass or any metal 12 inches long with threads cut on one side as shown, about 40 threads



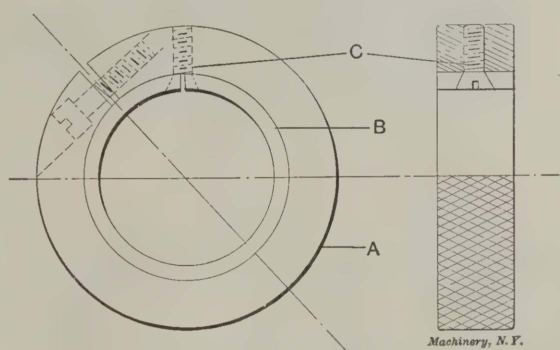
to the inch, a wooden triangle and a pin driven in as indicated and filed to fit the thread into which it is to engage. The other boys and myself have used it and find it to be a good thing. JOHN H. CRAIGIE.

Boston, Mass.

ADJUSTABLE RING GAGES.

There are plenty of precise mechanics who will say that adjustable tools and gages are unsafe, and that because of this particular feature some workmen are apt to get an adjustment over or under size and spoil something. While this really is true in a measure, the same workman could, with a new sharp tap or reamer, make a hole too large, or too small with one that was worn and dull. Adjustable tools are a great help and if properly used will never cause trouble.

The cut shows one of the most satisfactory adjustable ring gages I know of, having used this form quite a number of years and prefer it to others. It is adapted for either thread



or plain gages, being used in both forms. *A* is a soft split steel ring. *B* is a split tool steel ring, hardened, ground, and lapped. The cylindrical truth of the gage remains perfect at different adjustments. The adjusting is done by the screw *C*, which should have a wood screwhead, 30 degrees included angle. This gage is both a convenience and a time saver—a practically solid gage in a few minutes changed from a standard size to several thousanths inch plus or minus. After the gage is adjusted to the desired size, which is easily and quickly done, it is as substantial as a solid gage. M. S. W.

PERMANENT SET OF SPIRAL SPRINGS.

The question and answer regarding spiral springs in the November issue of MACHINERY interest me. Evidently "F. S." met difficulty in attempting to prevent the spring from taking a permanent set. I should suggest that the spring be manufactured with an increased pitch, so that after hardening and tempering the permanent set may be taken out by compressing solid. If the spring still remains too long, a little more tempering will bring the desired result. It will be impossible by any method of hardening or tempering to prevent a spring of the dimensions given from taking a permanent set. Furthermore, do not consider that closing the coils tightly together will take out the entire set, but the spring must be compressed solid for ten or fifteen hours before the permanent set can be entirely overcome. A.

SHOP RECEIPTS AND FORMULAS.

A DEPARTMENT FOR USEFUL MIXTURES.

This page will be used for the publication of shop receipts which the contributors know from experience to be practicable. Nearly all readers of MACHINERY can add something, and it is desired that they use this page as a medium for exchanging useful formulas. It makes no difference if they are old and supposedly well-known, provided they have not already appeared in this department.

283. MALLEABLE BRASS.

Brass which possesses malleability in a high degree can be obtained by alloying 57 parts of copper with 43 of zinc.

Pittsburg, Pa. U. PETERS.

284. STEAM PIPE CEMENT.

Mix equal parts, by weight, of oxide of manganese, pipe clay and white lead, ground with linseed oil varnish.

West Somerville, Mass. E. H. McCLINTOCK.

285. TO TURN VERY HARD IRON AND STEEL.

Use a drip can for the tool with the following solution: petroleum, 2 gallons; turpentine, 1 gallon, and 2 ounces of camphor. J. H. HOLDSWORTH.

Toronto, Canada.

286. TO BLACKEN ARTICLES WHICH ARE NOT SOLDERED

Heat the article to a low heat and dip into a solution of nitrate of copper, made by dissolving copper in nitric acid. Then heat the piece dipped over a spirit lamp or Bunsen burner until from greenish color it finally turns black.

Bridgeport, Conn. H. A. SHERWOOD.

287. ALLOY FOR FILLING HOLES IN CAST IRON.

Melt together 9 parts of lead, 2 parts of antimony, and 1 part of bismuth, and pour this mixture into the hole, first somewhat warming the hole. This alloy possesses the quality of expanding when cooling, hence becomes solid in the holes when cold. E. J. BUCHET.

Dubuque, Iowa.

288. MIXTURE FOR HARDENING SPIRAL SPRINGS.

The following oil bath mixture gives excellent results for hardening spiral springs: Two gallons best whale oil, 2 pounds Russian tallow, and ½ pound rosin. Boil the tallow and the rosin together until dissolved; add the whale oil and stir up well, and then it is ready for use.

Birmingham, Eng. W. R. BOWERS.

289. TO CASEHARDEN CAST IRON.

To caseharden cast iron use a pot of suitable size for the piece, packing it in with 2/3 raw bone and 1/3 charcoal ground to about the same size as the bone. Seal the pot cover with fire-clay and place in a furnace and run it about 5 hours. Then take out the work and dip in oil or water.

E. W. NORTON.

290. TO TURN ALUMINUM.

To produce a smooth surface when turning aluminum use kerosene oil for a lubricant. If turning in a turret lathe provided with an oil pump, mix the kerosene oil with lard oil, 1 part of lard oil to 3 parts of kerosene, as kerosene itself is too thin to be fed through the ordinary oil pump without being mixed with a more heavy flowing fluid. Kerosene oil is also the best lubricant for use in boring, threading and reaming aluminum. JOHN C. MONRAD.

East Hartford, Conn.

291. TO CLEAN TRACINGS.

Tracings that have become badly soiled from handling or other causes, may be easily cleaned by thoroughly sponging the cloth with benzine or gasoline. Kerosene will serve the purpose, but is not so good. It does not injure the cloth in the least, but on the other hand has the effect of re-establishing the color of a much used tracing, and will remove pencil marks perfectly. When some compound has been used on the tracing to remove the ink lines, leaving a sticky and gummy surface, benzine will quickly clean and dry the affected portion, so that it can be worked over again.

Olney, Ill. T. E. O'DONNELL.

292. TO COAT IRON WITH COPPER.

Polish the iron by rubbing it well with cream of tartar, and afterward with charcoal powder, and place the metal in hydrochloric acid diluted with three times its volume of water, in which a few drops of a solution of sulphate of copper is poured. After a few minutes withdraw the iron and rub with a piece of cloth, then replace it in the solution, to which add another portion of sulphate of copper. By following on this plan the layer of copper may be increased at pleasure. Finally, immerse the iron in a solution of soda, wipe clean and polish with chalk. The coating thus obtained will be as firm and durable as that deposited by the electrotype process.

Pittsburg, Pa. U. PETERS.

293. STEEL BLUE ENAMEL.

A steel-blue enamel suitable for applying to steel and also other metals to give them a steel-blue polished surface, may be made in the following way: Dissolve 1 part of borax in 4 parts of water. Macerate 5 parts bleached shellac in 5 parts of alcohol. In a small quantity of alcohol dissolve some methylene blue of sufficient amount to give the color desired. Heat the first or watery solution to boiling, and while constantly stirring add the alcoholic solution. Stir until all the lumps are dissolved, and then add the blue solution. Before applying, the surface to be blued should be cleaned and brightened with emery cloth. The enamel is best applied with a soft brush. The solution may be put into a bottle and set aside for future use, provided the bottle is securely corked.

Olney, Ill. T. E. O'DONNELL.

294. TO PREVENT DRAWING TITLES FROM SMEARING OR RUBBING OFF.

A great many of our railroads and large manufacturing concerns throughout the country are using small printing presses for the purpose of putting titles on their drawings. It is titles put on in this manner with tracing cloth printing ink to which I refer. After the title has been printed on the drawing, lacquer it over with a very thin coat of French varnish (such as is used by artists). This can be best applied with a chisel-shaped camel's hair brush, equal in width to the height of the letters in the title. A good substitute where French varnish cannot be obtained is made by cutting ¼ ounce of the best grade of white shellac in ½ pint of alcohol. As either of these varnishes dry very quickly, the tracings may be used soon after the titles are put on.

Meadville, Pa. E. W. BOWEN.

295. SATIN FINISH ON ALUMINUM.

The article should first be dipped in a caustic soda or caustic potash solution—potash preferred—then thoroughly washed in clear water and dipped in a bath of concentrated nitric acid, after which it should be thoroughly washed and dried in hot sawdust. The caustic solution should be prepared in a tank provided with a steam coil and should test with Baumes' hydrometer at anywhere between 20 and 30. The length of time an article should remain in the caustic solution is a matter of judgment. The solution should attack the aluminum rapidly, and upon removing the article from the solution, the solution should boil furiously on the metal. After washing, the article should show a very black color, which turns to a silvery white finish upon dipping in the nitric acid. The best temperature for the caustic solution is at 200 degrees F., just below the boiling point. By the use of a steam coil the solution can be kept at an even temperature, and the strength of the solution can be maintained by adding small quantities of caustic from time to time. The temperature and strength of the solution are very important.

The principal point to bear in mind in washing and drying is to dry without streaks, which is accomplished if the sawdust contains no pitch or rosin.

This finish can be improved by scratch-brushing the article before dipping or by first dipping in the two solutions and then scratch-brushing and afterward dipping again. The scratch-brushing destroys the grain of the metal and reduces the possibility of the article drying with streaks.

Bridgeport, Conn. S. H. SWEET.

HOW AND WHY.

A DEPARTMENT INTENDED TO CONTAIN CORRECT ANSWERS TO PRACTICAL QUESTIONS OF GENERAL INTEREST.

Give all details and name and address. The latter are for our own convenience and will not be published.

36. A. L.—Please give a general rule for finding the angular setting of a milling machine head when it is required to mill a flat side on a tapered pin which shall be proportional in width throughout its length to the varying diameter of the pin. For example, what is the proper setting for the milling machine head when making four-sided reamers for standard taper pins ¼-inch taper per foot?

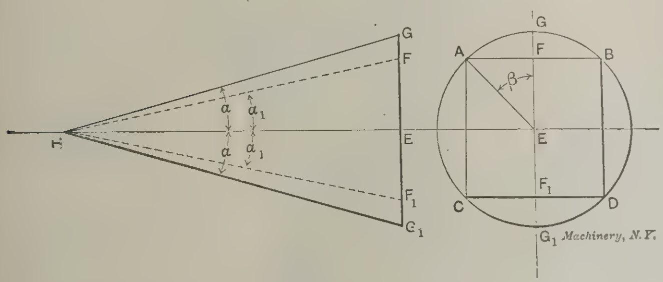
A.—Divide one-half the taper per foot by 12, and multiply the quotient by the cosine of 360 divided by two times the number of sides. The result is the tangent of the required setting of the index head. Expressed as a formula, using the symbols and lines shown in the cut we have

$$\tan \alpha_1 = \frac{GE \times \cos\beta}{HE} = \frac{\frac{1}{2}T}{12} \times \cos\frac{360^\circ}{2N}$$

α = one-half included angle of cone.

α_1 = angle made by flat with the axis or center line.

$$\beta = \frac{360^\circ}{2N}.$$



N = number of sides.

T = taper per foot.

Expressed in words, the formula reads:

$$\text{Tangent angular setting} = \frac{\frac{1}{2}\text{ taper per foot}}{12} \times \text{cosine}\,\frac{360\text{ degrees}}{2 \times \text{number of sides}}.$$

Taking the quoted example, we have:

$$\text{Tan } \alpha_1 = \frac{\frac{1}{8}}{12} \times \cos 45 \text{ degrees.}$$

$$= \frac{\frac{1}{8} \times 0.707}{12} = 0.01041,$$ the tangent of the required angle.

Referring to a table of tangents discloses that the angle is 25 minutes, or the required setting.

---

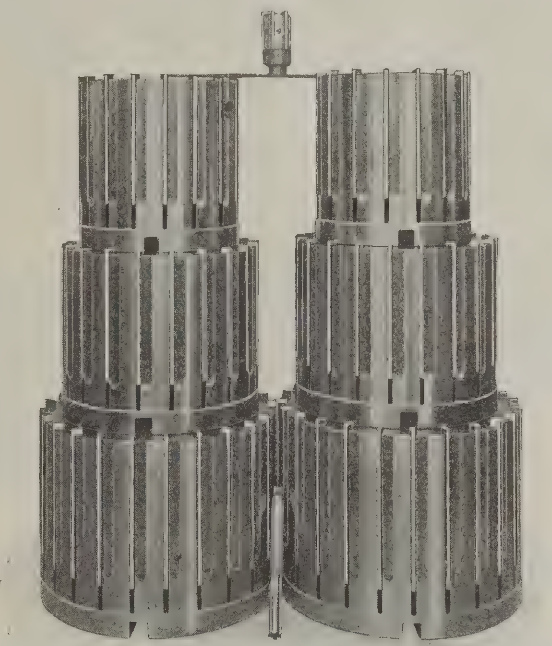
35. A. L. F.—Having given the number of teeth and the pitch angle (or edge angle) of a bevel gear, how can I find the number of teeth of the mating gear, the axes being at 90 degrees?

A.—The number of teeth in the given gear is to the sine of its pitch or edge angle as the number of teeth in the mating gear is to the cosine of the pitch angle. For example, suppose the pitch angle is 56 degrees 59 minutes and the number of teeth is 40. The sine of 56 degrees 59 minutes is 0.83851, and the cosine is 0.54488. Hence $40 : 0.83851 = x : 0.54488$, or $x = 26$, the number of teeth in the mating gear. You will observe that the result figures almost exactly 26 teeth; if it does not closely approximate a whole number then the pitch or edge angle is incorrectly given for, of course, no fractional tooth numbers can be used. The rule may be used to give both of the two possible combinations of a pair of bevel gears. Let us take for example the case of a pinion having 40 teeth, assigning to it for the moment the pitch angle 56 degrees 59 minutes, then the nearest whole number of teeth in the mating gear is 62, but the actual result is 61 and a fraction. Taking 62 as the probable number and working backward we find that the actual pitch angle of the 62-tooth gear must be 57 degrees 10 minutes. The method of finding this is simple: square the numbers of teeth in each gear, add their squares, extract the square root and divide either number of teeth by the root. The quotient is the sine of its pitch angle. To illustrate: $\sqrt{62^2 + 40^2} = 73.78$; $62 \div 73.78 = 0.84034$, the sine of 57 degrees 10 minutes. If, instead, we divide 40 by 73.78 the quotient is the sine of the pitch angle of the 40-tooth pinion, or 0.54216, the sine of 32 degrees 50 minutes. Of course it is simpler to subtract 57 degrees 10 minutes from 90 degrees, but the foregoing illustrates the process more clearly.

* * *

A GROUP OF LARGE REAMERS.

The constant extension in the range of usefulness of the adjustable reamer could not be shown in a much better way than it is in the group pictured below. Probably the dimensions of these tools will seem rather large to most mechanics, and indeed it is rather difficult to imagine just what field of usefulness has been found for adjustable reamers of this size.



Group of Large Reamers.

They were built to order, however, by the makers, Schellenbach & Darling Tool Co., Cincinnati, Ohio, and the purchaser doubtless has confidence in their capabilities. The diameters of these tools are as follows: 7¾, 8, 9¾, 10, 11¾, 12. The bores are 4 inches, 4½ inches and 5 inches respectively. The smallest shell reamer shown (at the top) is 1½ inch in diameter, the hand reamer at the bottom is 11/16 inch in diameter. The whole group weighs in the neighborhood of 1,000 pounds and certainly represents a remarkable feat in toolmaking.

* * *

One of the drawbacks to the use of wire hoisting rope has been the spinning to which it is ordinarily subject when raising a load. This is troublesome and dangerous, as oftentimes a bucket will spin so rapidly that the material loaded above the rim will be thrown off by centrifugal force and cause the injury of workmen beneath. We understand that a rope is now on the market which is not subject to this trouble, it having little or no tendency to spin as the load is raised or lowered. This example shows one the peculiar difficulties that mechanical engineers are often required to overcome. New questions in engineering are arising every day for which there is little or no direct precedent, but the solutions may often be found by analogy, reasoning from the known action of materials under similar conditions, but used for entirely different purposes.

* * *

One of the oldest blast furnace blowers in the world is undoubtedly one still in existence at the Lowmoor Iron Works in England, which according to the *Foundry Trade Journal* was built in 1791. The blast furnace itself, which was built in 1802 is also still preserved.

MACHINERY AND TOOLS.

A MONTHLY RECORD OF NEW APPLIANCES FOR THE SHOP.

PRECISION GEAR-CUTTING MACHINERY.

The Sloan & Chace Mfg. Co., Newark, N. J., concerning whose work we have had something to say in this and the preceding issue of MACHINERY, have recently built an automatic gear cutter and an automatic rack cutter of larger size than their regular line of machinery, to meet the demand for the larger gears used in light mechanisms and instruments of various kinds. This work includes that required for cash registers, typesetting machinery, the heavier parts of typewriters, etc.; but the gear cutter shown has given such a good account of itself on comparatively heavy work that gears as large as those used in automobile construction are found to be easily within its range.

In the rack cutter shown in Fig. 1, the general design is that of the milling machine. The rack cutting spindle is driven from the main spindle by suitable gearing enclosed within a case, the axis of the cutter spindle being parallel, naturally, to the direction of the index travel of the work table. The movements of the machine, other than the rotating of the cutter, are accomplished by a vertical cam-carrying shaft, driven by the bevel gears and worm wheel shown attached to the knee. This gearing takes its motion

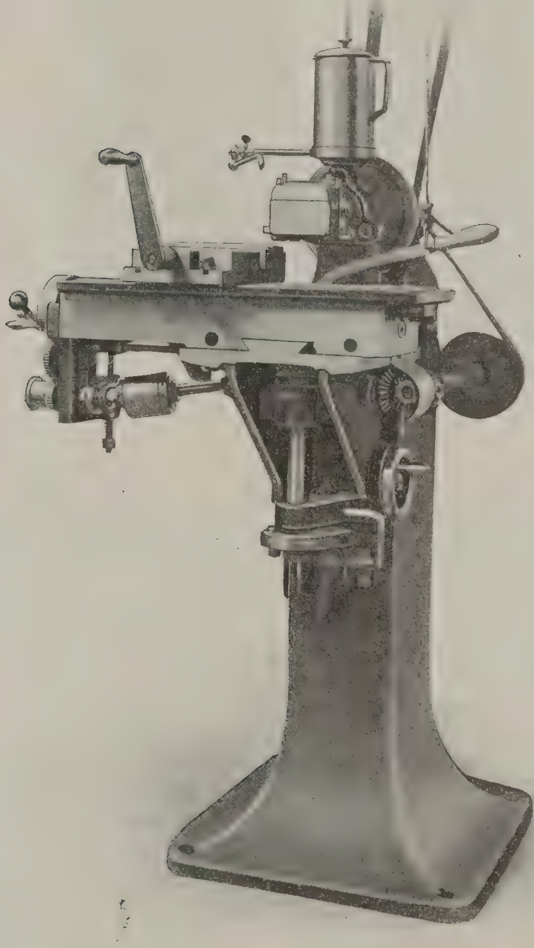


Fig. 1. Sloan & Chace Automatic Rack Cutter.

from a belt connected to the spindle at the back of the machine. The cam shaft referred to is the heavy vertical shaft journaled in bearings in the knee beneath the table; this shaft makes one revolution for each tooth cut, if a single cutter is used, or for each feeding stroke of the table if a multiple cutter is used. The cam for feeding the saddle inward for the cutting motion and backward for the return, is located at the upper end of the shaft. At the lower end is another cam, not clearly shown, which allows the knee and table to drop on the return stroke, thus relieving the cutter. This is effected by the partial rotation of a screw having a very coarse pitch, threaded into the boss projecting from the front of the column. Within this screw, but prevented from rotating with it, is a nut on which the elevating screw of the knee acts. Immediately on the completion of a cut, the partial rotation of the first mentioned coarse pitch screw, under the influence of the cam, thus serves to depress the elevating screw and with it the knee and the work, raising it again to its former position

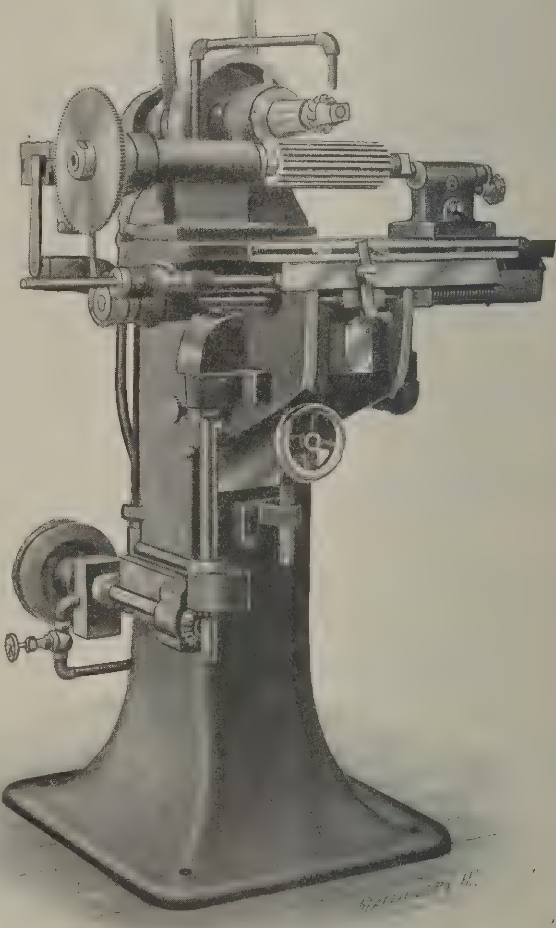

Fig. 2. Sloan & Chace Automatic Gear Cutter.

as the upper cam again commences to feed the work forward toward the cutter. A continuation of the bevel gear-driven shaft, which through the worm gearing rotates this cam shaft, operates the indexing mechanism, motion being conveyed to the change gearing at the right-hand end by a telescopic shaft with universal joints and a friction slip device. A trip on the vertical cam shaft releases the index gearing at the proper time when it is rotated through a complete revolution by the friction drive. An adjustable stop at the back of the work table, not shown in the cut, releases the shipper lever whose handle is seen projecting at the right, and stops the machine after any desired number of teeth. The countershaft used has a spring return and is held in engagement by the locking of this lever at its lowest position. The whole mechanism is thus arrested as soon as the last two have been cut with the work dropped away from the cutter and brought outward to the full extent of the return stroke.

The gear cutter shown in Fig. 2 shows plain evidences of the watch machine makers' ideas in its design, but it is intended to show the watch machine makers' ideas in the accuracy of its workmanship as well. The column is practically the same as that of the machine just shown. It is of the same general milling machine design. The cutter, of which a comparatively coarse pitch is shown in the cut, is mounted on an arbor in a rugged prolongation of the main spindle. The work is held between centers and is indexed by a notched

disk, as is usual in precision machine practice. The various movements, other than the cutting feed, are obtained from the pulley shown near the base of the column at the left-hand side. From here the motion is transmitted to the knee by means plainly visible. A feed screw is used in this case instead of a cam employed in the rack cutter shown in Fig. 1. The quick return of the feed motion is effected by the connections just described, while the forward feed is driven by a three-speed change gear box on the other side of the machine. The three feeds obtainable are approximately 0.010, 0.017 and 0.030 per revolution of the spindle. With the four-pitch cutter shown in place in the machine, without the slightest signs of distress in machine, cutter or work, 6½ inches per minute have been obtained in cast iron, 2⅛ inches per minute in machine steel, and 7¾ inches per minute in bronze. The travel of the table is determined by stops fastened in a T-slot at the front acting on a clutch lever which throws in, in turn, the feed and the quick return. A rather ingenious indexing mechanism, which entirely avoids the use of spring action in the withdrawal of the locking pin and the indexing of the work, rotates the blank the proper amount on the first half turn of the feed screw at the commencement of the feeding movement. A one-revolution clutch has been provided for this motion which has been specially designed to be operative even when the parts are rotated by hand at a very much slower rate than would occur when the machine is power driven. All the gears in the knee and the change gear box are of steel.

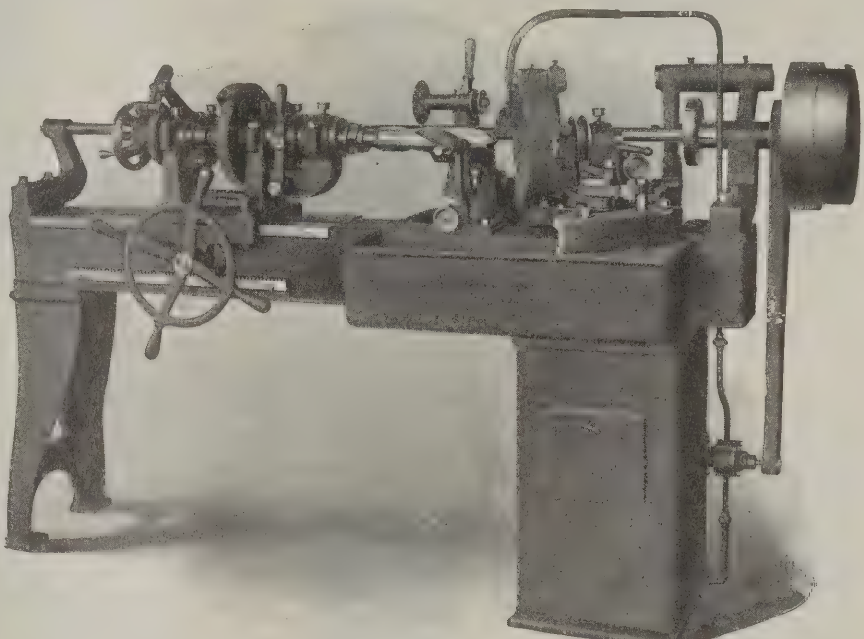
The head is adjustable in and out of the bed for centering the cutter. It has a three-step cone for a 2-inch belt, and gives speeds of 121, 217 and 312 revolutions per minute to the cutter. In both the spindle and the work arbor the usual No. 10 Brown & Sharpe taper is provided. For cutting steel the work table is provided with a pan lip, and an oil pump is arranged to be driven by the quick movement shaft at the lower left-hand side of the column; the reservoir for oil is inside of the frame. The makers call this their No. 3 automatic gear cutter.

THE DAHL AUTOMATIC DRILL GRINDER.

A glance at the accompanying halftone shows that this drill grinder is decidedly different from the type to which we have become accustomed in the last ten or fifteen years. There is, in fact, almost no element in this mechanism corresponding in any particular to that of the usual machine. The drill is placed in the chuck of this machine, brought up to the wheel, and the machine is started, after which it continues to grind the end of the lips to the proper contour until the dull portion has been removed when the operator, who has not meanwhile touched the machine, throws off the power and removes the drill.

A shaft at the rear extending the whole length of the bed and driven by the two-step cone at the right, furnishes the power for all the movements, excepting the rotation of the emery wheel itself. The wheel is of the cup type, grinding on its face, and is mounted on an independent spindle driven by a round belt from the countershaft. On flat ways on the left end of the bed is mounted a carriage provided with a quick traverse movement through the pilot wheel shown. This carriage carries the work-holding spindle, which is provided with a tapered hole and suitable collets for holding the drill in the same way it is held in the drill press. The spur gear shown in this spindle meshes with a pinion of half its diameter on the driving shaft in the rear, so that for every revolution of the spindle, which rotates continuously, the driving shaft makes two revolutions. After the work has been once set, the carriage is clamped in place by the handle shown at the right of the pilot wheel. The feed of the drill toward the wheel, as the grinding progresses, is accomplished by the mechanism shown at the rear of the carriage or an extension of the drill holding spindle. An eccentric on the rear driving shaft, acting on the feed screw, through the levers and ratchet wheel plainly shown, advances the drill a little at a time as each lip passes the face of the wheel. A slotted link in the connection between the eccentric and the ratchet wheel allows a variation in feed to suit the size of the drill and the amount of stock to be removed. As will be seen later, it is necessary that the cutting edge of the drill should preserve a constant angular position in relation to the driving shaft at the rear. To preserve this relation, use is made of the gage pin shown in the V-block support in which the outer end of the drill rests. With the back shaft in a definite position, the clutch is loosened by the operating lever seen between the right hand and the central bearings of the work spindle, and the drill is rotated until its cutting lip is properly located with reference to the gage just mentioned. The clutch is then thrown in again, when the drill and the other mechanism of the machine are fixed in proper relation to each other.

The wheel itself, driven from the countershaft by a round belt as before described, is mounted in a headstock which is free to swing about a vertical axis passing through the center line of the drill and its spindle, near the point of the drill. The cam shown on the back shaft just at the left of the right-hand bearing next to the pulley, through a system of levers,



Machine for Automatic Sharpening of Twist Drills.

imparts to the headstock and the wheel mounted in it a vibratory motion about its vertical axis, performing two complete cycles for each revolution of the drill by virtue of the fact that the driving shaft and work spindle are geared in the ratio of 2 to 1, as before described.

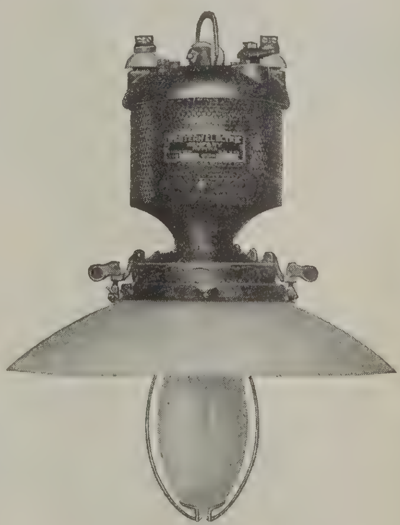
The action of the machine will now be readily apparent. The drill, rotating continuously and fed forward slowly, is pressed against the face of the revolving wheel which, being set at the proper angle for the cutting edge, is swung around to a gradually increasing angle as the heel of the drill is presented, thus giving to the tool its proper clearance. As the second cutting edge approaches, the cam swings the wheel back out of the way until the lip reaches the proper point for presentation to the wheel which, as before, swings in toward it again following the curve around to the heel. The drill, meanwhile, is advanced a slight amount by the feeding mechanism between the grinding of each lip.

A number of interesting points will be noticed in the mechanism. Provision is made, for instance, to insure an even wear across the whole face of the grinding wheel. At the front of the pivoted carriage on which the wheel is mounted will be seen a ratchet wheel adapted to engage with a stationary dog on the bed. As the wheel support is vibrated under the influence of the cam, this ratchet wheel passes toward and away from the dog in turn, receiving by this action a step by step rotating movement. To this ratchet

wheel is attached a crankpin and a connecting rod, which is, in turn, pivoted to a stud in the headstock casting, which carries the wheel. This headstock is not one piece with the pivoted carriage which forms its base, but is fastened to it through sliding ways. The gradual rotating of the ratchet wheel through the medium of the connecting rod gives to the wheel a slow reciprocating movement which continually presents to the work a new portion of the grinding face, over which the wear is thus evenly distributed. Messrs. Manning, Maxwell & Moore, Inc., 85-87-89 Liberty St., New York, who have placed this machine on the market, make the following claims: An unskilled operator can grind a drill at a true angle without difficulty; the adjustments for taking care of drills of different sizes from ½ to 3½ inches in diameter, are rapid and simple; the design of the machine insures equal height and even cutting on the lips of the drill; the wear on the face of the emery wheel is uniform. Suitable gages are provided for adjusting the wheel to make allowance for wear. A separately-driven small wheel is provided for thinning the points of the drill. This operation is performed without removing the drill from the machine. The wheel for this is shown in the position it occupies when not in use, at the rear of the drill being sharpened. The machine weighs approximately 1,900 pounds and is furnished regularly with one large emery wheel, one small wheel, and bushings for tapered shanks. Each machine is furnished complete with countershaft and necessary wrenches.

THE WESTERN ELECTRIC CO. SHORT ARC LAMP.

To meet the demand for a line of arc lamps to use in places where head room is scant, the Western Electric Co. of Chicago have designed the lamp shown in the accompanying cut. They believe that they have attained a more graceful and pleasing form, a more compact arrangement, and a better light distribution than have been reached by other manufacturers who have attempted a solution of the same problem. The over-all length has been reduced to the minimum obtainable, it being but 20 inches from the top of the lamp to the lower end of the inclosing globe; and this has been done without reducing the length of the carbon enough to materially cut down its life below that obtained in the ordinary five-ampere lamp. A life of 100 hours with each trimming is guaranteed. Instead of the large bulky case ordinarily found in short lamps, the use of indestructible windings and specially designed resistance units has resulted in very small dimensions and a design quite as symmetrical as that of the standard type manufactured by the company. In the choice of material for the different parts, only such have been used as have been found adapted for rooms where considerable heat is liable to be met with. The lamps are expected to be used in low cellars, engine rooms, boiler rooms, etc., so that this precaution is a necessary one.

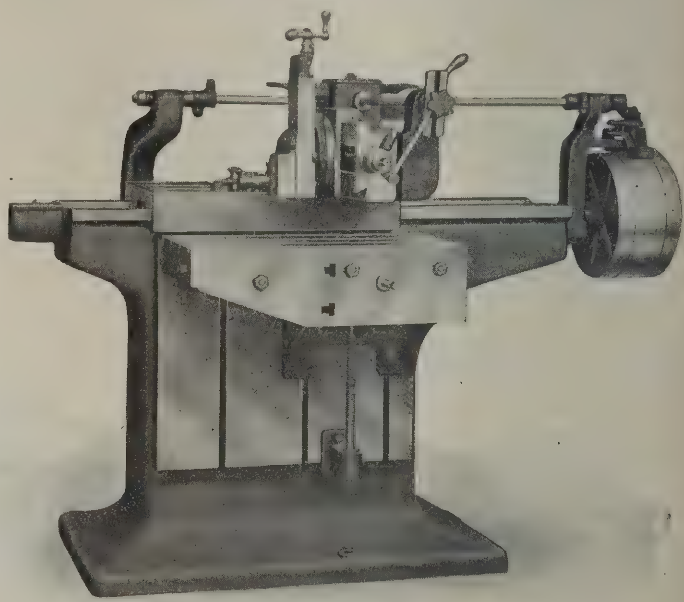


An Arc Lamp for low Ceilings.

It is found quite difficult in practice to apply any effective safeguard against injury by the use of fuses in lamps of this kind as ordinarily constructed, and it is not infrequently found that elements, which were thought to have been provided against, have wrought serious damage. In the new lamp provision is made to preserve it from injury even where fuses are omitted. The lamp may, in fact, remain with the arc entirely short circuited for hours without material injury; after which it will be found ready for normal operation the moment proper conditions are restored. This lamp may be obtained for use on 110-volt or 222-volt circuits, direct current.

THE CINCINNATI OPEN SIDE SHAPER OR PLANER.

The shaper of the "Richards" or "open side" type has so many advantages over the usual type for some kinds of work, that it seems strange that it has not come into more common use. Among other good points the design possesses, is the property of not making a "fan tail" cut; that is to say, the aggregate of the deflections of the members of the machine is constant throughout the stroke. It is not constant, of course, between the first stroke and the last stroke, but since most shaper cuts are longer than they are wide, the tendency of this condition is toward greater accuracy. On this machine also there is practically no limit to the diameter of shaft which can be key-seated. In the ordinary shaper usefulness in this direction is limited by the size of the opening through the column under the ram. The Richards shaper can be used on castings which are entirely beyond the range of the ordinary tools, for taking cuts of certain kinds; in fact, it may be said to have the advantages of the open side planer in this respect without its disadvantage of requiring the moving of the work back and forth.



Richards or Open Side Shaper, Built by the Cincinnati Shaper Co.

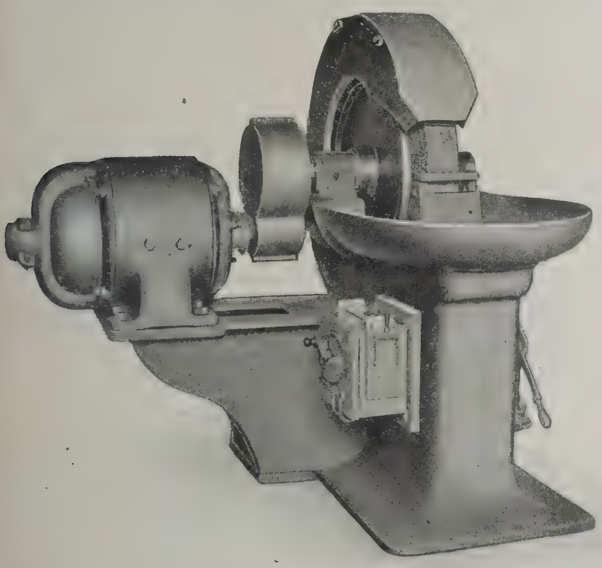
The machine here shown is the smallest of the line recently designed by the builders. It planes an area of 15 inches wide and 30 inches long. The ram is driven by a single screw and bronze nut without the intervention of any gears, this screw being 2⅛ inches in diameter and made of 0.50 carbon steel. The saddle has a long and wide bearing on the column with a narrow and deep guiding surface to prevent binding, particularly when the tool is at the outer end of the rail. A taper gib, adjustable longitudinally by means of screws at each end, is used to take up the wear uniformly throughout the length of the slide. The reversing mechanism, which is of the planer type, is operated by a means original with the builders. The rod extending across the rear of the machine is provided with stops adjustable longitudinally to vary the length and position of the stroke; two projecting wing-like cams at the rear of the slide are adapted to engage these stops; this engagement rotates the stop rod slightly in one direction or the other, depending on which direction the slide is traveling. There is no longitudinal movement of the stop rod, and it is supported on ball bearings for the rotating movement. The feed motion is derived from this partial rotation of the shifting mechanism. The adjustable feed crank is geared with the stop rod and partakes of this motion, giving it in turn to a ratchet feed of the usual construction at the end of the feed screw on the cross rail. The head has a down feed of 6½ inches. The swivel is graduated and is provided with a micrometer collar reading to 0.001 inch. The table is raised and lowered by means of a crank handle, not shown, and is provided with a supplementary table at one side, as may be seen from the cut. This supplementary table may be removed so that the work may be bolted against the side of the table proper, or the whole table may be removed, when pieces may

be fastened directly to the column. All flat bearings are hand scraped to surface plates, and all T-slots are cut from the solid.

The size shown, 15 x 30 inches, has a net weight for the machine and countershaft of 3,450 pounds. The ratio of cut to return is 1 to 2. The length of the table with the extension is 30 inches, and it has a width of 18 inches and a depth of 12 inches. The Cincinnati Shaper Co., Garrard Ave. and Elam St., Cincinnati, Ohio, are the builders.

THE BRIDGEPORT GEARED MOTOR DRIVEN TOOL GRINDER.

The Bridgeport Safety Emery Wheel Co., Inc., Bridgeport, Conn., have placed on the market the geared motor driven wet tool grinder shown in the cut below. As may be seen, the motor is mounted on a shelf cast to the base of the machine, and is connected to the wheel spindle through gearing in the ratio of 3 to 1. This arrangement runs very quietly; the gears are carefully cut, are encased to exclude dust and grit, and the bearings are self-oiling. The machine can be started up when the power starts in the morning and run as long as the shop does if desired, avoiding the need for starting and stopping the machine each time it is used. Any motor required by the customer can be fitted to this machine. The No. 5 size here shown takes a 5 horsepower motor. The bearings are 8 inches in length. The emery wheel used is

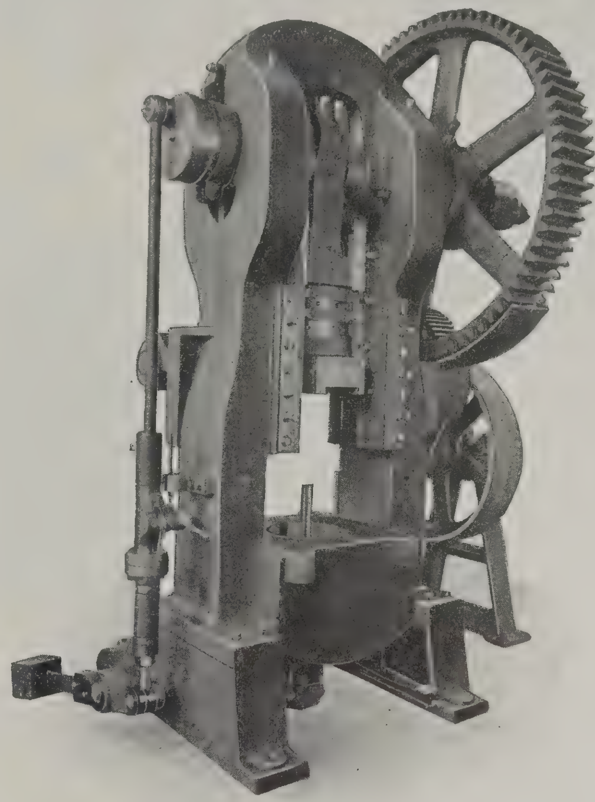


A Geared Motor-driven Tool Grinder.

36 inches in diameter with a 4-inch face, and the machine occupies a floor space of 30 x 47 inches. The wheel runs at 425 revolutions per minute. The weight of the machine with the motor is 2,650 pounds.

A LARGE SINGLE CRANK PRESS.

The E. W. Bliss Co., 5 Adams St., Brooklyn, N. Y., have recently completed the largest single crank press ever built in their shops. The constant demand for increased size in the product of power presses has necessitated a constant growth in their dimensions. The press we show is one that would a few years ago have seemed of abnormal size—beyond the capabilities of the makers to build or the purchaser to use. It is now, however, simply an unusually large machine of a well-known type, with the addition of certain improvements in detail which adapt it more nearly to the work it has to do. The machine is double geared, with an automatic jaw clutch on the crank shaft as in smaller presses. This clutch is positive in its action, and is silent whether in operation or not. The ratio of the gearing is 25 to 1, and the entire train is made from steel castings with the teeth cut from the solid. The large gear is 80 inches in diameter by 10 inches face and weighs 4,500 pounds. The arrangement is such that the gearing will not interfere with the operator in work that requires his attendance at the rear of the press. The knockout, which is plainly shown, is operated from a crank at the left-hand end of the crankshaft. It is adjustable for length by means of the stop screw and lock nut in the projecting bracket at the lower left-hand side of the frame; this operates a releasing mechanism in the knockout connecting rod and limits the upward movement, which is thus adjustable to any point



Bliss Single Crank Press of Unusual Size.

required. Through a crank and rock shaft the knockout motion is carried to the vertical plunger in the center of the bed, where it is applied to the parts provided for removing the work from the die. The crank operating the knockout is held to the shaft by a ratchet disk, which allows it to be shifted in any angular position to suit the requirements of the work being done. This adjustment is in addition to the variable stroke obtained by the releasing mechanism just described. The slide has an unusually long bearing in the frame and is scraped to it; the pressure strain comes against solid metal rather than against the gibs which are provided to take up the wear. A vertical adjustment of 3 inches in the slide is obtained by a screw 18½ inches in diameter. This screw is made with a flat thread on the pressure side, thus preventing all side strains.

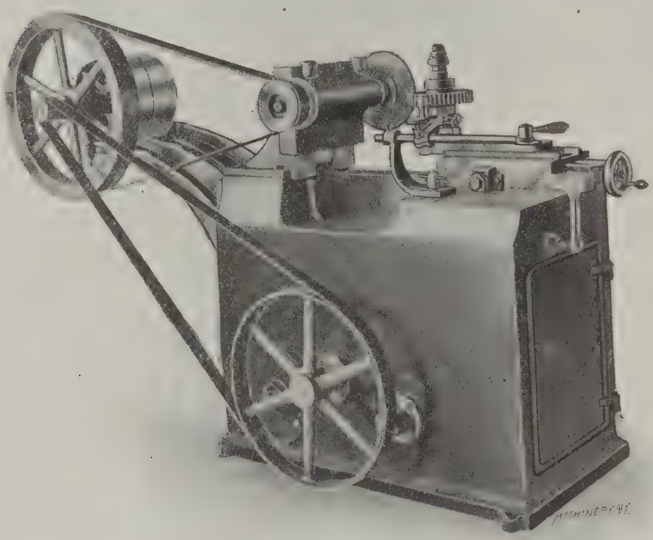
An idea of the size of this press may be had from the following facts: The frame is a solid casting and weighs over 18,500 pounds. The area of the bed is 31 inches by 32 inches. The distance from the bed to the slide with the work and adjustment up is 30 inches. The shaft is 9 inches in diameter and has a 12-inch stroke. The flywheel is 50 inches in diameter by 10 inches face and weighs 2,500 pounds, making 250 revolutions per minute. The total height of the press is 12 feet 9 inches, and the total weight is something over 41,000 pounds.

A FINISHING GRINDER FOR CAST GEAR TEETH.

The machine which we illustrate herewith is for a somewhat unusual purpose. Immense quantities of cast gearing are used in agricultural and textile machine and other products of that kind, a field in which the cut gear has as yet made little impression. Cast teeth are on the whole made more accurately and smoothly than ever before, but it is still necessary to resort to the file and cold chisel very often in preparing the gear castings for service, as fins and lumps are liable to occur on the tooth faces of even the best work of this kind. To perform this operation automatically Messrs. Upton & Gil-

man, of Lowell, Mass., have devised the automatic gear grinding machine here shown.

The gear blank is mounted on a vertical arbor in a slide on top of the bed. The grinder wheel is presented to the work on a horizontal axis held in a vertical reciprocating slide whose travel may be adjusted from 0 to 5 inches. A quick return crank motion is provided for this. While the grinding wheel is returning to commence a new stroke, the mechanism within the base of the machine withdraws the work, indexes it, and again presents it to have a new tooth smoothed off.



Machine for Smoothing the Teeth of Cast Gears.

The working parts are all so far as possible carried inside of the base, where they are protected from the grit of the emery wheel. The capacity of the machine is for spur gears from 4 to 36 inches in diameter and up to 4 inches in face. Its weight is about 2,200 pounds. The original machine has been successfully run in one of the largest shops in Lowell for several years and has proved its usefulness and durability. To this shop the makers will be pleased to refer inquiry.

A HEAVY NEWTON SLAB MILLER.

With the considerable increase in the size of machinery of various descriptions, especially in the case of locomotives, on which there is a great deal of forging and other steel work; with the growth of the modern practice of forging roughly and depending on the finishing process to bring the forging to shape and in condition to use; and with the demand for the greater strength and stiffness required by high speed steels, the weight, power and rigidity of the heavier machine tools such as slab milling machines, for instance, has been increased to a remarkable degree. The miller shown in the accompanying cuts, built by the Newton Machine Tool Works, Inc., Philadelphia, Pa., reflects very plainly the influence of the considerations just enumerated. In fact, the builders believe that they have successfully discounted the severest conditions likely to be met with in service.

The spindle of the machine shown is 6½ inches in diameter and has a main bearing 15 inches long; it is driven by a phosphor bronze worm wheel and a casehardened worm of steep lead, provided with a roller thrust bearing, and is positively geared to a 35 horsepower 2 to 1 variable speed motor. The driving worm and worm wheel have a ratio of 20 to 1. The spindle has an 8-inch adjustment lengthwise (that is to say, across the table of the machine) for convenience in setting the cutters after the work has been located on the platen. To permit this the spindle is driven from the worm wheel by a double spline. The arbor is driven by a "butterfly" key, it being provided with a tongue on the face of its collar which engages the groove milled across the front end of the spindle. The outboard bearing for the arbor is bushed; the bushing is tapered on the outside and split to allow adjustment for wear. It is arranged to fit over the arbor bushings and to be adjusted to support the arbor close up to the work. The cross rail on which the main and outboard spindle bearings are attached has an inclined face bringing the bearing surface normal to the resultant pressure caused by the rotation of the cutter and the feeding of the work. This does away with the tendency of the tool to pull in or gouge into the work.

The main upright has a bearing surface 25 inches wide while the outboard bearing has a face 12 inches wide; the length of the bearing of the cross rail on these two uprights is respectively 38 inches and 31 inches. This gives some idea of the ample proportions followed in designing the machine. The cross rail is counterweighted, has hand adjustment with quick power movement in both directions, and its power movement is so designed as to be available for sinking the cutter to the required depth by power. The makers believe that this is a new feature. To permit this the elevating screws are arranged to pull the cross rail down into the work instead of pushing it as in other designs, this arrangement overcoming the tendency of the cross rail to rise. Besides being a great time saver, this feature overcomes the chief difficulty previously experienced in fluting locomotive connecting rods, where it is necessary to sink the cutter to a depth of from 1½ to 1¾ inch in the rod. In connection with this a provision is made to prevent the table from pulling forward when sinking in, thus overcoming the breaking of cutters and arbors and the consequent damage which results from this cause and from the upward spring of the cross rail. The fact that the center of the spindle is 4 inches below the lower edge of the cross rail makes the machine convenient in working around oil cup bosses on locomotive connecting rods, and in sinking in and milling keyways on shafts of large diameters having collars and projections of considerable size. The table, which is gibbed to the outside of the bed, is driven from the motor through positive gearing entirely. The feed provided gives from 1 to 10 inches per minute with quick power movement in either direction, obtained through a compact gear box easy to control and more rigid in construction than any that has yet been designed for this work. Sliding gears are used,

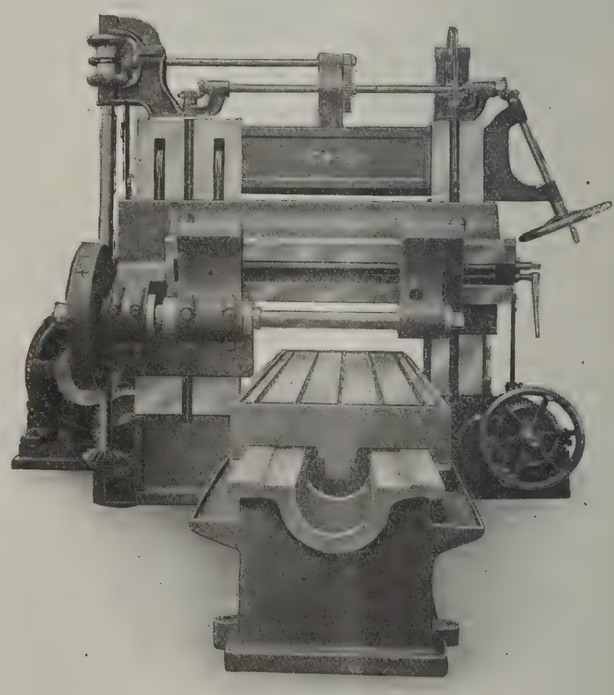


Fig. 1. Front View of Newton Slab Miller.

the contact edges of the teeth being beveled so that the change can be readily made while the machine is running. From this gear box motion is transmitted to a bronze spiral pinion on an angular shaft meshing with a steel rack 4 inches wide on the under side of the platen. The gears in the gear box are all of steel and run in oil.

In actual service for something over six months, the time maintained for two different jobs (of which large quantities have been performed) are as follows: In a milling cut with a width of 9½ inches and a depth of cut of 9/16 inch a linear feed of the platen has been maintained at 8 inches per min-

ute, giving a removal in chips equal to 43 cubic inches per minute, or about 1¼ cubic inch per minute of rated horsepower. The makers believe that this extraordinary record is in part due to the rigidity and weight of the machine, and in part to the worm drive. The Newton Machine Tool Works have been using the worm drive for many years, and to them is due a large share of the credit for the change of opinion which has lately taken place in favor of this method of transmitting power. In fluting or channeling locomotive connect-

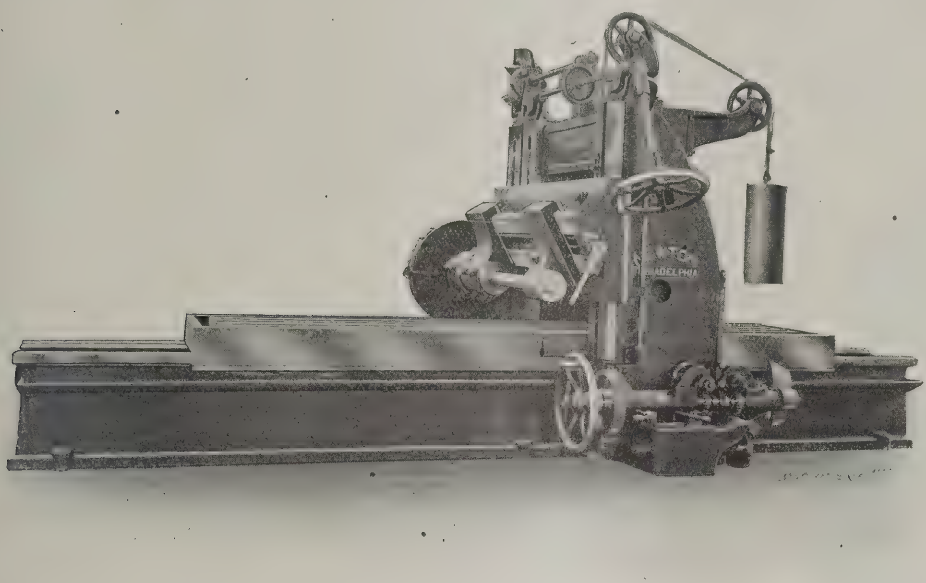

Fig. 2. Side View of Newton Slab Miller, showing Feed Mechanism.

ing rods, doing two at a time, a cut is taken 3 inches wide and 1½ inch deep, the feed of which is 3¼ per minute, this making a section of 9 square inches being removed at the feed just given. The figures given above have been maintained on this work for some time past. The cutter used is of the inserted tooth type, the teeth being of air-hardened steel inserted on a true helix. The cutting speed is about 86 feet per minute at the periphery of the cutter.

ALTENEDER'S DRAFTSMEN'S PEN-FILLING INK STAND.

Since the discarding of the old-fashioned process of grinding India ink as fast as it is used, the troublesome question has arisen of where to put the ink bottle so that it may be safe from overturn and still be convenient. To provide a bottle holder that will be both safe and convenient, and in addition to that, to provide a means for filling the draftsman's pen very much more quickly and easily than it can otherwise be done, Theo. Alteneder & Sons, of Philadelphia, have devised the ink stand shown in Figs. 1 and 2.

Fig. 1. The Alteneder Pen Filler and Ink Stand.

The first of the two halftones gives an idea of the construction of the device. The cast-iron base is sufficiently heavy to supply the element of stability, an element whose need is strongly felt when working with a bottle unprovided with a holder. This base is designed to receive and securely hold the standard bottle now in general use. The forked spring shown surrounds the neck of the bottle and holds its base firmly within the recess provided for it. Pivoted to the frame at the rear end of the device is a lever with a rest for the palm of the hand at one end, and a stopper and pen filler at the other. The stopper is a disk of soft rubber, held down over the mouth of the bottle by the weight of the lever to which it is attached. Experiment has shown that this arrangement is as efficient in preventing evaporation as is the cork now in use. The pen filler or "dipper" consists of a coiled spring fastened at the end of a stem projecting down from the end of the lever through the rubber cap. Three or four of the lower coils of this spring are pulled away and bent slightly to the rear of the upper portion, while the lowermost loop is turned at right angles to its normal position, in a way which cannot be easily described, but which works beautifully in actual use. This little arrangement is adapted to picking up and holding a sufficient amount of ink for one filling of the pen, this ink being immediately released when contact is made between the lower loop of the spring and inside of the nibs of the pen.

In inserting a bottle in this holder, first remove and discard the stopper and quill which come with it. With the right hand placed on the rest, raise the dipper and hold it at the limit of its upward movement, then with the left hand insert the bottle in the recess under the spring. If, after the bottle has been inserted, it is found to be so much shorter than the average that the dipper touches the bottom and holds the rubber cap away from the mouth, shift the cap to a lower groove on the dipper stem. Three of these grooves will be

Fig. 2. The Pen Filler in Use.

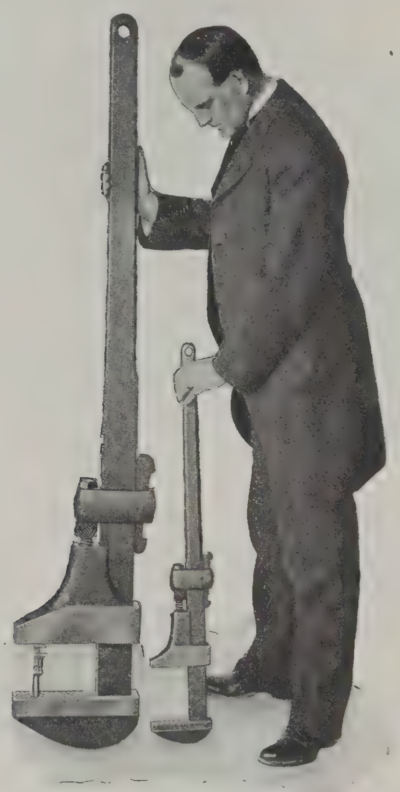
found. This should also be done when the dipper is found to be picking up sediment. In using the ink stand, place it on the drawing board within easy reach, slightly to the right and with the name-plate end nearest the body, as shown in Fig. 2. With the point held precisely as when ruling a line, place the hand on the rest, depressing it and holding it firmly at the limit of its movement; then bring the point directly under the dipper. Raise the point until the dipper loop has entered between the blades, and move the hand slowly so that the loop will just touch the blades, when the pen will fill instantly. Without trying to draw the loop through the blades, lower the pen, move it one side and take the hand from the rest, when the cap will descend and close the bottle. The entire operation consumes less than five seconds.

The advantages claimed for the device are: a saving of time in filling the pen; a certainty in the amount of ink delivered each time the filler is used; safety and convenience in holding the ink bottle of standard form; provision of an automatic stopper; efficiency in preventing evaporation; and the

avoidance of the necessity of using more than one hand in filling the pen, leaving the other one free to hold the T-square, triangle, or other instrument being used.

THE LARGEST SCREW WRENCH YET MADE.

One would scarcely expect that any practical use would be found for an adjustable screw wrench of as great size as the largest one shown in the cut below, yet there has been a sufficient demand for a tool of this magnitude to induce the Coes Wrench Co. of Worcester, Mass., to undertake its manufacture. The wrench is of their T-model pattern, which provides a quick adjustment to two or three different positions, after which the final tightening is accomplished by a nut in the usual manner. This wrench is 72 inches in length. An idea



Three Members of the Coes Family of Screw Wrenches.

of its great size is obtained in comparing it, on the one hand, with the stature of Mr. Coes who holds it, and on the other hand with the smallest size wrench of the Coes line, which it held between its jaws. This series of key wrenches is made from steel forgings and steel castings throughout, all the parts being hardened.

The use to which this tool is put is in the tightening of the large nuts used in bridge construction. It was built in response to inquiries from bridge-building companies, and it was concluded, from the nature of the inquiries, that a tool of this size would be required to meet extreme conditions. The wrench has a full jaw opening of 12 inches with a depth of 8 inches. The jaw weighs 33½ pounds, the screw weighs 8½ pounds, the bar 114 pounds, and the total weight is 160 pounds. The complete line now includes 28-inch, 36-inch, 48-inch and 72-inch sizes. The 36-inch size, shown also in the cut, has been found especially useful for opening hopper-bottom cars, and many have been sold for that purpose.

* * *

Water-proof glue is manufactured of gum shellac, three parts and India-rubber, one part by weight, these constituents being dissolved in separate vessels in ether, free from alcohol, subject to a gentle heat. When thoroughly dissolved, the two solutions are mixed, and kept for some time in a vessel tightly sealed. This glue resists the action of water, both hot and cold, as well as most acids and alkalis. If the glue is thinned by the admixture of ether, and applied as a varnish to leather along the seams where this has been sewn together, it renders the joint or seam water-tight, and almost impossible to separate.—*Scientific American.*

EUROPEAN INDUSTRIAL NOTES.

PRESENT CONDITION OF BRITISH MACHINE BUSINESS.

It is perhaps superfluous to state that, speaking generally, business over here in the engineering and tool-building lines is booming. At the same time it cannot be said there is any particular symptom of feverish "hustling." People are, so far as the available supply of competent men allows, working their plants as many hours as they think pay, and extending their equipment as current deliveries of tools and considerations of prudence permit. After doing this they cease worrying, knowing everyone else is too busy to do them much harm. Looking back, say about six or eight years, it is interesting to note how the jeremiades then more or less current as a result of loose journalistic generalizations have been falsified. Far from foreign competition extinguishing any really staple industry, most have only been revitalized as a consequence of investigation into weak spots thus caused. It is almost safe to say the lessons the United States then had to teach have been taken to heart with comparatively little whining, and so gradually utilized that shop practice has, almost unconsciously, undergone a virtual revolution.

In the tool trade, the Taylor-White steel demonstration at Paris in 1900 found the British makers at some advantage over the Americans, as most of their (the British) tools had more "weft" in them than the American ones, though less handy in some particulars. Following up this fortuitous circumstance, they have easily kept pace with the advances in high-speed steel, and have seldom been confronted by really serious competition in the heavier branches. At the same time, the undoubted merits of the best class of American tools have met, and still meet with, the heartiest recognition on the part of British users, as shown by the fact that deliveries of this class of machinery are spoken for, in some cases, eighteen months ahead. Incidentally, it may be stated that any first-class American tools which by any means come to auction or forced sale, are as eagerly picked up as though new, but much of the rubbish sent over here at the time of the cycle boom is now to be found in marine store dealers' establishments, drifting toward the scrap heap.

The system of confining productive energies to a comparatively limited variety of machinery has made rapid advances, coincidently with the fact of several American concerns broadening out in the direction of greater variety. Even where strict specialization is not—probably for good reasons—over-favorably viewed, tools are produced in larger batches at a time than formerly, thus allowing a greater net profit or productivity than might perhaps be expected. Further, travel in the States and on the Continent of Europe on the part of works proprietors, managers, business men, and, to a greater extent than perhaps imagined, workmen, has tended to rapid assimilation of cosmopolitan methods, a process assisted to a not inconsiderable extent by the spread of technical education in various forms. On this side, some of the old-established concerns hold a very strong position as regards the supplying of heavy tools for ordnance purposes, and this position has been further strengthened since the building of large steam turbines called for tools of extremely wide range. Then, again, the automobile industry, which is advancing in a remarkable manner, has enormously stimulated the demand for high-class tools of medium and light weight, in addition to encouraging cognate industries in the way of driving chains, roller and ball bearings, milling cutter manufacture, gear-cutting specialization, etc. Concurrently with these developments, gas engines of large power—utilizing blast-furnace and producer gas—are being built in increasing numbers, and the manufacture of electrical plants of most classes is now firmly established in this country, another circumstance explaining the present condition of affairs in the tool shops. An interesting sequence of these developments is the diminution of output of former types of "merchant" tools which were built with low first cost as the sole motive of production. Users of every degree of familiarity with tool practice are so well posted comparatively that selection of plant is now accorded more intelligent consideration, and the demands the toolmaker has to meet become correspondingly more exacting. A noticeable feature at the moment is the

tendency of manufacturing industries to leave the neighborhood of London for localities where land, rates, taxes, and labor are cheaper, and the increasing alertness of local governing bodies in the matter of encouragement of such migration. A movement is also afoot, in the form of "Garden Cities" associations, to create industrial communities in which manufactures may be carried on with a minimum of objectionable features, and the maximum of healthful and pleasant living and social conditions. Another form of industrial association, originated in this country, touches the cotton industry directly, and thus, practically every other industry. The organization alluded to is the "British Cotton Growing Association," formed, as a consequenece of the last attempts to "corner" American cotton, for the purpose of encouraging the growth of cotton, primarily in the British empire, and secondly in other portions of the two hemispheres. This beginning has led to combined action of all the European cotton-using countries to enlarge the sources of supply of the raw material, and thus circumvent and minimize the activity of parasitical cotton speculators. This association is supported by employers, work people, and government colonial departments, and can point to very definite results already. It is a rather ironical fact that a committee of the association is about to visit the United States with a view to formulating a report on the possibilities of the improvement of cotton growing, harvesting, packing and shipment. It may be news to many that American cotton is packed and shipped in the most slovenly and wasteful manner of any in the world. Egypt and India are miles ahead in this matter.

The immediately preceding remarks may appear to have little bearing on the machinists' and toolmakers' business, but, more probably than any other class, are the people interested in these branches of work influenced, favorably or otherwise, according as the raw materials of industry are, or are not, available in sufficient quantity at the right price and right time. In a further letter I hope to give some details of British activity in toolmaking and engineering generally.

Manchester, Eng., November 23, 1906. JAMES VOSE.

THE AUTOMOBILE INDUSTRY OF ITALY IN 1906.

The automobile industry in Italy, though dating only from five years ago, continues to develop and increase in importance so rapidly that it is recognized and valued as one of the larger industries of Italy. Great strides have also been made in the mechanical arts, especially in the manufacture of machine tools. Official statistics of the automobile industry in Italy are as yet few, but it is very instructive to note some returns published lately by the eminent engineer, Prof. Effen Magrini.

From these may be seen that previous to the year 1905 there were only nine manufacturers of automobiles in all Italy, with a total effective capital of about 85,000,000 francs (17,000,000). During the year 1905 this number was increased by twenty-five with a capital of 45,000,000 francs ($9,000,000), and in the first six months of 1906 seventeen more companies were founded with an effective capital of about 100,000,000 francs ($20,000,000).

Over and above this must be counted the carriage manufactories, which in July, 1906, numbered 19 with a capital of about 24,000,000 francs ($4,800,000), and the other industries connected with automobiles, such as the manufactories of chassis, lamps, lubricators, tires, brakes, etc., the garages for testing and repairing, amounting to 30 firms, with a capital of about 24,000,000 francs ($4,800,000).

Examining the number and value of the automobiles imported and exported in the last five years, we find that from 1900 till 1903 the imports were 1,070, with a value of 8,402,548 francs ($1,680,510); in 1904 the imports were 410, with a value of 4,110,860 francs ($822,172); and in 1905 the number imported was 667, with a value of 6,239,000 francs ($1,247,800). For the present year, 1906, it may be safely assumed that the figures will be: 1,200 automobiles imported, corresponding to the sum of 12,000,000 francs ($2,400,000).

With regard to the automobiles exported, the figures are: From 1900 to 1903, 98, with a value of 894,750 francs ($178,950); in 1904, 127, value 1,112,560 francs ($222,512); in 1905, 287, value 3,646,000 francs ($729,200); and this year the number exported will be about 462, with a value of 6,450,000 francs ($1,290,000).

After France, the United States does the largest trade with Italy in the automobile business; in the year 1904, for example, of 410 automobiles imported in Italy, 304 were from France, 48 from the United States, 43 from Germany, and 15 from other European countries. Of 126 exported, 70 were sent to France, 24 to the United States, 15 to Austria-Hungary, 7 to South America, and the remainder to other parts of Europe, Asia and Africa. Perhaps we may account for active business relations between Italy and the United States in this branch of industry by the great demand in the Italian market for American machine tools. I. E. T.

Milan, Italy, December 1, 1906.

MISCELLANEOUS FOREIGN NOTES.

HIGH-TENSION CONDUCTORS.—At the Milan exhibition experiments were undertaken with insulated cables manufactured by Pirelli & Co., Milan. These cables were tested to breakdown, which occurred at voltages varying from 208,000 to 210,000 volts. Pirelli & Co. claim to be the first makers of cables for commercial use intended to withstand such high pressures.

THE MACHINE TOOL TRADE BUSY AND PROSPEROUS IN GERMANY.—According to *Zeitschrift fur Werkzeugmaschinen und Werkzeuge*, the German machine tool builders are very busy at the present time and the business is in a prosperous state. In many places it has been necessary to work overtime even during the summer months, although this has sometimes met with objections on the part of the men. Wages have increased from 10 to 25 per cent, due mainly to the increasing difficulty of securing skilled help.

THE ALLGEMEINE ELEKTRICITÄTS-GESELLSCHAFT, with works at various places in Germany, reports for the year ending June 30, 1906, a growing business. The total capital has been increased by $3,500,000 to $25,000,000, on which, for the past year, a dividend of 11 per cent is proposed. The output of machines, electromotors and transformers was numerically greater by 34 per cent than in the previous year, the increase reckoned in kilowatts was 26 per cent, and in value the receipts were greater by about 20 per cent. The total number of the employes was 33,906, as compared with 30,366 in the previous year.

WEBSTER & BENNETT, LTD., Coventry, England, have recently brought out a two spindle high speed drilling machine intended for drilling holes with small center distance. The machine is designed for obtaining the maximum work from ½ inch to 1½ inch high-speed drills. The minimum center distance between the spindles is 4 inches, and the maximum distance 18 inches. The maximum distance between the spindle and the table is 24 inches. The spindles are fitted with a No. 4 Morse taper. The table is of the usual form for this class of machines with T-slots on the top as well as on the vertical front face. The table is 24 inches square, and the height of the vertical face is 20 inches. The two spindles are independent as to drive and feed.

JOHN LANG & SONS, Johnstone, N. B., have brought out a 36-inch facing and boring lathe fitted with their patent variable speed drive and automatic speed changing mechanism. With these in operation, when facing work, such as cylinder covers, faceplates, etc., the revolutions of the spindle automatically increase as the diameter being turned becomes smaller. The hexagon turret is fitted for carrying ordinary or special tool holders. The self-acting feed motions are positive and four different feeds may be had without stopping the lathe. When specially ordered eight feeds may be provided which can be thrown in without interrupting the work on hand. The standard feeds per revolutions of spindle are 1/4, 1/8, 1/12 and 1/16 inch. The approximate floor space required is 12 x 5½ feet.

IMITATION OF DAMASCUS GUN BARRELS BY BELGIAN MANUFACTURERS.—According to a report from Consul J. C. McNally, Damascus gun barrels are imitated so closely by Belgian manufacturers that the imitation is very difficult to detect. The manufacturers in practicing this deception use silk paper, and by

means of a decalcomania transfer, this design is attached to the plain barrel by the use of certain acids and processes which are kept secret. It is almost impossible for any one not thoroughly familiar with the manufacture of these guns to distinguish between the real and the imitated Damascus barrel. In order to make a test it is necessary to erase the design. If an imitation, the design cannot be restored, but if the Damascus is genuine the application of sulphuric acid will immediately bring out the original design. According to the consular report 200,000 barrels are annually manufactured with this imitated design. Most of them are sent to the United States and to South America. Double-barrel shot guns are usually the only kind thus imitated.

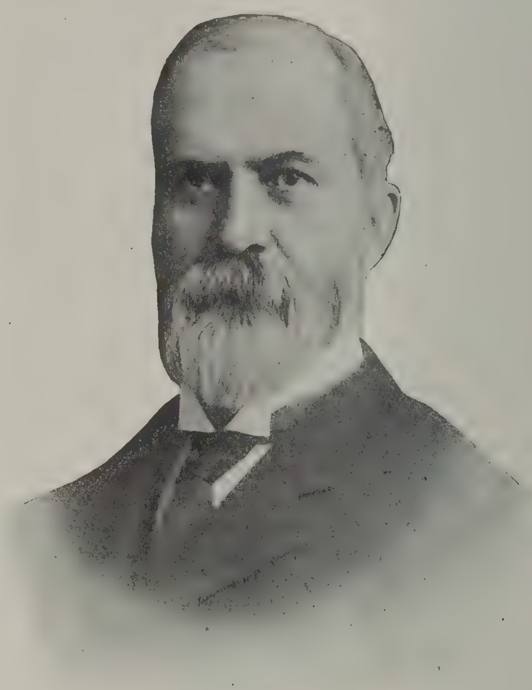
American Machine Tools in Great Britain.—Consul Albert Halstead, of Birmingham, advises that the market for standard American machine tools gained in the United Kingdom and the Continent through their superior excellence, is threatened, chiefly because of the inability of American manufacturers to make reasonably early deliveries. Because of the present long delays in filling orders for American machine tools, British manufacturers are, to a large extent, buying tools that can be delivered immediately. British tool makers, who have heretofore pushed their own designs, noting the inability of American machine tool makers to fill orders promptly, as well as the financial success of several British firms in copying American tools, are now spurred on to make tools on American models. The delay in the delivery of any reputable American lathes and milling machines averages now from three to six months. Until quite recently these tools were kept in stock and a delay of six weeks was unusual. The delivery of universal milling machines is now made in from six to nine months and gear-cutting machinery often cannot be obtained under twelve months. When they cannot be assured of getting standard American machine tools promptly, British and other foreign manufacturers buy those they can secure as soon as ordered. If such substitute tools work well, they will naturally order similar tools when they require more, which means permanently lost trade for the American tool builder. Every machine tool-making industry in the United Kingdom is reported to be overhauling its patterns and bringing them up to date; in short, the British tool makers are Americanizing their tools.

* * *

OBITUARY.

Henry J. Hendey, president of the Hendey Machine Co., Torrington, Conn., died at his home in that town December 8 after an illness of several weeks with a complication of diseases, principal of which was nervous exhaustion. Mr. Hendey was born in London, England, December 29, 1844. He came to this country with his father in 1858, and located at Waterbury, where he learned the machinist's trade. In 1865 he went to Torrington (then Wolcottville) and entered the employ of the Turner & Seymour Co. as a machinist. In 1870 Mr. Hendey in company with his brother Arthur started in business for himself in a small machine shop on Litchfield Street. The motive power of the shop was a small rotary steam engine of three horsepower which had been built by Mr. Hendey for amusement. The engine has been carefully kept and is now to be seen in the power plant of the Hendey Machine Co. alongside of the 500-horsepower Harris-Corliss compound engine driving the present shop. At first the business of the brothers in the original 18 x 24-foot shop was principally repairing machinery, but they soon began building planers and other machine tools, and in a few months the work had increased so that they employed one man and a boy. In 1871 the brothers removed to part of a factory known as the East Branch spoon shop, and later, in 1874, the Hendey Machine Co. was organized with a capital stock of $16,000. A factory was built on the present site near the Coe Brass Works. The growth of the business of the company has been rapid, both in the United States and abroad; the Hendey-Norton lathes are favorably known wherever machine tools are used. The shops are modern, up-to-date structures, with electric drive throughout, and about 600 men are now employed. In the early part of their career the company built planers, but the planer business is now discontinued, and the product is confined to lathes, shapers and milling machines, the milling machine having been added to the product a few years ago. The present capital stock of the company is $300,000. Mr. Hendey had been president of the Hendey Machine Co. since 1883.

Mr. Hendey was prominent in the local affairs of Torrington; he was the first warden of the borough and afterward served as burgess. Later he was elected a member of the State Legislature, where he was made one of the committee of manufactures. For many years he had been a senior warden of Trinity Church, and he was a past master of Seneca Lodge,



Henry J. Hendey.

No. 55, F. & A. M. Until only recently he took an active part in the local affairs, and always stood for those things which helped to make the community stronger and better. His way of looking at public matters was broad and just. The struggles of his early life developed within him a vigorous habit of thought and action, but no inclination toward anything except absolute justice. Mr. Hendey was a great lover of his home and found there the principal source of the joy of living.

Arthur R. Jones, superintendent of the American & British Mfg. Co., Bridgeport, Conn., died suddenly October 11 after a few hours illness. Mr. Jones was about forty years old and was born in Willimantic, Conn.

Henry C. Clark, president of the Clark Bros. Bolt Co. and the Aetna Nut Co., Southington, Conn., died December 4 of pneumonia at the age of 78. Mr. Clark was one of the pioneers in the bolt and nut business.

Wallace J. Johnson, for the last twenty years with the Niagara Falls Hydraulic Power & Mfg. Co., died at Niagara Falls, December 15, at the age of 50 years. He was born in Granville, Mass., and was a well known civil and hydraulic engineer.

Edward Payson Bullard, Sr., president of the Bullard Machine Tool Co., died suddenly December 22 at Braidentown, Florida. He left Bridgeport December 19 in apparent normal health for his regular Southern trip. A biographical article on Mr. Bullard will be published in a later issue.

B. H. Warren died of apoplexy October 20, in New York City. He was at one time vice-president of the Westinghouse Electric and Manufacturing Co., and later president of the Allis-Chalmers Co. Upon his retirement from the latter company he entered into consulting work in company with Messrs. Kafer and Mattice in New York.

* * *

PERSONAL.

Frank H. Taylor has been elected vice-president of the Yale & Towne Mfg. Co. Mr. Taylor was formerly vice-president of

the Westinghouse Electric & Mfg. Co. and is still a director of that company.

Henry G. Judd, for five years secretary and superintendent of the Mattatuck Mfg. Co., Waterbury, Conn., has resigned to become superintendent of the Noera Mfg. Co., of the same place.

On January 1 Mr. H. H. Lane, who has been editor of *The Foundry*, since October, 1903, will sever his connection with the Penton Publishing Company to engage in the practice of consulting foundry engineering with headquarters in Cleveland. Mr. Lane also expects to have New York connections, and will be in a position to advise on all classes of foundry construction and foundry metallurgy, including gray iron, steel and malleable. He will continue his position as secretary of the Foundry Supply Association for the present, and devote a much larger amount of his time to the work of the association than would be possible under the former management. This will redound to the success of the convention of the American Foundrymen's Association in Philadelphia, May 20 to 24 next. Mr. A. O. Backert, formerly Pittsburg editor of *The Iron Trade Review* and later western editor of *The Iron Age*, with headquarters in Chicago, will succeed Mr. Lane as editor of *The Foundry*. Mr. Backert has had a wide acquaintance among foundrymen, and was prominent in the work of the Pittsburg Foundrymen's Association for several years.

* * *

THE VALUE OF HAVING A FIRM NAME WELL-KNOWN.

In these days of advertising generally by concerns in all sorts of businesses, one is occasionally found which conservatively holds to the old idea that the best kind of an advertisement is a satisfied customer. While this idea is true enough, it has the fault of not being the whole truth. The satisfied customer does not usually go about the country drumming up business for the firm which filled his orders, although he may recommend it, perhaps, whenever occasion seems fit. Parenthetically we might remark, however, that a satisfied customer is usually quite willing that any competitor shall remain very much in the dark about the source of his machinery or other equipment if it can be conveniently concealed, and so far as "blowing a horn" for the builders of such he is more likely to discourage all inquiries. We speak from knowledge in view of our experience oftentimes in trying to get the names of builders of special machinery. As regards advertising it is worth much for any concern to get its name so well established that it can scarcely be quoted incorrectly. Bearing on this point, we recently published a short article describing a piece of engineering work done by a concern which claims to believe that doctors, lawyers and engineering concerns should follow about the same code of ethics, *i. e.*, depend upon the drumming for business done by their friends. Unfortunately and very much to our own vexation the name of this concern was given incorrectly. That it was given incorrectly is not so surprising, for we are unable to find in any publication coming into this office an advertisement containing the name of the concern in question although it is a fairly well-known institution in a restricted field. The point to be made is that while we were not by any means entirely dependent upon memory for the correct name we depended upon it in the absence of more convenient reference and this proved to be faulty, and the same mistake might have happened with a prospective customer. That this slip could have happened with one of many other engineering concerns which have followed a liberal policy in the matter of advertising is scarcely possible. How such desirable publicity shall be obtained is a matter that has to be decided individually.

* * *

FRESH FROM THE PRESS.

Proceedings of the 14th Annual Convention of the National Railroad Master Blacksmiths' Association. 203 pages, 5½ x 8½ inches. Illustrated. Edited by A. L. Woodworth (Secretary N. R. M. B. A.), Lima, Ohio.

This is a report of the proceedings of the 14th annual convention held at Chicago, Ill., August, 1906.

Ready Reference Tables and Price List for Railway Car Men. Pamphlet 6 x 9 inches. Published by McConway & Torley Co., Pittsburg, Pa.

The pamphlet is a compilation of tables beginning with a list of M. C. B. couplers giving weights and prices; then follow parts of freight cars; wheels and axles; cost of helical springs at 3½ cents per pound; cost of cast iron at 1¾ cent per pound, etc.

Historic Locomotives. By Alfred R. Bennett. 36 pages, 9¾ x 13½ inches. 10 full-page plates. Published by Castle & Co., Ltd., London, England, and Derry-Collard Co., New York. Price, $1.00.

The book describes and illustrates the Great Western Railway Co.'s broad-gage engine "Great Western"; London & South-Western Railway Company's four-coupled engine "Milo"; London, Brighton & South Coast Railway engine No. 122; Caledonian Railway 8-foot single driving wheel engine No. 83; Bristol & Exeter Railway Co.'s 9-foot driving wheel broad-gage engine No. 42; North British Railway engine No. 224; London, Brighton & South Coast engine No. 111; London & North-Western Railway engine "Prince of Wales" No. 291; outside cylinder Crampton locomotives and inside cylinder Crampton locomotives, South-Eastern Railway. The plates are gorgeously colored, the like of which we are inclined to say "was never seen on land or sea," but the author assures us that the colorings are faithful reproductions of the originals. As a picture book it will undoubtedly attract considerable attention, but to the practical railroader it has little interest.

Switchboards. By William Baxter, Jr. 192 pages, 5½ x 7½ inches. 150 illustrations. Published by the Derry-Collard Co., New York. Price, $1.50.

The importance of the switchboard in any electrical plant is so obvious that it is unnecessary to dwell upon it. The book in review is intended to be a practical description of the instruments, their method of connection and location; the things to be avoided; how to connect machines; how to balance on the three-wire system; connecting in parallel; and the many other features connected with the switchboard which have to do with the operation of a power plant. The work is profusely illustrated with drawings and half-tones and is written by one who by many years of practical and theoretical experience is well qualified to write a book of this character. His writings have the characteristics of lucidity of style and clearness of meaning which make them very popular with the class of readers to whom this book will appeal.

Practical Metal Turning. By Joseph G. Horner. 404 pages, 5½ x 8 inches. Illustrated with 488 cuts. Published by Norman W. Henley & Son, New York. Price, $3.50.

This work is the same as Engineers' Turning, reviewed in this column in October, 1905. It is intended to be a compendium treating in a comprehensive manner on the modern practice of machining metal parts in the lathe, including the engine lathe, its tools, attachments, manner of holding the work and performing the operations. It is decidedly British in its tone, as would naturally be inferred from the authorship, and the fact that the work was originally published in Great Britain by Crosby Lockwood & Son, London; Norman W. Henley & Son, New York, have brought out an American edition, believing that it will meet with favor among a considerable number. It is a work of value containing as it does much practical instruction and many good shop kinks for apprentices and journeymen machinists. The style is clear and simple; the book is gotten up in substantial style, well printed and well bound.

Walschaerts Locomotive Valve Gear. By W. W. Wood. 193 pages, 5 x 7 inches. Illustrated with 36 cuts and diagrams with two separate cardboard models of valves in pocket of book. Published by Norman W. Henley & Son, New York. Price, $1.50.

The book is composed of four general divisions, the first of which explains and analyzes the Walschaerts valve gear; the second takes up designing and erection; the third has to do with the actual work of the Walschaerts gear; and the fourth section is composed of questions and answers in the popular catechism style. The wide interest at the present time in the Walschaerts valve gear, due to its introduction in American locomotive construction, makes the appearance of this book timely, and it should meet the wants of a considerable class of railroad men who are looking for a practical work on the subject. The folding diagrams with cardboard valve models, by which the actual operation of the valve under the influence of the Walschaerts motion can be studied, is a novel and interesting feature.

Tools for Machinists and Woodworkers. By Joseph G. Horner. 340 pages, 5¼ x 7¾ inches. 406 figures. Published by Norman W. Henley & Son, New York. Price, $3.50.

The object of this book is to comprise a general description and classification of cutting tools, together with modern instruments of measuring. It takes up tool angles, and gives considerable space to the conditions affecting the cutting action of woodworking tools, including knives, chisels, planes, etc. Then follow scraping tools, tools related to both chisels and scrapers, percussion and molding tools, hardening, tempering, grinding and sharpening tools for measurement and testing, etc. Mr. Horner is a well-known English writer on technical subjects; he has done an enormous amount of this kind of work for various English technical publications and in books of his own. The work is gotten up in attractive style and will no doubt interest a large class of amateur readers who desire information on the fundamental principles of cutting tools. Mixed in with it all there is a great deal of information of value to the journeyman machinist, carpenter and other tradesmen having to do with the use of cutting tools and tools of precision.

Practical Lettering. By Thomas F. Meinhardt. 16 pages, 9 x 14 inches, bound in paper. Published by Norman W. Henley & Son, New York. Price, 60 cents.

Ths work describes an original system for spacing which results in a superior appearance of lettering, especially when of the block type. Probably all draftsmen have noticed that uniform spacing between block letters does not give a good appearance. For example, the letters H I N in the word "WASHINGTON" will be too close together with a uniform system. Meinhardt's system gives variation in spacing for Gothic style or any variety of plain letters without shade. The height of the letter is divided into 16 parts, and one of these parts is taken as the unit of spacing, the chart giving the number of units to be used between any combination of letters. For example in the word WASHINGTON, instead of using a space between H and I corresponding to the width of the main stem of the I, as would naturally follow with the ordinary system of spacing, the space is made four units or twice the width of the stem. The work is one well worth the attention of those interested in ornamental and practical lettering.

Punches, Dies and Tools for Manufacturing in Presses. By Joseph V. Woodworth. 483 pages, 6 x 9 inches. 702 illustrations. Published by Norman W. Henley & Son, New York. Price, $4.00.

This work is gotten up in the same style as Mr. Woodworth's former book on dies—"Dies, Their Construction and Use, etc."—and is intended to be a companion and reference volume to accompany same. This book devotes much attention to sub-press work which is coming to be of more and more importance as improved methods of manufacturing such machines as typewriters, computers and similar products are developed. The sub-press principle makes each combination of punch and die a unit which may be brought into use at any time without the need of an expert to set up the press. Its general use tends to greatly simplify press working. A large part of the work has already appeared in the columns of the trade papers, having been contributed by various writers. The work is therefore largely one of compilation, aided by the author's expert knowledge on the subject. The book is timely and is one that should be appreciated by diemakers and others interested in modern methods of interchangeable manufacture of machine parts.

CONTENTS FOR JANUARY.

Engineering in the United States. By Frank Foster. 115 pages, 5¾ x 9 inches. Published by the University Press, Manchester, England.

This book is essentially a report made by Mr. Foster, who was a Gartside Scholar of the University of Manchester. Gartside scholarships were established in 1902, being open to certain university students to enable them to travel abroad and study existing industrial conditions in Germany Switzerland and the United States. This work is an account of Mr. Foster's experience in the United States and is a very readable and interesting work, although few Americans will read it and agree with all that Mr. Foster has said. It strikes one who is well acquainted with American conditions that some of Mr. Foster's observations are superficial and in some cases have illustrated what we presume is the traditional British lack of humor, especially when he dilates on the relations of superintendents and their men. However, the work as a whole gives evidence of very careful and systematic investigations of our industrial conditions. The writer not only visited many shops but worked in many as an ordinary workman for wages without favor, hence he was "up against the real thing."

Modern American Machine Tools. By Prof. C. H. Benjamin, 320 pages, 5½ x 9 inches. 134 illustrations. Published by Archibald Constable & Co., London.

This work was compiled by Prof. Benjamin, of the Case School of Applied Science, Cleveland, Ohio, at the instance of the London publishers, for the purpose of conveniently acquainting Europeans with the general characteristics of the American machine tools. It is consequently gotten up with this in mind and is a sort of amplified catalogue giving features of the various American lathes, planers, radial and upright drills, shapers boring mills, milling machines, gear cutters, grinding machines, key-seaters, punching and shearing machinery, etc., with brief descriptions derived from the author's knowledge and various catalogues, together with what has been published in the technical press. The work is gotten up in fairly good style considering the difficulties of such a work. A compilation of this sort should be of much value to a considerable class, not only abroad but here as well, who are desirous of being posted on the general characteristics of various machine tools and to obtain the matter in convenient form for reference. We should expect that its use in certain engineering schools will follow, where it is desired to give the students an idea of the scope and importance of the modern American machine tool.

The leading feature in the January issue of the *Century* is Mr. Roosevelt's latest essay, "The Ancient Irish Sagas." Other contributors of noteworthy papers are Cardinal Gibbons and Prof. Henry Fairfield Osborne. The serial story, "The Shuttle," by Miss Burnett, is continued, and the issue abounds with numerous short stories and fine art features.

NEW TRADE LITERATURE.

Fulton Machine and Vise Co., Lowville, N. Y. Catalogue of the Reed universal, vertical and horizontal swivel vise. The jaws and both swivels are clamped with one operation of the lever.

The New Era Mfg. Co., Kalamazoo, Mich. Booklet, "All About Babbitt Metals," containing valuable information for superintendents and master mechanics on the subject of babbitt metals.

The Car Interchange Manual, published by McConway & Torley Co., Pittsburg, Pa., and which was reviewed in the December issue, is sent free on request to those interested. We mentioned the price of 25 cents, but the distribution is free.

Ingersoll-Rand Co., 11 Broadway, New York. Form X 36 entitled Rand "Imperial," Type 10, Air Compressors giving a detailed description of the more important parts of the compressor and containing many half-tone and sectional drawings of the machine.

T. R. Almond Mfg. Co., 83 Washington Street, Brooklyn, N. Y. Pamphlet describing Almond adjustable electric lamp fixtures, and telling of some of their varied uses. These fixtures are flexible, being constructed in a way similar to the well known Almond flexible tubing.

Joseph Dixon Crucible Co., Jersey City, N. J., have published a booklet calling attention to the advantages of Dixon's Ticonderoga flake graphite as a cylinder lubricant for air compressors. Those who are interested in air compressors or drills should obtain a copy.

The Mark Flather Planer Co., Nashua, N. H. Bulletin No. 7 on Flather planers describing and illustrating the different types. The first page contains a general description of their product, detailed specifications of which will be submitted upon request.

E. W. Bliss Co., 5 Adams Street, Brooklyn, N. Y., 1906 catalogue describing and illustrating the various dies, presses and special machinery built by this company. It contains 578 pages, among which is included an alphabetical index of the subject matter.

Geo. V. Cresson Co., Philadelphia, Pa., have issued catalogue B for 1906 on power transmitting machinery. It is a cloth-bound book containing 349 pages, including many useful tables and illustrated by excellent engravings. A complete index of the contents is given in back of book.

The Abrasive Material Co., Philadelphia, Pa. Illustrated catalogue for 1907 of emery and corundum wheels. Descriptions of the product together with price lists are given. The materials used by this company are constantly being tested and thus a high standard of efficiency is maintained.

The Hisey-Wolf Machine Co., Cincinnati, Ohio., have redesigned their line of portable electrical hand drills and have succeeded in reducing the weight of them considerably. This is a very desirable feature in portable tools, as the lighter they are the less they will tire the user in handling them. The company now have in press a new catalogue of their newly designed portable electrically driven drills.

The Bridgeport Safety Emery Wheel Co., Inc., Bridgeport, Conn. New catalogue for 1907 treating of emery wheels and grinding machinery. The book calls attention to the changes which have been made in their former line of grinding machinery and illustrates other lines recently brought out. A new line of edge and surface grinders is being brought out which is not shown in this issue. Those interested may obtain blueprints and prices upon request.

Heinrich Dreyer, Berlin, Germany. Catalogue (in German) of machine tools and appliances, principally American. This handsomely illustrated catalogue lists and describes Bullard boring mills, Hendey-Norton milling machines, Whitcomb-Blaisdell lathes, Newton milling machines, Cincinnati tool grinders, Morse grinding machines, Garvin vertical milling machines, Hartford automatic screw machines, etc., and several other American machine tools; some foreign machines are also included.

The Reeves Pulley Co., Columbus, Indiana, have sent us an impressive list of the large metal working concerns using the Reeves variable speed transmission. These names include The Western Electric Co., Chicago, Ill.; American Tool Works Co., Cincinnati, Ohio; American Car & Foundry Co., Detroit, Mich.; Atlas Engine Works, Indianapolis, Ind.; G. A. Gray Co., Cincinnati, Ohio; Niles Tool Works Co., Hamilton, Ohio; Westinghouse Electric & Mfg. Co., Pittsburg, Pa., and many others.

The New Process Raw Hide Co., Syracuse N. Y. Catalogue of raw hide pinions giving a hint of the difference between the "New Process" and other raw hide gears. The catalogue contains a price list of pinions from 2 inches to 15 inches outside diameter and 1 inch to 10 inches face. It also contains a partial list of prominent users of the "New Process" pinions. The catalogue is sent out in a strong manila "wallet" which will be found convenient for carrying papers in the pocket, for which it was designed.

Gisholt Machine Co., Madison, Wis. Catalogue of the Gisholt universal tool grinder, and Gisholt lathes and boring mills. This handsomely gotten up piece of advertising literature is principally devoted to the Gisholt grinder illustrating the loss of time and productive effort which follows the old method of each individual machine operator grinding his own tools. It contains a reduced view of the chart which accompanies each Gisholt grinder, showing the correct angles for grinding lathe tools, and other matters of interest to machine shop managers.

MANUFACTURERS' NOTES.

The Wm. W. Gang Co., Cincinnati, Ohio, are making extensions and improvements in their factory which will give them about 3,500 square feet additional floor space.

The Hisey-Wolf Machine Co., Cincinnati O., advise that they have received from Washington a diploma and honorable mention on their exhibit of portable electrical drills and grinders, at the Liege, Belgium exhibition.

The Queen City Punch and Shear Co. are now located at 208-212 Lawrence St., Cincinnati, O. and will soon be ready with a full line of punches, shears and straightening and bending machines. Mr. C. F. Mayer is president of the company and C. F. Heinss is secretary and treasurer.

The Mueller Machine Tool Co., 216 W. Pearl St., Cincinnati, Ohio, have been incorporated, and the company will erect a new and up-to-date machine shop at Colerain Avenue, near Draper Street, to accommodate their increasing business. It is expected that the new shop will be completed some time next spring.

The International Railway Master Boiler Makers' Association and the Master Steam Boiler Makers' Association meet in joint convention at Cleveland, Ohio, May 21, 22 and 23, 1907, to organize one grand body of foremen boiler makers. Further information may be obtained from the secretary of the latter association, Mr. J. H. Smyth, 284 Totowa Avenue Paterson, N. J.

J. H. Wagenhorst & Co., Youngstown, O., have recently made the following sales of blueprinting machines: Oklahoma City Railway Co., Oklahoma; Ohio State University, Columbus O.; G. D. Peters & Co., Moorgate Works, London, England; Griffin Wheel Co., Chicago, Ill.; Alvey-Ferguson Co., Louisville, Ky.; New England Structural Co., Boston, Mass.; Eugene Dietzgen Co., Chicago, Ill.; American Steam Pump Co., Battle Creek, Mich.

The Billings & Spencer Co., Hartford, Conn., have decided to open a Canadian branch for the manufacture of drop forgings and drop forging machinery. It will be known as the Canadian Billings & Spen-

RAILWAY MACHINERY.

A special edition of MACHINERY devoted to Locomotive and Car Equipment and Mechanics.

February, 1907.

THROUGH THE SIMPLON TUNNEL.

A. R. BELL.

The new trans-Alpine route between Switzerland and Italy effected by the completion of the Simplon Tunnel has been one of the most notable engineering triumphs of the country. This road forms the sixth railway route over the Alps. The first tunnel constructed was that between Austria and Styria in 1848 on the railway through the Semmering pass. This line forms the through route between Vienna and Venice. The Semmering tunnel is less than a mile in length, but long and severe grades have to be encountered on either side to reach it. The Mont Cenis followed next in 1861-1870, about 7¾ miles long. The expresses from Paris to Turin and Rome are the principal ones traversing it. Then came the Arlberg between Switzerland and the Tyrol, about 5 miles long. The Brenner route was opened in 1867, but has no very long tunnels. A great undertaking was completed in 1882 by the opening of the St. Gothard, 9¼ miles long, and which took 10 years to construct. The scenery on this route is the grandest of any, and several viaducts, galleries, and shorter tunnels had to be provided before the main one could be reached. Surpassing the St. Gothard in length by over three miles, the tunnel just completed through the Simplon will prove of immense benefit to the district of Italy, of which Milan is the chief city. It is over 12½ miles long and has occupied 6½ years in building.

Fig. 1. Freight Train Approaching the Simplon Tunnel.

Fig. 2. Paris-Milan Express with Steam Locomotive about to be Detached at Brigue.

Fig. 3. Paris-Milan Express at Brigue, with Electric Locomotive Attached and ready to Enter the Simplon Tunnel.

Fig. 4. Entrance to the Simplon Tunnel at Brigue.

The diligence road over the Simplon was constructed by order of Napoleon in 1805 mainly for military transport, but has been used during many years for tourist traffic. A magnificent triumphal arch in Milan commemorates the opening of the pass, and during the past year the opening of the tunnel has been appropriately acknowledged by the Milanese in a grand international exhibition.

The traffic through the Simplon tunnel is now entirely worked by electric power on the three-phase system, the current being derived from dynamos and turbines driven by water power. The power plants are situated at Brigue on the Swiss side and Iselle on the Italian. At these places the steam locomotives are detached and electric ones substituted.

The absence of the suffocating atmosphere met with in the St. Gothard and Mt. Cenis tunnels is very noticeable when going through the Simplon. The time taken to go through the tunnel is about 25 minutes.

The contract for constructing the tunnel was left to Brandt Brandau & Co. in 1898, and the start was made from both ends soon after. The estimated progress was at the rate of 32.35 feet per day, but the actual average advance was less than this. Early in 1901 considerable interruption was caused by an inrush of water from a spring. The cutting through was

completed in 1905 and the enlarging to necessary dimensions completed in six months. At present only one tunnel is finished, but the second one is partly made.

The entrance at Brigue is 2,250 feet above sea level, and that at Iselle 2,073 feet. The summit of the tunnel is almost exactly under the frontier line, and is 2,312 feet above sea level, with about 7,000 feet of solid mountain overhead. The gradient from the Swiss end is 1 in 500, and that from the Italian 1 in 143. There is a short level stretch near the middle. The extreme width of the completed tunnel is 16 feet, and the height 17 feet. Three thousand five hundred workmen were employed in its construction, and the estimate for cost was $13,490,000.

In the central station at Brigue there is one three-phase alternator rated at 1,200 horsepower at 160 revolutions per minute, but which is capable of supplying temporary overload up to 1,500 horsepower. It is driven from a main transmission shaft by two Escher-Wyss turbines, each of 600 horsepower; the fall is 146 feet. The alternator is excited from a 95 horsepower dynamo. An automatic regulator is provided to adjust the capacity of the water resistance in accordance with the load on the line, so that the alternator is always kept fully loaded and therefore no risk of any serious variation of speed. All the instruments and controlling apparatus are fixed on one board from which connections are made with the conductors and rails by means of overhead wires.

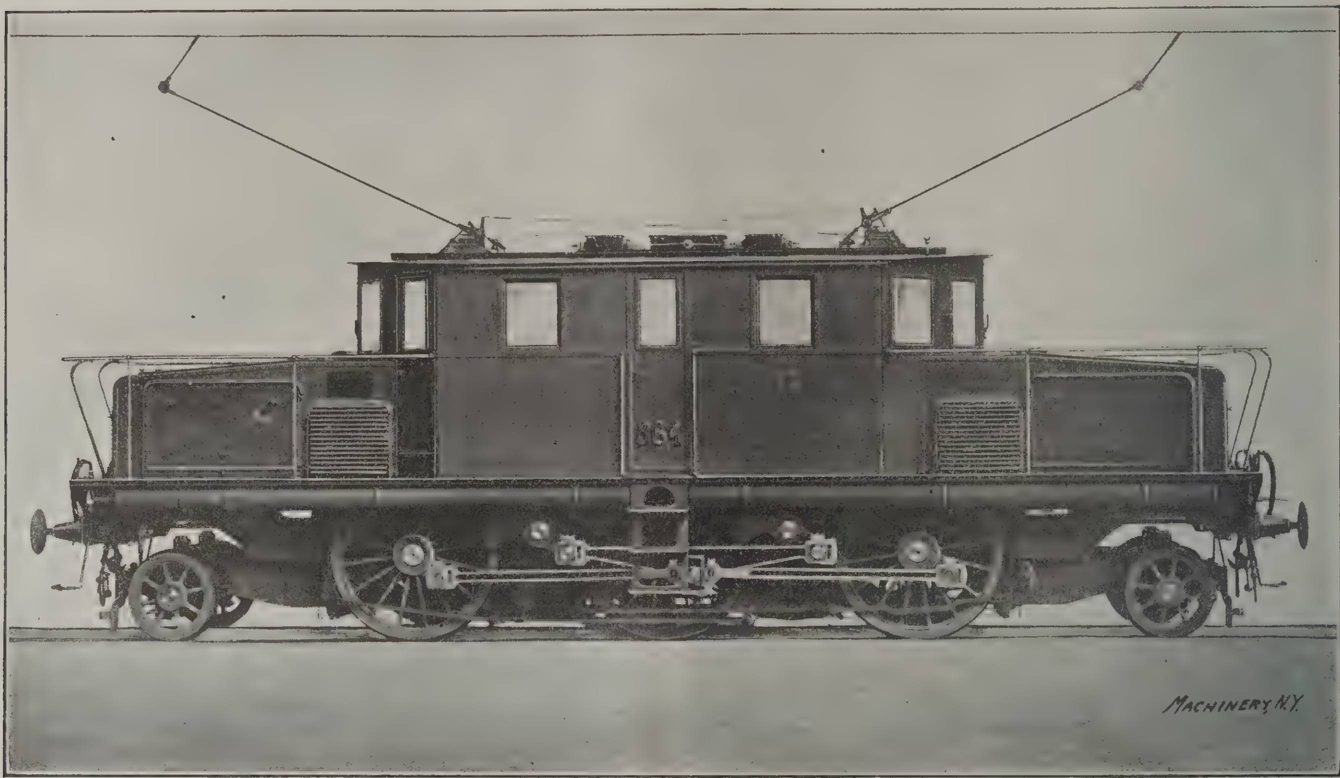


Fig. 1. Second Brown, Boveri & Co. Electric Locomotive in Use in the Simplon Tunnel.

Fig. 2. Ganz & Co. Electric Locomotive for the Simplon Tunnel.

At Iselle there is one three-phase alternator rated at 1,500 horsepower. It is direct coupled to a double-ended turbine from Picard & Pictet, of Geneva, each of the turbine units being capable of developing 750 horsepower. The set runs at 960 revolutions per minute with a fall of 460 feet, and is fitted with a sensitive governor which keeps the speed nearly con-

stant. This set can be overloaded up to 1,800 horsepower and even more. The excitation current is taken from a continuous current machine of 95 horsepower, and 125 volts, which was formerly used in the tunnelling operations.

The line is divided into five sections: 1. Brigue station to northern entrance to tunnel. 2. Northern half of tunnel. 3. Crossing in middle of tunnel. 4. Southern half of tunnel. 5. Southern end of tunnel to Iselle. Section switches are provided at Brigue, at Iselle, and in the middle of the tunnel. Telephonic communication enables the staff in charge to transmit orders.

The overhead line outside the tunnel is suspended on cross wires strained between steel poles placed on each side of the track. In the tunnel the conductors are carried on cross wires which go from one side to the other and are fixed by means of gun metal bolts cemented into the walls of the tunnel. The cross wires are fixed about 83 feet apart on the straight portions, and about 40 feet apart on the curves.

The rails themselves form the third conductor and have been bonded by a special system. The fish plates form the

Fig. 3. First Electric Locomotive for the Simplon Tunnel, built by Brown, Boveri & Co.

conductors. Perfect contact is insured by cleaning the joints with a sand blast and covering the contact faces with a special paste which prevents oxidation.

The locomotives are of the bogie type with five axles of which three are driven by motors. The motors are placed between the three pairs of driving wheels and both drive on the middle axle by means of a bar coupling them rigidly together. The axle in turn drives the other two by means of a coupling rod. The following are the leading dimensions of the locomotives:

Length between buffers............	40 feet 6 inches
Total length between axles..........	31 feet 10 inches
Distance between driving axles.....	16 feet 1 inch
Distance between bogies............	23 feet
Diameter of driving wheels........	5 feet 4½ inches
Diameter of smaller wheels........	2 feet 9½ inches
Weight on driving wheels..........	42 tons
Total weight......................	62 tons
Normal output of two motors.......	900 horsepower
Maximum output of two motors.....	2,300 horsepower
Normal speed..	42 miles per hour and 21 miles per hour
Drawbar pull at 42 m. p. h..	7,700 lbs. nor., 20,000 max.
Drawbar pull at 21 m. p. h..	13,500 lbs. nor., 31,000 max.

The traction motors are each rated at 450 horsepower and work with three-phase current at 2,700 to 3,000 volts. Their momentary overload capacity is as high as 1,150 horsepower per motor at the higher speed. At the lower speed they are rated at 390 horsepower, but can be overloaded continuously up to 575 horsepower.

THE SIMPLON TUNNEL ELECTRIC LOCOMOTIVE EQUIPMENT.

FRANK C. PERKINS.

The Simplon tunnel is about 12.5 miles in length and is the longest railway tunnel in the world. It was decided by the Swiss and Italian governments to operate trains through this great tunnel exclusively by means of electric power and the Swiss and Italian commissioners chose the three-phase high tension alternating current system as installed by Ganz & Co., of Budapest, Austria-Hungary.

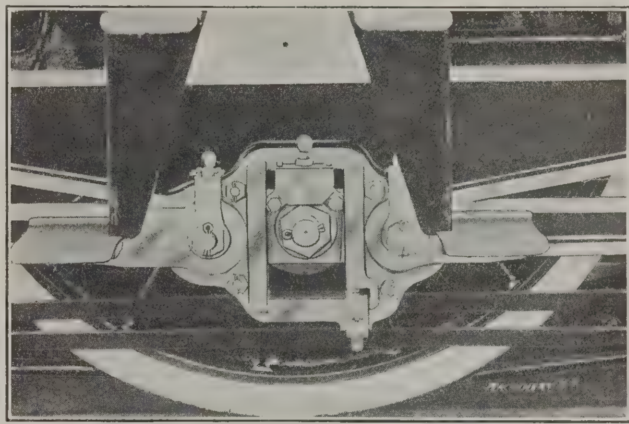

Fig. 4. Bearing of Connecting-rod and Side Rods on Middle Crankpin.

A most careful investigation was made of the various electric railway systems now in operation by the general director of the Federal railways, officials of the Swiss Post, as well as a special Italian and Swiss Commission for the study of electric traction, which included the well known engineers Thormann and Boveri, of Brown, Boveri & Co., of Baden, Switzerland.

After inspecting the electric lines and power stations in northern Italy, including the Morbegno hydro-electric plant, the Lierna transformer sub-station, the Valtellina railway and the Milan-Porto Ceresio electric line which uses the multiple unit system, with current supplied from the Tornavento power house and the Galarato sub-station, a decision was made.

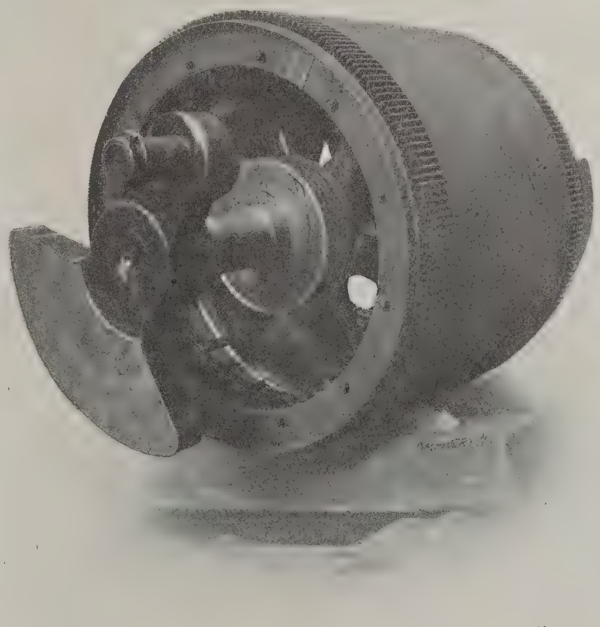

Fig. 5. Rotor of Brown, Boveri & Co. Electric Locomotive.

The accompanying illustrations show the construction of the Ganz & Co. Simplon Tunnel locomotive, also the first 1,000-horsepower Simplon locomotive No. 365, built at Baden, Switzerland, by Brown, Boveri & Co. and the Brown, Boveri Simplon locomotive completed at the time of the opening of the Simplon tunnel in 1906. The three-phase electric engine No. 365 is shown in end view; also the rotor of one of the motors, Fig. 5, is shown which develop normally 575 horsepower each with a maximum capacity of 1,150 horsepower. This gives a total maximum power of 2,300 horsepower for

this locomotive which is capable of hauling a heavy train of passenger cars through the tunnel at the rate of about 45 miles per hour. This latest type is 40 feet 5 inches long over the buffers and has a wheel-base of 16 feet for the driving axles and a total wheel-base measuring 31 feet 10 inches, while its weight is 124,000 pounds.

After a careful study of the details of construction of the new Ganz electric locomotives of the three-phase type, the motors and controlling apparatus as well as the track and overhead construction of the Valtellina railway, the sub-stations and power plant, it was considered best to adopt the

Fig. 6. Twin Motor of Ganz & Co. Locomotive.

three-phase system with a pressure of 3,000 volts and a frequency of 15 cycles per second. Trial runs were made for ascertaining the loads of the trains, the working of the electric locomotives on level track and while ascending and descending heavy grades. Tests were also made of starting and stopping heavy trains by this commission of 12 Swiss and Italian officials and electrical engineers.

There is every reason to believe that all of the steam railway lines in Northern Italy will soon be electrified, current being transmitted from hydro-electric stations in the Italian Alps. Electric locomotives have been decided upon as most satisfactory for the Simplon tunnel service on account of the ease of transfer of trains to and from steam-driven railway

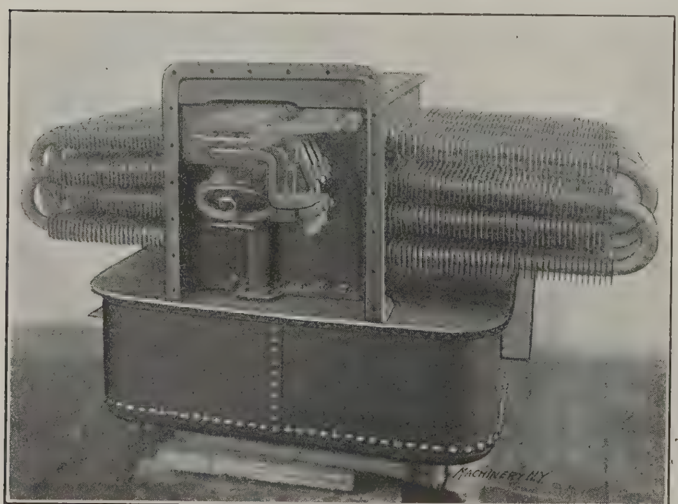

Fig. 7. Water Rheostat.

lines and the electrified railways, as it will undoubtedly be several years before all of the railways will use the electric power. Ultimately it may be found best to utilize motor cars more extensively instead of locomotives, but during the period of change from steam power to electric power the electric locomotive is considered to be the best, as more flexible, where both steam and electric systems of propulsion are in use.

The first six electric locomotives to be placed in service in the Simplon tunnel are of the gearless type, the wheel axles operating at the same rotary speed as the electric motors. These new locomotives have a double set of coupling rods and cranks with two pairs of motors connected in "cascade" and mounted, one pair on each shaft side by side. Each shaft runs in rigid bearings in the frame, the motors being mounted midway between the three driving axles with their centers about 9 inches above the level of the wheel centers, leaving space for an outside stator 1½ feet in diameter greater than if directly coupled to the axles. Each locomotive has a pair of very stiff coupling rods with direct connection by cranks to the two motor shafts.

Two balanced weights are provided for counteracting the weight and centrifugal force of each of the side-rods, these weights also balancing the motor shaft cranks. Dead points are avoided by having the cranks set at ninety degrees and secondary coupling rods are provided which exert horizontal driving forces upon the wheel crankpin.

In addition to the three driving axles these Simplon tunnel three-phase locomotives have each a trailing pony truck and a leading pony truck with a single axle and a pair of wheels 33½ inches diameter. These locomotives each weigh 124,000 pounds, the three driving axles each having wheels 60 inches diameter and carrying together about 84,000 pounds of the total weight of the locomotive.

* * *

SOME METHODS OF MAKING WROUGHT METAL CAR-WHEELS.

E. D. SEWALL.

In the fourth and fifth decades of the 19th century, while railroad transportation was still comparatively new, and the weight and strength of cars were being rapidly increased, the

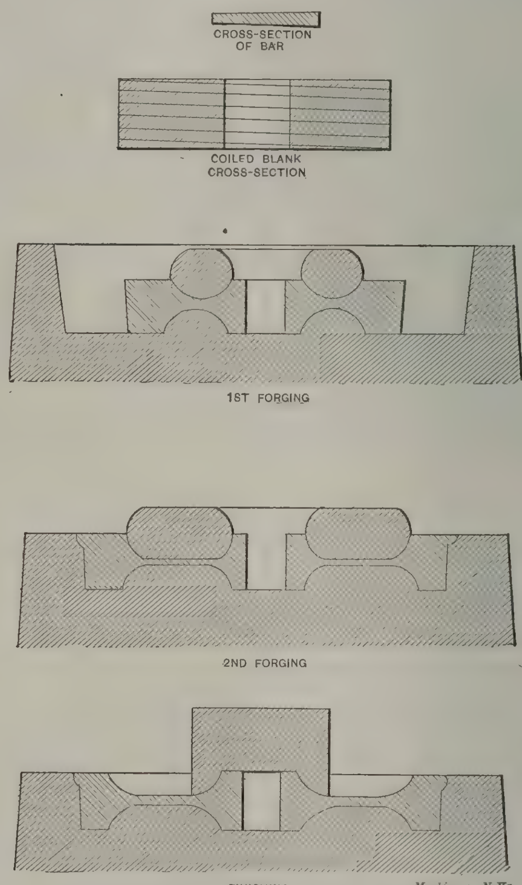

Fig. 1. Early French Method.

problem of making safe and durable car-wheels enforced itself upon engineers, and its solution was widely sought. Very naturally attention was then directed to the production of integral wheels of wrought metal, and although it would appear to be a simple enough matter to forge or press a car wheel, practical difficulties arose in attempts to make so comparatively large and complex a die-forging within reasonable cost and of such quality as to warrant intrusting to them human lives.

Successful methods of making car wheels of cast iron, suitable for the weights and speeds of that period, were then de-

vised, which destroyed for the time, and long postponed the demand for an integral wrought wheel, until, in recent years the higher train speeds, greater car weights, cheaper steel, and improved methods have encouraged the commercial manufacture of wrought steel car wheels of great durability.

One of the earliest methods of making wrought car wheels, patented in England, consisted in heating a circular slab of wrought iron, or a pile made of bars and scrap, thicker but of smaller diameter than the wheel, placing the slab in a die very roughly approximating the shape of one side of a car wheel and compressing or hammering it by means of a die of similar configuration. The rough shaped blank thus formed was repeatedly heated, placed in properly shaped dies, and hammered progressively all around by hammer dies having the shape of a sector of the wheel blank, and finally compressed at a low heat in a finishing die by a hammer of proper

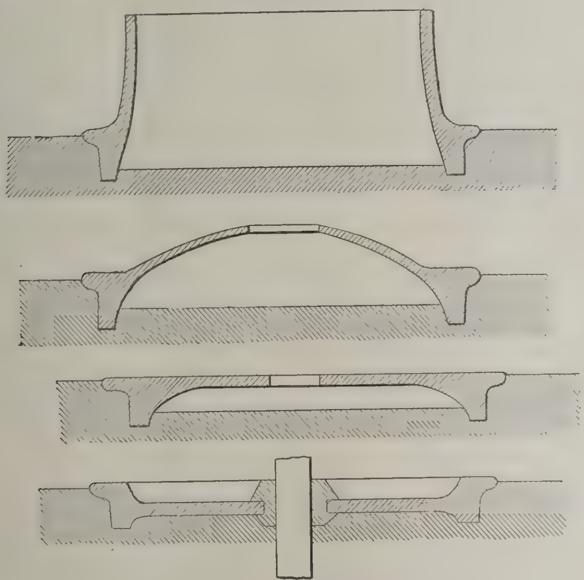

Fig. 2. Early English Method.

configuration. When the forged blank became cold the axle hole was bored and the tread turned in a lathe.

With the design of obtaining a wheel of very high quality, the following method, shown in Fig. 1, was developed in France near the middle of the last century. Rolled bars of iron or steel slightly wedge-shaped in cross-section were coiled upon a mandrel into rings having a weight about equal to that desired in the finished wheel. The bar was coiled so that its wide edge would form the outer surface of the coil. By so doing, the stretching of the outer edge and compression of the inner edge, due to the bending operation, thinned the

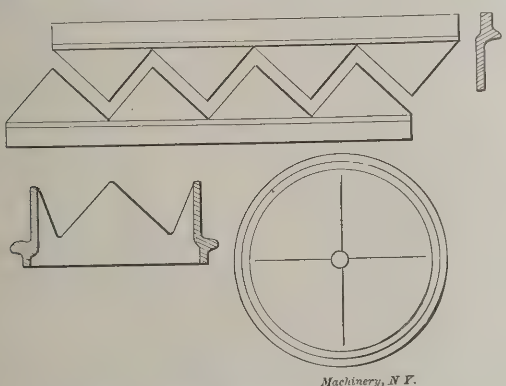

Fig. 3. English One-piece Welded Plate.

outer and thickened the inner edges so that the layers of the coil when wound would become of equal thickness and lie parallel, the wedge section being transformed into a rectangular section. The ring was then heated to a welding temperature and the layers welded into a solid annulus, which, by treatment in different dies, was expanded and forged into a solid wheel.

Another English method of making wrought car wheels from previously worked iron consisted in rolling a bar having a section which, on one edge, was that of the tread and flange of a car wheel, and the remainder of which was a plate of the thickness of the web and of a width equal to the radius thereof, but lying in a plane parallel with the tread surface, instead of perpendicular thereto, as in the finished wheel. See Fig. 2. A suitable length of such bar was then bent into ring form and its ends welded together. The cylinder thus formed was then placed in a die shaped to conform to the tread and flange portions. The web portion was then bent

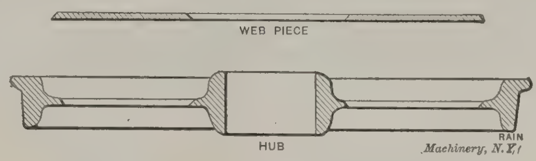

Fig. 4. French Three-part Wheel, Welded.

inward by means of cup-shaped drawing dies into the approximate shape of a car wheel but without a hub. A wrought metal tube was then inserted in the central opening and upset by properly shaped dies to the form of the finished wheel. The blank was then reheated and welded into one mass.

A similar English method (Fig. 3) consists in rolling a plate having a thickened tread and flange portion on each edge. From this plate two shapes, each suitable for making a wheel were sheared by a zigzag cut lengthwise of the center. Each shape thus formed had four triangular projections on one edge, the point of each projection forming an angle of 90 degrees, and on the other edge the thicker tread and flange portion. This scalloped bar was then bent and its ends welded together. The four projecting triangular portions were then bent inward and forced downward until the edges of the triangles met and formed the web of a wheel blank. A hub piece was then inserted and the whole heated and welded in suitable dies.

In order to avoid the difficulties incident to forging a large slab it was early proposed in France to separately produce a wrought hub, a wrought rim, and a web stamped from rolled plate, each having beveled edges to provide for lap-welding the

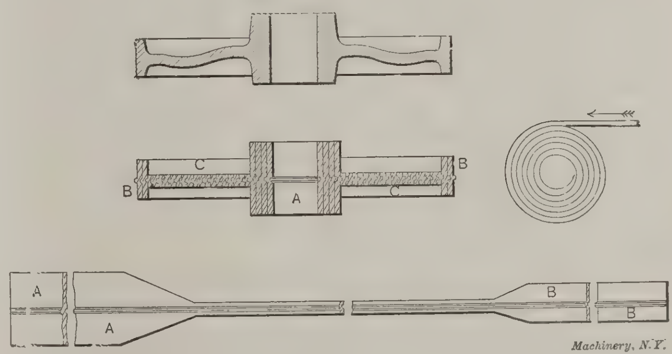

Fig. 5. Krupp Wheel Structure.

parts together. These three parts were then assembled in a matrix having the contour of the wheel, as indicated in Fig. 4, and the whole welded and finish forged into a wheel.

By the German Krupp method (Fig. 5) a long bar was rolled of a length sufficient when coiled upon itself to produce a disk equal in diameter to the intended wheel. Each end of this bar was wider than the main portion, one end, *A*, being of a width equal to the depth of the hub and the other, *B*, equal to the depth of the rim. This bar was preferably rolled with a groove on one side and a corresponding rib upon the other. It was then wound upon itself over a mandrel, the wider end forming the inner portion for the hub, the outer end forming the portion for the rim, and the intermediate portion, *C*, forming the web. The rudimentary wheel thus formed was heated white hot, placed in a matrix and welded and forged into a car-wheel for which great strength and durability has been claimed.

With the increasing use of steel as structural material, methods of making car-wheels from solid masses of steel have been developed. Most of these methods have consisted in casting a steel blank approximating the wheel in size and shape, and then rolling the web and tread, or the tread alone, to weld the pipes and blow-holes, which are incident to steel castings, and to compact the surface metal. Some processes, however,

contemplate more thorough working of the steel for the purpose of securing greater strength, and to couple with this thorough kneading such rapidity of operation as to enable the production of a wheel at a single heating to save time and labor and to avoid waste of metal by oxidation. In most of these processes a steel ingot is first cast of a length considerably greater than the thickness of the hub, and of a diameter much less than that of the wheel.

Fig. 6 illustrates a method which starts with the production of a steel ingot which is pressed or hammered into a flat disk of about the thickness of a car-wheel. As the pressure applied endwise on this ingot will somewhat stretch the periphery and possibly develop cracks or radial checks therein, the disk is set up on edge and hammered by dies shaped to form the tread and flange and solidify them. The axle hole is then punched, the blank placed flatwise in a properly shaped die and pressed therein by a mating die into the form of a finished car-wheel. In this process two heatings are necessary, a high heat for the rough forging and a low heat for the final pressing and finishing.

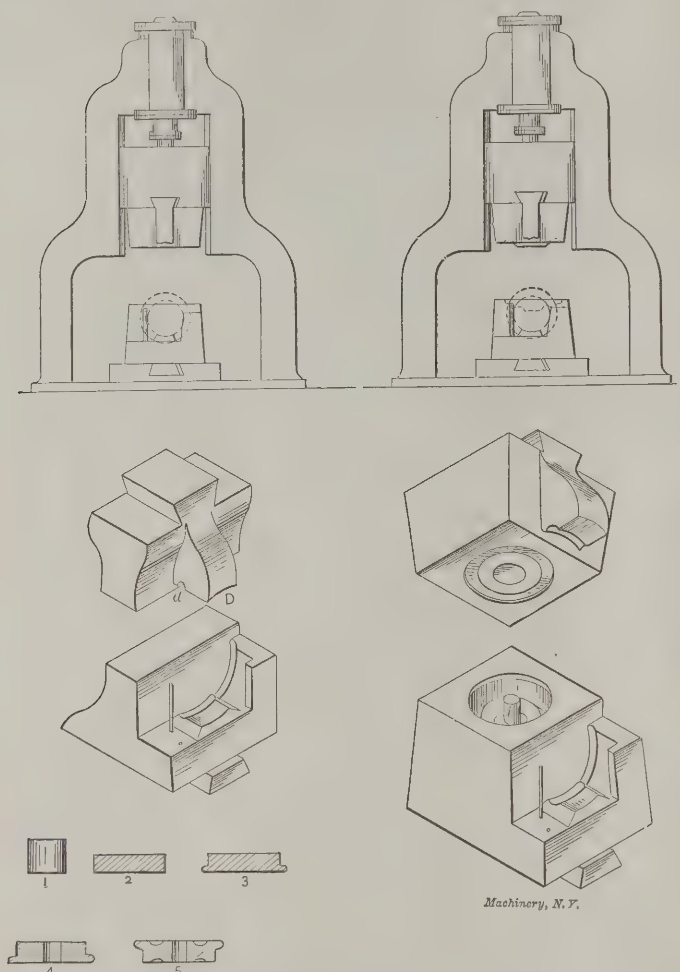

Fig. 6. Steel Ingot Wheel Making.

Another method designed to finish forge a steel wheel at one heat is illustrated in Fig. 7. This method consists in taking an ingot of metal of suitable size and shape, preferably round or octagonal, and placing it with its axis perpendicular to the faces of flat dies and by vertical blows bringing it to a diameter slightly less than the diameter of the blank and of somewhat greater thickness. Then convex forming plates are placed successively upon the upper flattened faces of the blank, which, under the action of the hammer, displace metal and form the rudimentary flange. The lower die, with its centering-plug and shoulder, is changed into a forming die by placing upon the shoulder a wall-ring bored to the form which the tread and flange is to take. Into this forming die the blank with its rudimentary flange is placed. The blank is driven home into the wall-ring so that when the onset of the dies is complete the flange is turned downward and outward. The flanged blank is then turned upside down and pressed out of the wall-ring. Then it is placed between dies having raised collars on their working faces of similar section and size, surrounding and concentric with the hub pocket. The lower die is so formed that besides the collars its top forms a centering plug and shoulder for the wall-ring. By

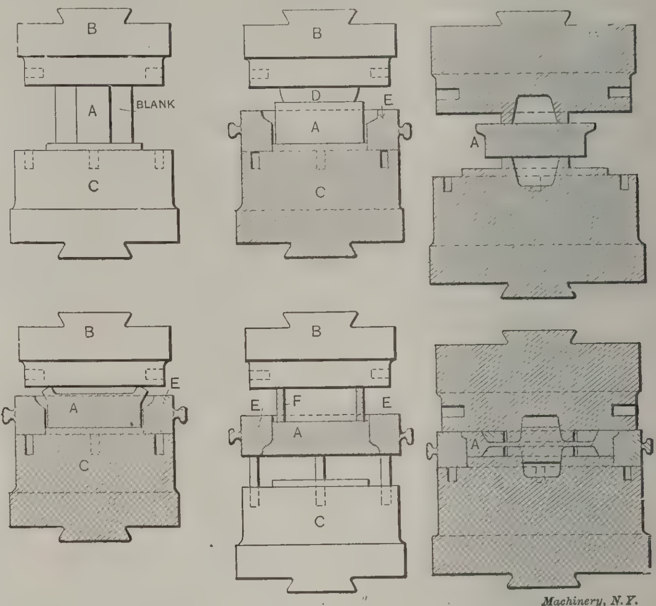

Fig. 7. Steel Ingot Wheel Making.

the action of the dies the metal around the hub is displaced and forced radially outward into the rudimentary rim, leaving part of the plate between the collars. The rim and web are enlarged by means of loose plating rings or collars used in pairs between the dies. Successively larger pairs of rings are used until the forging is almost equal in diameter to the finished wheel. The forging is then removed and upon the

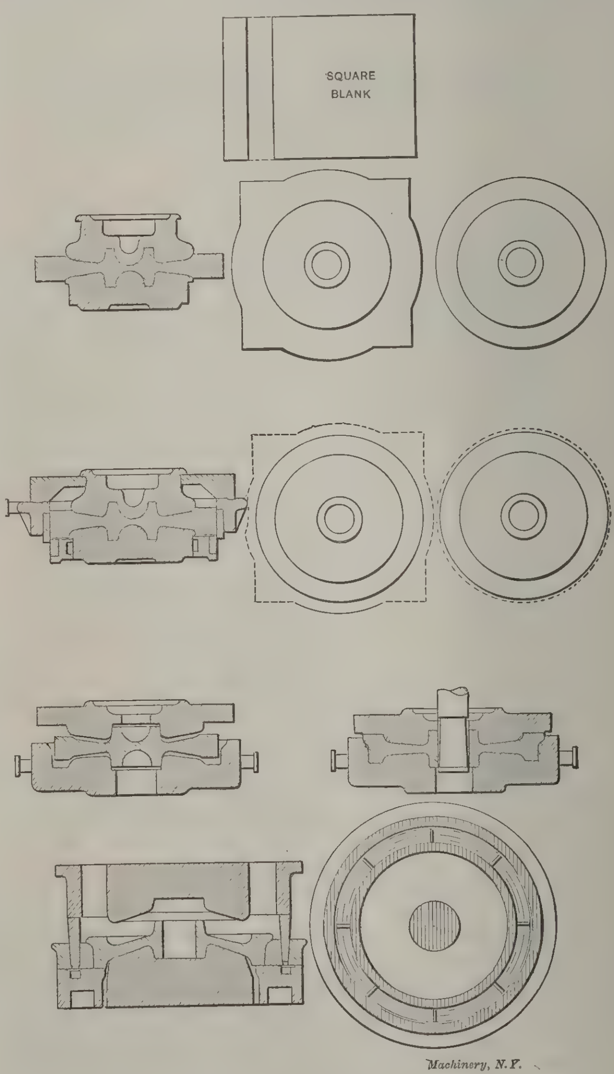

Fig. 8. Schoen System.

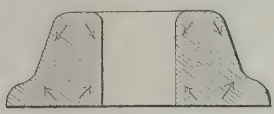
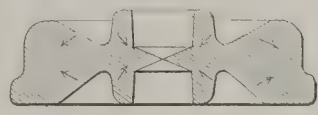
shoulder of the lower die is placed a wall-ring which is so made that when in position it alters the die to a finishing die. The upper die and lower die with the wall-ring, and a final pair of collars, form a matrix for the finished wheel. The forging is then placed therein, resting upon one of the loose collars. The mate of this collar is then put in position on top of the forging. The upper die is lowered, driving the collar home, thus forming the finished wheel.

drawn blank is then flattened out and the tread portion forged in dies.

A recent invention in making forged steel wheels starts with an annular ingot of steel considerably thicker and less in diameter than the finished article. By this method it is designed to forge the completed wheel at one heating. The central opening in the ingot is designed to receive the excess of metal flowing into it from the forging operation and the





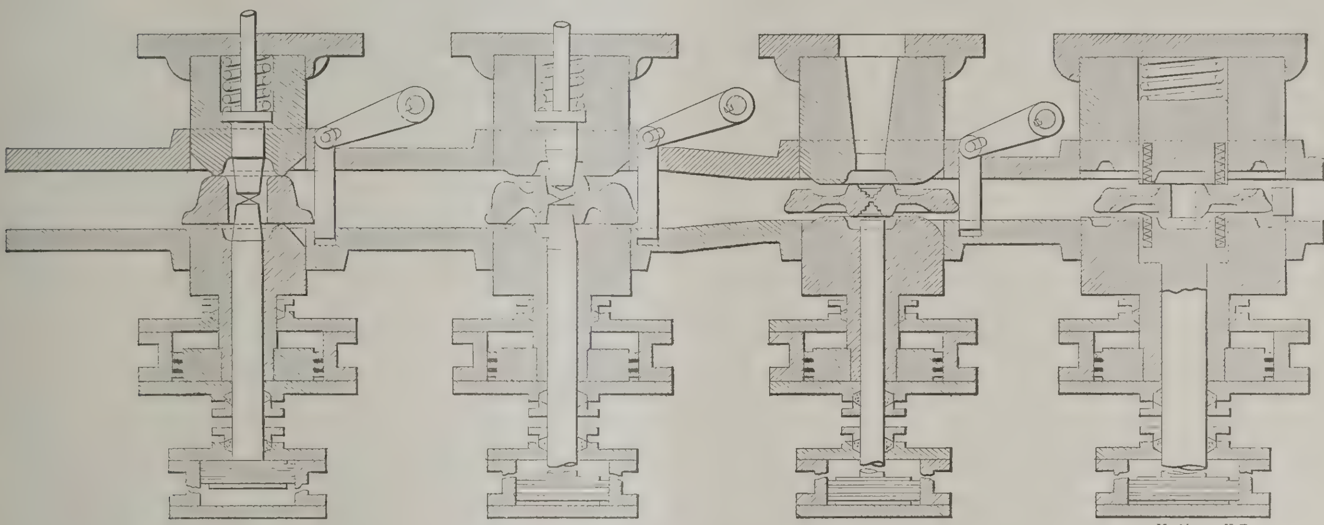


Fig. 9. Method for Making Car-wheels by one Heating.

In the German Ehrhardt method (Fig. 10) a hot ingot or blank of steel, (or several of them), of square or hexagonal section, of a weight equal to that of a finished car wheel, is placed in a cylindrical die and a hole punched through by means of an expanding punch. One of the rings thus formed is then placed in a matrix having the shape shown, and a plunger having a projection on its end considerably smaller than the opening in the annular blank is brought down upon

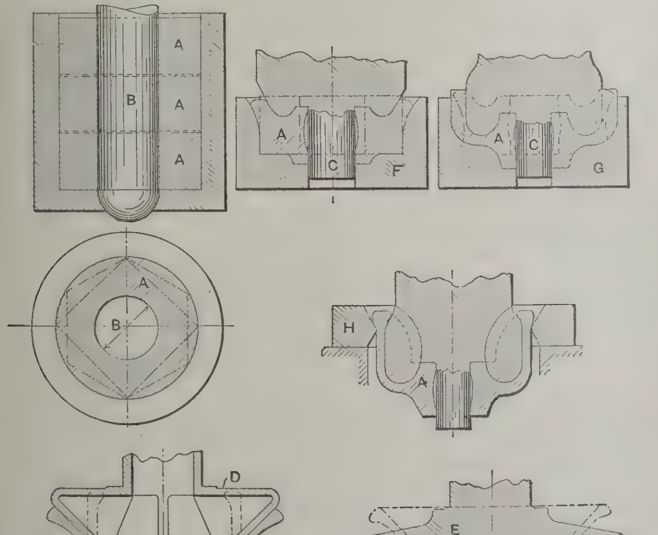

Fig. 10. Ehrhardt Method.

it, thus shaping the blank and causing the metal to flow both outward and inward, thus providing for a very rapid reduction. The blank is then placed in another die and another plunger forced into it, cupping the blank still more. This cuplike blank is then forced through a draw die by means of a properly shaped sectional punch and the walls drawn so as to lay the fibers parallel with the die axis, thus imparting to the blank the tough fiber resulting from drawing steel. This

pressure of the dies is so distributed that the interior portion of the ingot will be forced to the central opening whence the most of it may be subsequently removed by the punch when the axle hole is made, and whatever may remain will be in a position where it cannot materially weaken the wheel. The series of dies are illustrated in Fig. 9. In the center of each of the two preliminary pairs of dies are punches spring pressed toward each other. When the annular portions of the dies enter the hot metal it flows outward toward the rim and also inward against the punches which yield to excessive pressure. The metal is thus allowed to flow freely, rapid forging is thereby accomplished and the poorer portions of the ingot squeezed into the central opening whence it is removed by the punch which sizes the axle opening.

In the Schoen method, Fig. 8, the blank is obtained from selected rolled stock free from pipings and other defects. The blank is sheared of a size greater than the wheel and by the first operation is die-pressed to form a rudimentary hub and the web adjacent to the hub. In this operation the metal is spread radially, but the excess of metal around the outside acts as a confining band, thus preventing the checking that is apt to occur when the diameter of a metal blank is increased by expanding it. After the preliminary forging, as above, the blank is sheared to the size of the wheel. It is then examined for defects that may possibly be developed by the spreading action of the dies. Such defects, if there be any, may be readily detected on the sheared surface and the blank then discarded early in the process before much work has been done upon it. The blank, if perfect, is then confined around its edges and other dies brought into action to complete the exterior of the hub, reduce the web and form a flanged rim. When the dies have been closed to perform these operations, a punch is forced through the center to complete the axle hole. The forged wheel is then subjected to the action of a rolling machine to finish the reduction. The wheel is then dished by means of dies, and the thread trued by segmental die sections forced radially against the tread. During this truing operation the faces of the die segments are treated with oil, which with the comparatively cool dies has the effect of chilling the rim, and the tread is completely finished without any subsequent machining.

D., N. & P. RAILWAY ROTARY SNOW PLOW.

The snow conditions this year on the northern transcontinental lines are the worst experienced in ten years, and at this time the rotary snow plow is one of the most important features of the equipment of those roads. These mechanical snow fighters have played a most important part in the history of railroading in the West, and have greatly benefited conditions attending the use of the wedge plow. The rotary is adapted to removing snow of any character and of any depth, quickly and easily, with no danger to equipment or men. To cope with drifts 15 to 20 feet high, something besides brute force is required. The old method of bucking drifts of this character with the wedge plow with six or seven heavy locomotives behind it, resulted in many casualties among railroad men engaged in this dangerous work. The rotary will bore its way through drifts packed in a hard icy mass in front of the plow with perfect safety to those operating it. Except in the most extreme conditions, one heavy consolidation locomotive provides sufficient power for its propulsion. The rotary herewith illustrated is the largest ever built, and was recently completed at the Cooke Works of the American Locomotive Company for the Denver, Northwestern & Pacific Railway. This plow will clear a cut 13 feet 4 inches wide. The wheel consists of ten cone-shaped scoops, fitted with knives which adjust themselves automatically into cutting position. The wheel is encased in a drum, which is provided with a reversible hood operated by an air cylinder, so that the hood may be turned to either side to suit the direction in which the wheel is turning. The boiler is of the locomotive type with Belpaire firebox. The engine consists of two horizontal cylinders with slide valves operated by the Walschaerts valve gear. The plow is carried on a steel I-beam frame, and is mounted on two 4-wheel steel frame trucks. To prevent the derailment of the plow, the front truck is provided with ice cutters and flangers. The ice cutters are attached to a frame hung on the forward end of the front truck and operated by means of an air cylinder, so that it may be raised and lowered in crossing frogs or switches. The flangers are hung in the rear of the truck and connected to the axle and are also operated by an air cylinder. With the ice cutter and flanger in perfect working order, it is absolutely impossible for the rotary to be derailed by ice or snow. The halftone, below, of a cut made by one of these plows, shows the clear rail which they leave.

THE MANUFACTURE OF SHOT-GUNS AT THE ITHACA GUN COMPANY'S WORKS.

W. L. McLAREN.

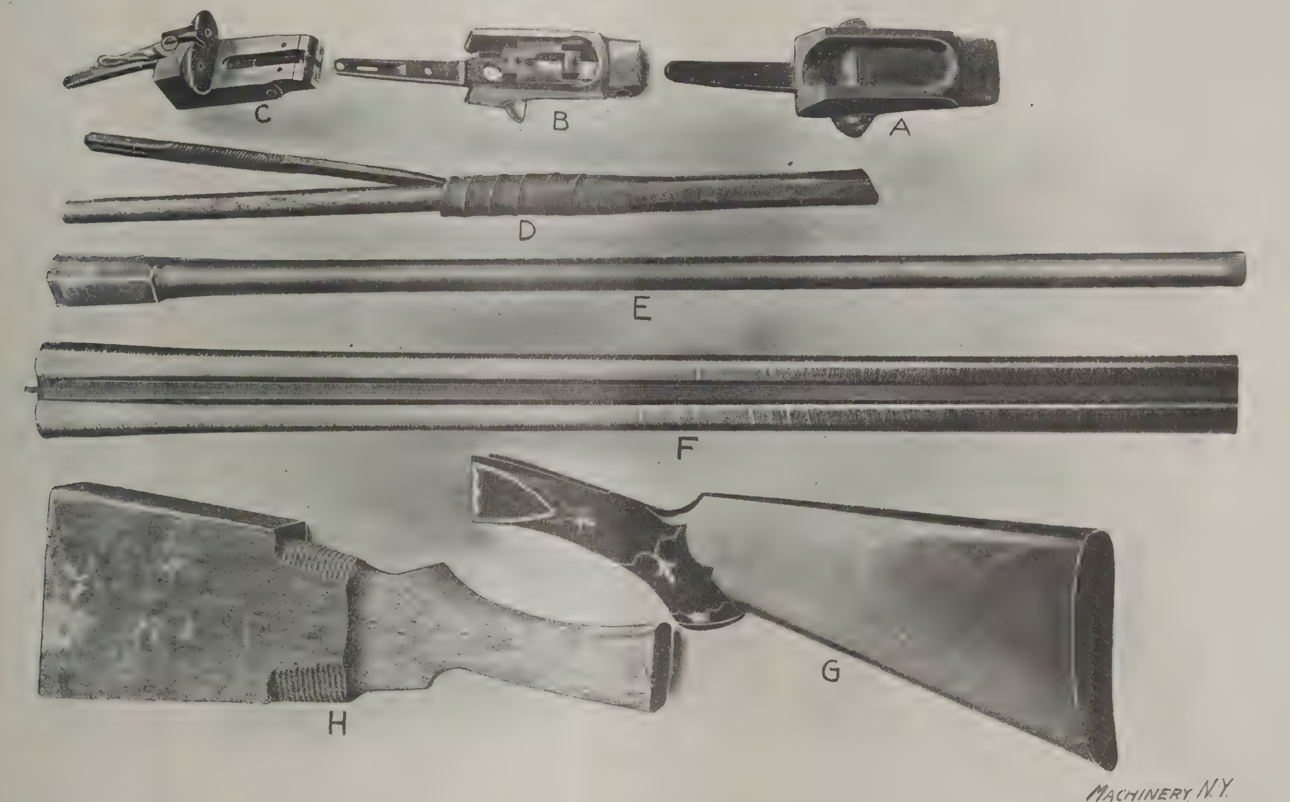
The accompanying halftones show some views taken recently in the works of the Ithaca Gun Co., Ithaca, N. Y., and will serve to help in conveying an idea of this branch of manufacture as it impressed the writer. The Ithaca Gun Co. was established in 1880 and incorporated in 1904. The business was started by Messrs. L. A. Smith and George Livermore, and is entirely devoted to the manufacture of double-barreled shot-guns of different sizes and grades. No cheap guns are manufactured, but only high-grade fire-arms, many of which are highly ornamented and finished, and priced as high as $300.

The barrels are all imported; they come in boxes containing 50 pairs of barrels each, rough-turned and rough-bored to within 0.030 inch of finished size. The lower-priced guns are fitted with the famous Cockerill steel plain black barrel; then, next in price comes the laminated twist steel barrels; then in order are barrels of Damascus steel, following which in quality come the Krupp-Essen fluid steel barrels with their stamped trademark showing a little soldier holding a gun; the last and highest grade in price are the guns with Whitworth fluid steel barrels, these barrels all being numbered and accompanied by a certificate. In case of breakage or failure through a flaw "it is up to the manufacturer" to replace them.

The first operation on a pair of shot-gun barrels is to turn them to size, and then to chamber the breech for the cartridge shell. It requires at least five operations to remove the 0.030 inch stock left by the barrel makers. After being bored to size the barrels are hand polished with emery and the opposite sides of a pair of barrels are milled for the lug which is brazed in. The steel rib joining the barrels is then brazed in and the assembled barrels are mounted in the milling machine and the rib milled concave. The next operation is "matting" the rib, which is done on a special machine, the top surface of the rib being knurled or matted with a single revolving tool mounted on the end of a spindle controlled by a cam. The cam causes the tool to raise and lower every half revolution to conform to the concave surface of the rib. The table is fed one mat cut for each revolution of the tool, producing much the same effect as a knurling tool would on circular work. This machine is one of many special machines designed and made by the company for the manufacture of shot-guns.

After going through various milling operations on the lug, the barrels are polished and sent to the finishing room where they are rusted with chemicals from five to six days, according to weather conditions. This rusting brings out the figure or pattern of the barrels; the iron blackens while the steel shows white, producing the well-known twist and Damascus effect. The fluid steel barrels of course show no such variations of color and are finished to a dead black.

The frames are received in the shape of rough drop forgings and are mostly machined by milling operations. One interesting operation on the frames is that of forming the "ball," as it is called, on each side of the frame. The table of the milling machine is fed longitudinally until the work reaches the point where the ball is to be machined. Here a trip is thrown which engages the circular feed of an auxiliary table and an instant later another trip is sprung, throwing out the first feed. Of course the reason for throwing one feed in before letting out the other is to avoid leaving a mark on the surface, which would surely follow the stopping of the first feed before throwing in the circular feed. The frame now revolves through a half circle while the cutter mills both the flat and the curved surfaces. Various shaped cutters, according to the style of the frame, are used, the principle of the cutters being a combination of a plain and corner-rounding cutter. The ball formed is in reality a quarter of an ellipsoid. The diameter, measured vertically as the gun is held in shooting position, is about as 5 is to 4 to the diameter in the other direction. To get this curve requires some careful calculation and setting, and there are four of these special milling machines for this particular operation.



A.—Rough-forged Frame. B.—Milled Frame. C.—Finished Frame. D.—Barrel under Construction, showing Belgian Method of Forging. E.—Imported Rough Tube for Barrel. F.—Pair of Finished Barrels. G.—Finished Stock. H.—Stock Partially Turned.

There is a slot in the lower side of the gun frame where the lug of the barrel fits when the gun is closed and locked. For years this slot had been machined by milling and broaching, until very recently a Hendey-Norton oscillating milling machine, as shown in Fig. 4, was installed for this work. This machine does the job in quick time and very accurately. The cutter is mounted on the end of a U-shaped arm attached to a spindle which oscillates. The center of the cutter is coincident with the extension of the spindle axis. Various sized cutters are used, of course, for various sized slots; the teeth have no clearance and cut in both directions. The holes for the slots are drilled first, the same as formerly. The slot

Fig. 9. "Bob" Edwards, Veteran Barrel Borer, straightening Tubes before Brazing together.

that is worked out by this operation is plainly shown at C, in the first cut, it being the rectangular slot in the center of the machined frame. The work is mounted on the table and fed up while the cutter oscillates back and forth, removing the metal with each forward and backward stroke. In this manner it is possible to machine by an operation analogous to milling those parts which an ordinary milling cutter could not reach. (For a description of the Hendey-Norton oscillating miller see MACHINERY, April, 1905.)

The smaller parts of the guns such as triggers, guards, and lock mechanisms, are either drop forged or punched from steel stock; all parts are made from the best grade of steel obtainable. Each piece, except the smallest parts of a lock, is numbered and this system of numbering extends to the wooden stock and fore-end. The frames are not casehardened until after being fitted to the stocks. The casehardening process requires 2½ to 3 hours heating in the fire and is done in a pack of bone and charcoal. It requires an experienced man to produce the beautiful effects so noticeable on the casehardened parts of guns. The trigger guards are blued chemically.

The stocks and fore-ends are made of black walnut, the wood being mostly imported. They are rough turned on a rough turning gun-stock turning lathe, and are then passed on to another machine which completes the operation, both these machines, of course, being essentially of the Blanchard type of turning lathe. Next the stocks go to the inlaying machine which carves out the recesses for the inset metal parts to fit in. At H is shown a stock partly turned, and at G is one finished so far as machining is concerned, the rest of the finishing work before done by hand with sandpaper, etc.

The shop is driven by a 21-inch Morgan & Smith waterwheel working under a 39-foot head at 390 R. P. M. At this speed and head the wheel develops about 105 horsepower. A steam plant is also provided to run the works if necessary during low water periods, but it is seldom called into service. During the busy season in the fall and winter the plant runs night and day, the average production being about 80 shotguns a day.

While being shown through the works I was introduced to Mr. Bob Edwards, foreman of the barrel boring department, who is, I am informed, the oldest gun borer in the United States. Fig. 9 shows him in the characteristic attitude of examining a barrel and indicates the simple, not to say primitive, equipment with which the delicate work of straightening a barrel is done.

Mr. Patch, the superintendent, who has been with the company over twenty-three years, informed me that there are over 100 separate milling machine operations on each gun and these operations of course do not include the many drilling, reaming and other operations.

* * *

Plumbers' solder, or wiping solder as it is commonly called, is composed of 40 per cent tin and 60 per cent lead. It has the interesting and valuable feature that at certain temperatures it takes the form of a pliable mass, allowing it to be easily handled and molded to produce the characteristic form of plumber's wiped joint. This operation of wiping is briefly described by the *Valve World* as follows: "The parts to be joined are first freshly tinned at the points of contact, to remove the oxide, and then firmly placed and secured in position. The melted solder is poured on the parts for the purpose of heating them. As the parts become hot the solder becomes cool, taking on the pliable form above mentioned, and is easily manipulated by the mats in the hands of the mechanic, when the joining is completed." It might be added that the ability to make a wiped joint is the principal stock in trade of the average plumber as distinguished from a steam fitter, and that no good reason for maintaining this ancient method of making plumbing connections exists in general. There are a number of mechanical joints on the market which have the merit of cheapness, ease of application, and which can be readily disconnected in case of needed repairs. Needless to say, the plumbing fraternity have worked tooth and nail against the general adoption of this needful improvement, which is bound to come sooner or later, nevertheless.

A MID-WINTER PICNIC AT SANDY HOOK.

R. E. F.

When secretary and president-to-be Hutton, at the Wednesday morning session of the A. S. M. E., finished his explanation of the pleasure and instruction to be derived from the trip to Sandy Hook, I was so much impressed that I immediately made my way to the desk on the floor below where the tickets were sold, and bought one. I was pleased to discover, after some questioning, that the ticket was good not only for the railroad journey but for lunch as well—going at least, and perhaps on the way back also. The day before the event, Thursday, was very nasty, and it had begun to look as though the party for the proposed trip would be a small one, but Friday morning dawned bright and clear with nothing more disagreeable in sight than a 40-knot breeze and a temperature hovering around zero, so a majority of the members changed their minds about staying in town and hastened to the ferry station instead, where a great many tickets were sold. Some of them took their wives and other female relatives with them, despite the warning Prof. Hutton had given that it was likely to be a disagreeable trip for them.

There were ten cars in our train when it left the station of the Central Railroad of New Jersey at Jersey City, and they were all just about full. Probably there were 600 of us, more or less. The train was like most excursion trains, rather hesitating in its movements, and not given to making up its mind very rapidly. It hesitated some time before it worked up courage to cross the draw in Newark Bay, and had a still longer period of indecision before the combined efforts of the train force and the earnest prayers of the excursionists, gave it courage to cross the Raritan at Perth Amboy. During this state of indecision, we were out on an open causeway with no obstructions of any size between us and the North Pole whence the wind was coming. Some people in our car had friends in the next, and some people in the next car had friends in ours, so we were never in any doubt as to what the weather was outside. It must be said, however, that this deliberation of movement had the advantage of giving us all a very clear and vivid impression of the geographical features and industrial development of western New Jersey.

Enter—The Caterer.

It was about this time, an hour or so from the time the train started, that the caterer began to show signs of life. We had been wondering for some little time how he was going to handle us all, but he evidently knew his business. The front car appeared to be his storehouse. At intervals of two or three minutes a procession of waiters would pass along the aisle, some of them carrying large packages of square pasteboard boxes, and others with things in their hands that looked like watering pots with the sprinklers removed. From such of these pots as had their spouts turned in my direction it was possible to detect an odor which at once detracted one's attention from the landscape outside of the window. Two bundles of boxes and two watering pots were deposited at the rear end of each car, and then the distribution commenced. Each member of the party was given a box about 6½ inches square and a little glass of drinkable —either red or yellow, according to his principles. The caterer displayed very good judgment in deciding on the contents of these little boxes; each contained a napkin, a dried beef sandwich, a chicken sandwich, two hard boiled eggs, a little package of salt and pepper, a small cake, a big red apple, and a pickle. After one box had been emptied it was entirely possible to get another. After this we arrived at Sandy Hook.

Special Courtesies to Foreigners.

When the train stopped at the entrance to the government reservation out on the bleak and windy sea coast, a number of the military officers of the place were there to welcome us. Here again we stayed several minutes, during which time our interest was diverted by the passage through each car of a member of the party deputed to inquire of each if, on his word of honor, he would be willing to admit that he was an American citizen. Every one in our car seemed to be guilty,

but apparently this was not the case throughout the train, for a few minutes later an officer, accompanied by a soldier with a megaphone, made his way down through the aisle with a train of attending foreigners behind him. As he entered each car he announced: "Will all members of the party in this car not citizens of the United States please attach themselves to the party which I am to lead? Special courtesies will be shown them." After the excitement caused by this incident had had plenty of time to die away, the train started up again and we made our way toward the north end of Sandy Hook, where the proving grounds and the fortifications of Fort Hancock are located.

An Interview with a Big Gun.

First the train was backed up on a long Y-track to the place where was set up the great 16-inch gun recently built for coast defence service. Here Brigadier-General Crozier, Chief of Ordnance, met us and, as we assembled on the platform around the breech of the big gun, made a little address of welcome, giving a brief description of the manufacture and capabilities of this immense piece of ordnance. After a lot of figures as to weights, muzzle velocities, powder pressures, etc., which slip out of one's mind as rapidly as they are given, he told us that the gun had been built to see whether we could do it or not. He was happy to be able to tell us that the experiment had been a complete success in every particular; that the various laws relating to gun design and construction which had proven true in the case of small sizes had also held good in this, and that all the calculations had been found correct. He told us that so far as any present vessels of possible enemies are concerned, 12-inch guns are big enough, so for the present no more of the 16-inch size are to be built. It is a pleasure and a satisfaction to know, however, that we can build them if we want to.

The gun is a monster. Some of the party climbed up on top of it and went out to the overhanging end. Two or three other inquisitive ones piled a couple of boxes on an empty barrel and climbed to the top for a view into the throat of the creature, at imminent risk of having their shins barked for their pains. A crank was applied and the breech was opened and closed for our benefit. The movements involved in this motion are very interesting. The process is a continuous one. First, a worm meshing in worm-wheel teeth in the breech block gives it a partial rotation to unlock it; the worm is not only a worm in one direction, but is a spur gear as well in the other; as soon as it has ceased to act on the worm wheel, it takes hold of a rack on the side of the breech block and backs it out of the chamber. On reaching the extremity of its movement in this direction, the continued movement of the handle through the action of the connecting bevel gear between the crankshaft and the worm wheel shaft, swings the block and its carrier around to one side, leaving the chamber open and unobstructed for the projectile and the charge of powder. The gun is set up on a temporary foundation in the sand, just rugged enough for the purpose of trial firing.

From here we plowed our way through the sand and dense undergrowth of scraggly, thorny shrubs to the shore, where a couple of targets were set up, one of them being a section of the armor of the Iowa, the other of the battleship Tennessee. These are to be fired on by guns further up the beach to determine the effect produced under varying conditions. We then returned again from the beach to the train, and were taken back to the main line and started for the proving grounds, but not until President Taylor, President-elect Hutton, and Generals Crozier and Murray had had their pictures taken at the breech of the 16-inch gun.

The Proving Grounds.

At the proving grounds we again debarked. Here were all sorts and sizes of rifles, mortars, field guns, rapid-firing guns, etc. These are mounted on concrete platforms with concrete buttresses or bulwarks behind them, presumably provided so that if anything bursts, the fragments will hit the mass of concrete and not go beyond it. Back of these is a high tower of steel with a large room on top from which the firing is directed and observations taken. We passed along the platforms from gun to gun, examining the mechanism, looking into muzzles and working various handles and levers, and then we were all grouped on the concrete structure in back and the firing commenced. A 6-inch rapid-fire gun, throwing a cast-iron shell, was twice discharged. There was nothing very depressing about the report from this gun, and the nervous members of the party began to feel reassured. Next came five rounds from a 15-pound gun fired in remarkably fast time. Two or three other reports were heard from different parts of the platform and then, at a signal from the officer in charge, a 10-inch rifle on a disappearing carriage arose from its bed as lightly and gracefully as a feather, without shock or sound of any kind. After a little delay due to the arranging of the electrical connections of the speed indicating mechanism, the order was given to fire, and we stuck our fingers in our ears and gritted our teeth. A dull, heavy report followed and the gun was down in its bed again. Several seconds after, I neglected to take my watch out so I do not know just how long, out toward the east somewhere a white cloud of spray shot into the air to a considerable height, and a great flock of gulls which had been floating on the water arose, filling the air with the flash of light from their wings. Their excitement could be very plainly seen through the glasses.

Gun Maneuvering and Sub-caliber Practice.

From here we made our way to Fort Hancock, whose batteries we were to inspect. Brigadier-General Murray, Chief of Staff of the United States Army, led the procession and explained the guns and fortifications as we went along. From the front there is little to be seen that would cause one to suspect that dangerous weapons are concealed here; there is a simple bank of sand and nothing else. Down behind it, however, are all the great rifles, crouched on their haunches, ready to spring up and show fight at a signal from the officer who controls them. For our benefit General Murray had one of these monsters maneuvered, he explaining the movements as they took place. The catch holding the gun in its lower position was released and the counterweight threw the rifle into place above the level of the parapet. Then, a light touch on the controller swung the muzzle to the right and to the left, and up and down. Of course when the gun is fired, the recoil seats it again in its recumbent position, but in this case, since no firing was done, it was brought down by hand, two men turning the crank and working hard to do it.

We were then shown some sub-caliber practice. We were told that this sub-caliber practice is largely responsible for the proficiency in marksmanship which the American artilleryman has shown. A small barrel, perhaps 2 or 3 inches bore, is placed inside the chamber of the big gun, being held in a truly central position by supporting disks. The weight and charge of the smaller projectile are such that its trajectory bears a definitely determined relation to that of the large projectile. It is thus as useful for target practice as though the $200 or $300 required for a single discharge of 12-inch ammunition was expended. It was some little time before they could get around to firing this sub-caliber ammunition. The passing body of visitors, not realizing that it was desired to fire the gun, all preferred to pass by its muzzle end, and each one stopped to gaze into the gloomy depths of its throat. Owing to the inconvenience of discharging the gun under such circumstances, everyone was allowed to satisfy his curiosity before the firing commenced. The sharp "spat" of this sub-caliber ammunition was so ridiculous when compared to the heavy reports we had just heard, that a number of us became quite brave, and gathered about the barrel of the gun, even getting to the point of leaning up against it and placing our hands on it. No one, however, showed any further desire to pass in front of the muzzle, although, so far as one could see, that would have been a perfectly harmless proceeding.

Sandy Hook as a Winter Resort.

After this exhibit, a long, chilly, windy walk took us to the mining casemate, where a description of the principles of sub-marine mine defence was given us. One great advantage of this lecture and exhibit was the fact that it was held in a hole in the ground entered only by a tunnel. Although open to the sky, this pit was so deep that there was not much

of any wind. After this respite, we turned our backs on the shore batteries and made our way toward the center of the peninsula where the mortar batteries were located. One could not help thinking, as he plowed through the sand and turned his face away from the biting wind, that life in this part of the world in winter, at least, possesses few charms. The officers and men were going about in fur caps and huge gloves, the women and the children of the post were all indoors, and all the inhabitants except the officers—whose dignity forbade them—seemed to enjoy slapping their chests as long and as hard as they could, when they had nothing else of particular importance to occupy their time. When, however, the soldiers were in line, receiving and executing orders, they were as straight and still and attentive to business, and as little conscious of the elements, as a soldier is supposed to be.

A Salvo from the Mortar Battery.

The mortar battery proved to be one of the most interesting exhibits of the day. The formation of the earthworks is that of a series of deep pits in the ground, possibly 40 or 50 feet deep or more. These pits are connected with each other by tunnels and have smooth concrete sides. At the bottom of each is a group of four 12-inch mortars, looking, as one man expressed it, like a lot of big bull dogs. We were to witness the firing of a "salvo"—that is to say, the simultaneous discharge of four of these guns at one time. It was explained to us that mortars were always aimed by the indirect method; as the enemy's ships are approaching, their range is rapidly obtained, calculations, facilitated by instruments provided for the purpose, are made to determine at what angle and in what direction the mortars shall be pointed, and then, after the aim has been taken, they are discharged. They cannot of course be fired point blank at the approaching vessel, but are aimed up in the air. The missiles go to a tremendous height and, in falling, come down nearly vertically on the deck, the weakest point of the approaching vessel. Strange as it may seem, the science of mortar firing has been developed to such an extent that they are fully as effective as rifles aimed directly at the object it is desired to hit.

Nowhere, as when we were grouped on the verge of these pits, did we realize so well at once the beauty of the day and the force and coldness of the wind. Long heavy swells were coming in from the southwest, whose tops, as they broke on the beach, were shattered by the gale from the north and whirled in a line of flashing spray that extended as far down the coast as the eye could reach. The herring gulls, which swarm the harbors of our Eastern cities during the winter, were flying in great flocks through the air or resting in countless numbers on the undulating surface of the ocean. A couple of huge freighters, from the East Indies perhaps, or some other foreign place, were steadily ploughing toward the great city to the north of us. Nearer in and to the southward, a little tug could be seen making her way toward us along the shore.

Meanwhile they had been loading the four 12-inch rifle mortars below us. The projectiles and powder bags were pushed into place, the breech blocks were closed, and the guns were aimed in accordance with instructions given by the officer who stood with us on the parapet—and then we waited for the firing. These guns looked very business like, all standing at attention with heads up, ready to do as they were told as soon as they were told to. Then came a dull boom and a trembling in the ground, and the pieces were fired. Away up in the sky, so far up that they were almost out of sight (in fact they finally did disappear) were four, or was it only three, little black specks side by side, headed in this round-about fashion for the definite little point out in the ocean at which they had been aimed. A few seconds later a column of spray shot in the air, and we knew that the projectiles were back to sea level again. The little tug shifted its course, and gave us a wider berth.

After this, from our elevated station, we were treated to the sight of an explosion of a mine laid in the sand. So far as one could see it lay in about the direction of the territory we had been tramping over some hours before. Over this same spot were also exploded, one after the other, four shells, two loaded with black and two with smokeless powder. These were fired from a point half a mile further back at the proving grounds. Again, congratulating ourselves that we had gotten away from that spot earlier in the day, we made our way back to the train and started for home.

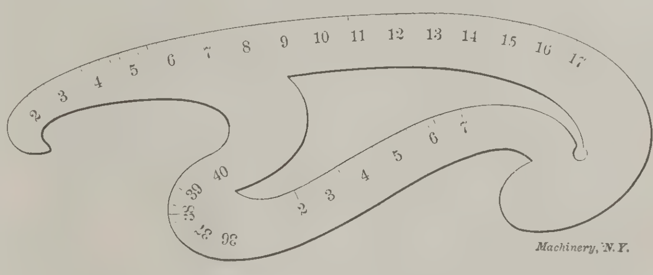
A Lesson in Journalism.

The papers in the city had a surprise for us when we returned. "Foreign spies at Sandy Hook—Attempt by foreigners to witness gun tests at Fort Hancock—Tried to board special train of engineers—Attempt believed, however, to have been foiled."—A sensation was caused when word was passed from car to car that President Hutton was holding up members and guests and requiring them to give evidence of their American citizenship." There were seven of the disappointed aliens in all; two Germans, an Englishman, a Japanese, a Frenchman, a Canadian, and a Scotchman. It seems that they were allowed to witness the tests at the proving grounds, but were entertained during the rest of the day in a comfortable steam-heated room in the post library, while the rest of us were shivering around the fortifications of Fort Hancock. One had the impression at the time that this "special courtesy" that was shown to the aliens was merely a matter of red tape and nothing more, but the newspaper reporters evidently saw a chance to make something startling out of it, and they gave a very interesting exhibition of the way in which most startling news is manufactured.

* * *

GRADUATED CURVE FOR DRAWING SYMMETRICAL LINES.

Many curves drawn by means of the so-called French curve, such as the ellipse, hyperbola and parabola, require that the same parts of the French curve are used on each side of the axis of symmetry. The regularity of the curve and the degree of perfection of the symmetry will then depend on one's ability to reproduce in proper sequence on one side of the curve the parts of the French curve used in drawing the other side first. The cut shows a curve graduated on its edges with some arbitrary divisions, say, in eighths. At every fourth one of these divisions a number is placed, starting with one at any convenient point on the curve and increasing by one until the



Draftsman's Graduated Curve.

graduations come back to the starting point. If the curve is made of celluloid the figures may be put on in black, so that when the curve is turned over with the figures down, they can be seen readily. If the curve is made of an opaque substance the numbers must be put on both sides. The numbers on the back should exactly coincide with the numbers on the face, and should proceed around the curve in the same order. In the cut the graduations are not shown all around the edges of the curve, but in graduating a curve they should, of course, be carried all around.—*Browning's Industrial Magazine.*

* * *

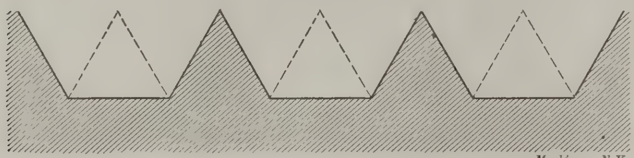
According to recent reports the largest wireless telegraph station in Europe is at present being erected at Norddeich, Germany, by the German postal department. The range of this station will be a circle of 950 miles radius and it will cover practically the whole of Europe, reaching as it will St. Petersburg at the north, and Naples at the south. The height of the tower of this new wireless telegraph station is 275 feet. Experiments undertaken so far have been successful in transmitting messages to steamers on the Norwegian coast, 650 miles away, across the Baltic as well as a considerable portion of the Scandinavian peninsula.

MACHINE TAPS.

ERIK OBERG.

As the name implies, the machine tap is used for nut tapping in tapping machines, the same as the tapper tap which was treated of in the December issue of MACHINERY. It was mentioned in that issue that the names of these two taps are often confused. From a manufacturing point of view, however, there is distinct difference between the two kinds of taps. The tapper tap embodies, in fact, the very simplest design possible for its purpose. It cannot be successfully used in many instances where the machine tap will be satisfactory. The machine tap being threaded and relieved in a different manner recommends itself for use in very tough material, and for heavy duty.

The general appearance of the tap may be seen from Fig. 4. It consists of a threaded portion *B*, having a straight part *D*



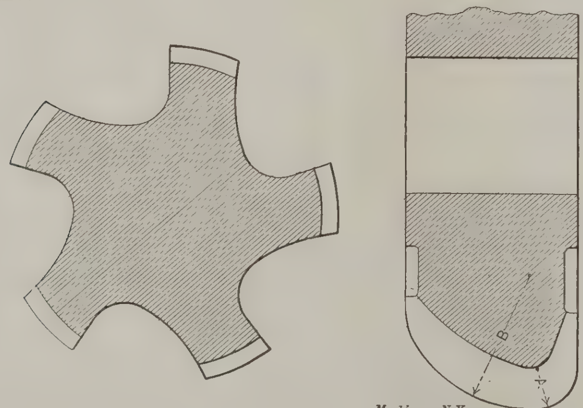
Machinery, N. Y.

Fig. 1. Diagram of the Echols' Thread.

and a chamfered portion *E*, and a shank *C* which is provided with a square, enabling the tap to be securely held in a chuck without danger of slipping. The extreme end of the threaded part is provided with a secondary chamfer, the purpose of which is to facilitate the entering of the tap in the hole in the nut blank. The diameter of the shank should be from 0.01 to 0.02 inch below the root diameter of the thread, the same as for tapper taps and for the same reason, *viz.*, to permit the threaded nuts to slide freely over the shank.

Turning and Threading.

In turning machine taps the straight portion of the threaded part must be left a certain amount oversize. The reasons for this were set forth in the article upon tapper taps previously referred to. The amount which the tap should be left over the standard diameter before hardening may, for general purposes, be between the limits of from 0.0005 inch to 0.0015 inch for sizes not over ½ inch diameter, from 0.001 inch to 0.002 inch for sizes between ½ and 1 inch, from 0.0015 inch to 0.003 inch for sizes between 1 and 2 inches, and from 0.002 inch to 0.0035 inch for sizes between 2 and 3 inches in diameter.

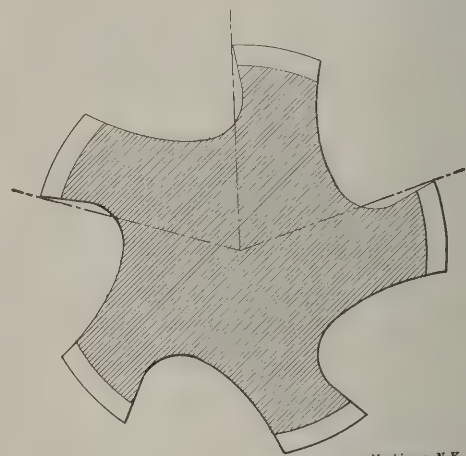


Machinery, N. Y.

Fig. 2. Section of Machine Tap and Fluting Cutter.

The main difference between tapper taps and machine taps will be found in the threading and relieving of the taps. While the tapper tap is threaded straight for the whole length of the threaded portion, the machine tap is threaded on a taper for a certain distance from the point. The length of this taper thread, and also the length of the part chamfered on the top of the thread depends, of course, primarily upon the conditions under which the tap is to be used: the material to be tapped as well as the length of the nut. When making taps in large quantities, however, whether for the market or for shop use in a large establishment, it is evidently impossible to know beforehand exactly what the taps will be used for, and certain standards must necessarily be adopted. Experienced makers of machine taps adhere to the rule of chamfering about twenty to twenty-five threads on the top of the threads and taper the root of the thread for a distance equivalent to eight or nine threads from the point. Formulas will be found below which will give the length of the chamfered part and the length of the taper thread for various sizes of taps; these dimensions will be so selected as to provide for a length equivalent to at least twenty and eight threads, respectively, on standard thread taps.

While a long taper on a tap is desirable in regard to diminishing the amount of stock that each tooth of the thread will remove, it has the disadvantage of making the cutting edges toward the point of the tap very broad with a very small space between them. This impairs the cutting quality of the tap, inasmuch as the action is rather that of reaming than of cutting. It is in order to overcome this disadvantage that machine taps are tapered in the angle of the thread for some distance from the point. This makes the width of the tooth smaller and increases the cutting qualities of the tap considerably. This taper in the angle of the thread constitutes one of the principal differences between the machine tap and the tapper tap, the latter being simply chamfered off on the top of the threads. If we analyze the action of the tap when provided with too many cutting edges we will find that the metal is either ground down very fine, and an unnecessary amount of power is consumed in performing this, or some teeth may



Machinery, N. Y.

Fig. 3. "Hook" Flute.

in fact not cut at all, simply compressing the metal, making the work of removing it still harder for the next cutting edge. On the other hand, a short taper takes away a great amount of the chip room necessary for the removed metal. While this may not be of great consequence in regard to a hand tap where the motion is slow and the tap is often reversed, it is of great importance in regard to machine taps and tapper taps where the cutting speed is high and always in one direction. The tap as well as the nut to be threaded is liable to be injured if ample space for the chips to pass away from the cutting edges is not provided.

An ingenious method of decreasing the number of cutting edges, as well as increasing the amount of chip room, is embodied in the "Echols' thread," where every alternate tooth is removed, as shown in Fig. 1. The removal of every other tooth in one of the lands evidently is equivalent to the removal of the teeth of the continuous thread in every other land of the tap. It is therefore obvious that taps provided with this thread must be made with an odd number of lands, so that removing the tooth in alternate lands may result in removing every other tooth in each individual land. If there were an even number of flutes, the cutting away of the teeth in alternate lands would result in removing all the teeth from certain lands and none from the remaining ones. Machine taps are often provided with the Echols' thread.

Fluting.

In considering the fluting of machine taps we find another difference from the tapper tap. The former tap requires greater strength on account of its harder service, and at the same time as much chip room as possible. The flute that best fills these requirements may, however, not be the flute commercially possible for the purpose, because the factor of

cost is greatly important, and unusual or formed shapes of cutters will cost more in themselves and also require slower cutting speed. In the article about tapper taps, two forms of flutes were shown. Another form of flute introduced by the Pratt & Whitney Co, for machine taps is shown in Fig. 2. This latter form is to be recommended in all cases where a tap of unusual quality is required. The tap will not break as easily, and the chips are carried off in a more satisfactory manner. A certain kind of flute of late used extensively by certain concerns is the "hook" flute, shown exaggerated in Fig. 3. This flute provides for a keener cutting edge, and is recommended for very tough materials. Some users, however, do not look upon this flute as favorably as others, and opinions vary considerably as to the superiority of this flute, excepting if the "hook" be made very slight. It is advisable to make the lands fairly narrow as compared with hand taps, inasmuch as this will increase the chip room and but slightly decrease the strength, the reason for the wide lands of hand taps being not reasons of strength but of good guiding qualities. If provided with a straightsided flute with a radius in the bottom, which is largely used by manufacturers, this radius may be approximately determined by the equation:

$$R = \frac{\sqrt{D}}{6} - \frac{1}{32}$$

R being the radius in the bottom of the flute and D the diameter of the tap. In the case of a fluting cutter such as shown in Fig. 2 the radius A should be about one-eighth and the radius B about one-third of the diameter of the tap for taps with five flutes. For taps with four or six flutes these radii should be slightly larger or smaller, respectively, relative to the diameter of the tap. The numbers of the flutes for various diameters are given below:

Diameter of Tap.	No. of Flutes.	Diameter of Tap.	No. of Flutes.	Diameter of Tap.	No. of Flutes.
$\frac{1}{4}$	4	$\frac{3}{4}$	5	2	5
$\frac{5}{16}$	4	$\frac{7}{8}$	5	$2\frac{1}{4}$	6
$\frac{3}{8}$	4	1	5	$2\frac{1}{2}$	6
$\frac{7}{16}$	5	$1\frac{1}{4}$	5	$2\frac{3}{4}$	6
$\frac{1}{2}$	5	$1\frac{1}{2}$	5	3	6
$\frac{5}{8}$	5	$1\frac{3}{4}$	5	..	..

Relief.

Machine taps are relieved as well in the angle of the thread as on the top of the thread for the whole of the chamfered portion, or in other words, the diameter measured over the heel of the thread should be smaller than the diameter measured over the cutting edge; the diameters measured in the angle of the thread at the same respective places should also differ in the same manner. The straight portion of the thread in a machine tap is for sizing only, the same as in the case of a tapper tap, and should as a rule not be relieved. However, the same as was said about the relief of the straight part of a tapper tap applies here also. In hardening machine taps they should be drawn to a temper of about 430 degrees F. This temperature should, perhaps, vary for different kinds of steel, but the figure stated will be found to constitute a good average.

Dimensions.

In the following are given two sets of empirical formulas for the most important dimensions of machine taps. In the formulas:

A = the total length of the tap,
B = the length of the thread,
C = the length of the shank,
D = the length of the parallel part of the thread,
E = the length of the chamfered part of the thread,
F = the length of the taper threaded portion,
G = the diameter of the tap.

For taps up to and including 2 inches in diameter, the following formulas will be suitable:

$$A = 5\tfrac{3}{4}\,G + 3\tfrac{7}{8},$$
$$B = 2\tfrac{1}{2}\,G + 1\tfrac{1}{4},$$
$$C = 3\tfrac{1}{4}\,G + 2\tfrac{5}{8},$$
$$D = \tfrac{3}{4}\,G + \text{3-16},$$
$$E = 1\tfrac{3}{4}\,G + \text{1 1-16},$$
$$F = \frac{3G + 1}{4}.$$

For taps 2 inches in diameter and larger the formulas will be:

$$A = 3\,G + 9\tfrac{3}{8},$$
$$B = 1\tfrac{1}{2}\,G + 3\tfrac{1}{4},$$
$$C = 1\tfrac{1}{2}\,G + 6\tfrac{1}{8},$$
$$D = \tfrac{3}{8}\,G + \text{15-16},$$
$$E = 1\tfrac{1}{8}\,G + \text{2 5-16},$$
$$F = \frac{2G + 3}{4}.$$

The table below is based upon the formulas given. All dimensions are given in convenient working sizes, and are

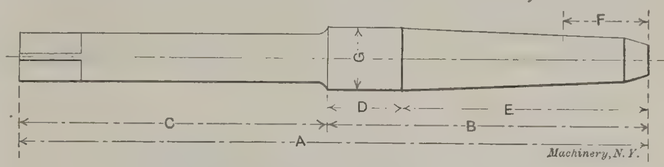


Fig. 4. General Appearance of Machine Tap.

DIMENSIONS OF MACHINE TAPS.

G	A	B	C	D	E	F
$\frac{1}{4}$	$5\frac{5}{16}$	$1\frac{7}{8}$	$3\frac{7}{16}$	$\frac{3}{8}$	$1\frac{1}{2}$	$\frac{7}{16}$
$\frac{3}{8}$	$6\frac{1}{16}$	$2\frac{3}{16}$	$3\frac{7}{8}$	$\frac{7}{16}$	$1\frac{3}{4}$	$\frac{9}{16}$
$\frac{1}{2}$	$6\frac{3}{4}$	$2\frac{1}{2}$	$4\frac{1}{4}$	$\frac{9}{16}$	$1\frac{15}{16}$	$\frac{5}{8}$
$\frac{5}{8}$	$7\frac{1}{2}$	$2\frac{13}{16}$	$4\frac{11}{16}$	$\frac{5}{8}$	$2\frac{3}{16}$	$\frac{3}{4}$
$\frac{3}{4}$	$8\frac{3}{16}$	$3\frac{1}{8}$	$5\frac{1}{16}$	$\frac{3}{4}$	$2\frac{3}{8}$	$\frac{13}{16}$

$1\frac{3}{8}$	$11\frac{13}{16}$	$4\frac{11}{16}$	$7\frac{1}{8}$	$1\frac{3}{16}$	$3\frac{1}{2}$	$1\frac{5}{16}$
$1\frac{1}{2}$	$12\frac{1}{2}$	5	$7\frac{1}{2}$	$1\frac{5}{16}$	$3\frac{11}{16}$	$1\frac{3}{8}$
$1\frac{3}{4}$	$13\frac{15}{16}$	$5\frac{5}{8}$	$8\frac{5}{16}$	$1\frac{1}{2}$	$4\frac{1}{8}$	$1\frac{9}{16}$
2	$15\frac{3}{8}$	$6\frac{1}{4}$	$9\frac{1}{8}$	$1\frac{11}{16}$	$4\frac{9}{16}$	$1\frac{3}{4}$
$2\frac{1}{4}$	$16\frac{1}{8}$	$6\frac{5}{8}$	$9\frac{1}{2}$	$1\frac{3}{4}$	$4\frac{7}{8}$	$1\frac{7}{8}$
$2\frac{1}{2}$	$16\frac{7}{8}$	7	$9\frac{7}{8}$	$1\frac{7}{8}$	$5\frac{1}{8}$	2
$2\frac{3}{4}$	$17\frac{5}{8}$	$7\frac{3}{8}$	$10\frac{1}{4}$	$1\frac{15}{16}$	$5\frac{7}{16}$	$2\frac{1}{8}$
3	$18\frac{3}{8}$	$7\frac{3}{4}$	$10\frac{5}{8}$	$2\frac{1}{16}$	$5\frac{11}{16}$	$2\frac{1}{4}$

approximate in such cases where the formulas give values which cannot be expressed in even fractions, or give fractional values inconvenient for working figures.

* * *

THE SPOTTER IN THE SHOP.

There may be a better word to express just the same meaning as is expressed by the above title, but if so it is not in the dictionary, and it wouldn't look well in print, and therefore this will have to stand.

We all have met him; he works in every shop from Maine to California. Sometimes he has charge of a department, but he seldom gets as high up as that. He depends more upon his capillary powers to hold a job than he does upon his ability as a workman. If you are a good workman you need never object to his presence in the shop; in fact, it is often of advantage to a good man to have him; but we all detest the principle which allows or compels an employer to use him. He must be regarded by the firm as a necessary evil that cannot be avoided, somewhat similar to the use of cotton waste; you use it, and get all you can out of it, and then chuck it out of sight as soon as you are done with it.

I have worked in shops where there were one or more in every department, and everything said or done went to the office on the "underground" route as soon as it happened. But it does not pay to act as a "spotter" when the old man is not of that kind of stuff as to appreciate your efforts. A good thing of this kind happened at the works of the * * * Company many years ago, which has the merit of being true. One of the men went to the "Professor" with a tale of woe: "There is a man up in room 16 who has a shop down in the basement of his house, and he is experimenting all the time evenings, and he steals all his stock in the shop." "Is that so?" said the "Professor," very much interested. "Well, if you will kindly tell him this for me, that any time he has any trouble stealing all the stock he needs or wants, let me know, and I will see that he has an order for all that he needs." It was a clear case of the spotter getting left.

One more case that came up will show the disadvantages of the "spotter system." A foreman had in his department a large amount of work stowed away under the bench. It was piece work; had been inspected, passed and paid for, and was simply stored there with the knowledge and at the wish of the foreman of the stockroom, who didn't have room to receive it. The spotter didn't know all this and thought it was piece work that was being held back and hadn't been paid for, and was done with the connivance of the foreman. Now, all you boys who read this, and have done contract work, will know just what I mean, so Mr. Spotter puts in his report to the office. The whole matter could have been investigated and settled without any trouble and without the foreman's knowl-

. . . "Caused by breaking off a tap at the bottom of a deep hole."

edge, but instead of that, Mr. Spotter was so sure about the matter that the foreman was called on the carpet to explain. When he had done this to the complete satisfaction of the management, as he turned to leave the office, he couldn't help giving them this shot: "If you had only waited until you got the *next* report from that spotter of yours, it would have saved you all this trouble." A. P. PRESS.

MR. EDITOR: The above was written while recovering from a bad attack of the blues, caused by breaking off a tap at the bottom of a deep, deep hole in a big casting. A. P. P.

* * *

Everyone working at the bench, desk or drafting table likes to have plenty of light, but as the direct glare of sunshine is intolerable, it is generally necessary to screen off the light of windows on the sunny side of the building with shades or ground glass so as to subdue and diffuse the light and thus relieve its intensity. Unfortunately this usually means that a large part of the light is shut out. A scheme which subdues and diffuses the light without greatly reducing its volume was described by Mr. W. J. Thompson at a recent meeting of the Illuminating Engineering Society in New York. He hangs a large sheet of tracing cloth over the windows; the light coming through the tracing cloth is apparently as bright as the direct sunlight but it is diffused, lighting up a room in very much the same manner as an ordinary skylight. He tried the tracing cloth scheme after trying to get proper illumination in other ways, using screens, awnings, shades, etc., but has found that the tracing cloth shades answer the purpose the best of all. The hint is one well worth consideration in the drawing room and is a scheme easily tried as the material is always at hand for a trial. It may be that the simple tracing cloth scheme answers the purpose for which expensive prismatic glass arrangements are often installed; that is, to throw light to the dark side of a room.

MAKING BLANKING DIES TO CUT STOCK ECONOMICALLY.*

C. F. EMERSON.

A most important point for the diemaker to bear in mind in making blanking dies for odd shapes is to lay them out so that the minimum amount of metal will be converted into scrap. In fact, hardly too much stress can be laid upon this one point alone. It is an easy matter to waste a considerable

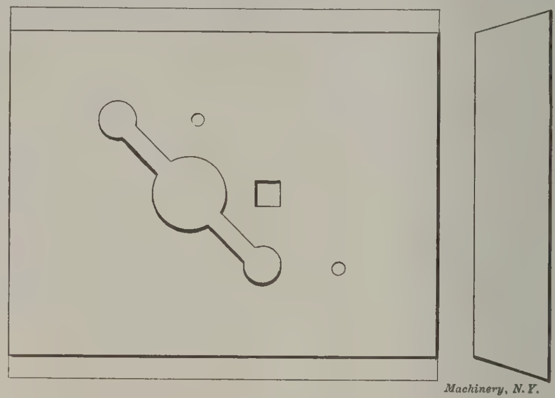

Fig. 1. Plan of Blanking Die.

percentage of the stock by lay-outs which may *appear* to be fairly economical. The diemaker should make a careful study of the most economical relation of blanking cuts to one another and to the stock. It is the object of the following article to point out by actual examples how stock can be saved which might be converted into scrap if the diemaker is not constantly watching out for possible economies. As an illustration, it

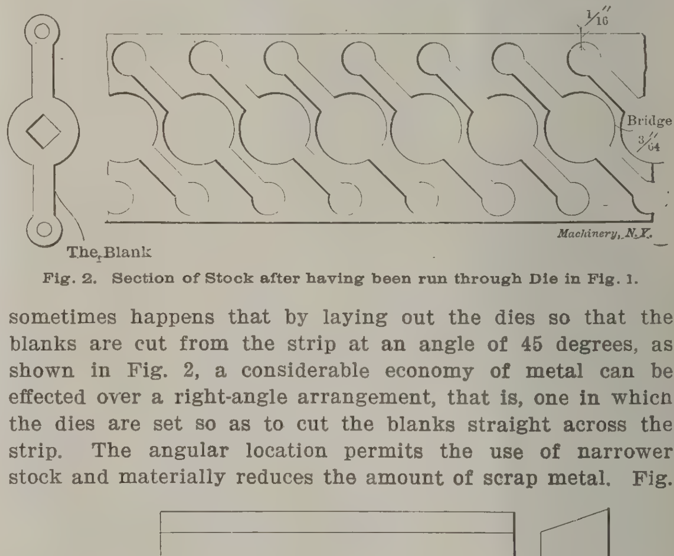

Fig. 2. Section of Stock after having been run through Die in Fig. 1.

sometimes happens that by laying out the dies so that the blanks are cut from the strip at an angle of 45 degrees, as shown in Fig. 2, a considerable economy of metal can be effected over a right-angle arrangement, that is, one in which the dies are set so as to cut the blanks straight across the strip. The angular location permits the use of narrower stock and materially reduces the amount of scrap metal. Fig.

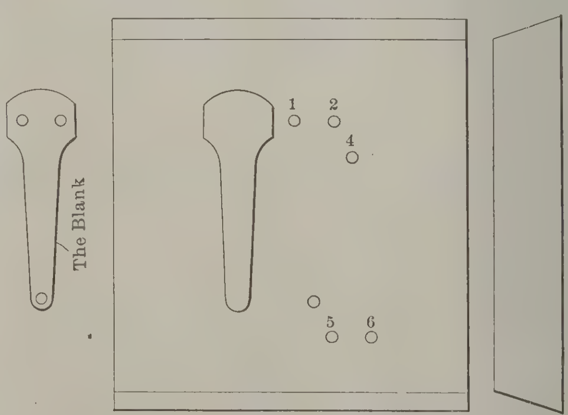

Fig. 3. Another Example of Blanking Die.

1 shows the plan of the die, and needs little or no explanation as the manner in which it is laid out is obvious; the plan of the strip shown in Fig. 2 also clearly shows how the die is laid out.

Another method that is often used to save metal is that shown in Figs. 4 and 5. This method is used where the re-

* This article is a continuation of the articles on die-making by Mr. Emerson, which appeared in the June, 1906, and October, 1906, issues.

quired amount of blanks does not warrant the making of a double blanking die; also when, unavoidably, there is a considerable amount of stock between the blanks after the strip has been run through as shown at *A* in Fig. 4. To save this metal the strip is again run through in a reverse order after the manner shown in Fig. 5, thereby using up as much of the metal as it is possible to do.

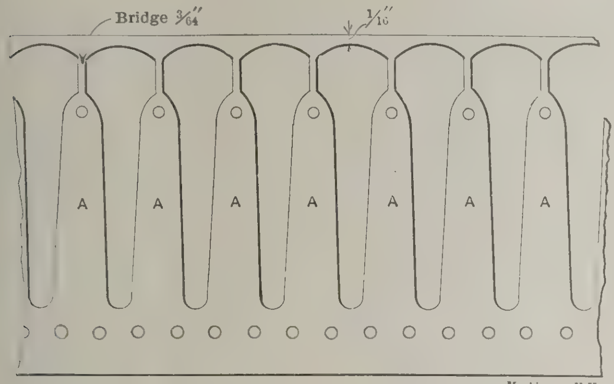

Fig. 4. Stock after having once been run through Die in Fig. 3.

Besides blanking and piercing the blank when running the metal through the first time the holes numbered 4, 5, and 6, Fig. 3, are also pierced. This is done for the reason that when the metal is run through the second time it prevents cutting of "half blanks" by "running in," or, in other words,

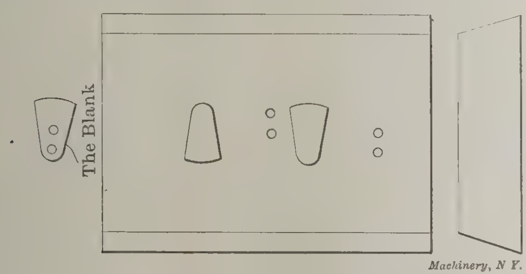

Fig. 6 A Third Example of Blanking Die.

the liability of cutting imperfect blanks by cutting into that part of the metal from which blanks have already been cut. This guiding action is effected by three pilot pins in the blanking punch (not shown) which engage in the three pierced holes, made when the strip was run through the first

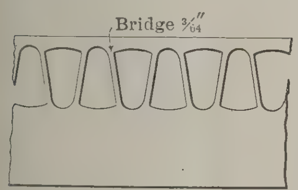

Fig. 7. Stock after having been run through Die in Fig. 6 once.

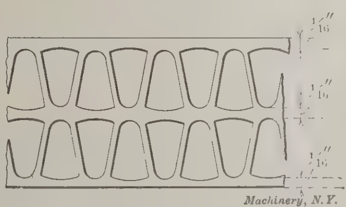

Fig. 8. Stock having twice been run through Die in Fig. 6.

time. The pilot pins engaging with the pierced holes cause the second lot of blanks to be cut centrally with the holes; also to be accurately centered between the portions of stock from which the blanks have already been cut. When this die is in use the metal is run through in the usual way from

holes numbered 1 and 2 in Fig. 3, and the line *B* is the center line of the blanking part of the die. The line *C* is the center line that shows the center of the next blank to be cut and is laid out 53/64 inch from the line *B*. This dimension is fixed by the fact that the widest part of the blank is 25/32 inch and the bridge between the blanks is 3/64 inch, the sum of which equals the distance from center to center of adjacent

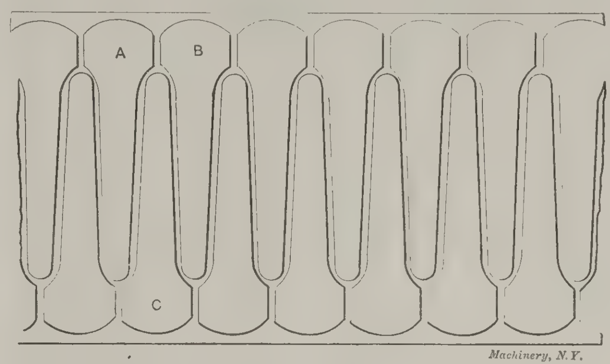

Fig. 5. Stock after having been run through Die in Fig. 3 twice.

blanks. The line *D* is the center line for the blank *C*, Fig. 5, that is cut when the metal is run through the second time, and is made at 0.414 inch or one-half of 53/64 from the line *C*, Fig. 11, inasmuch as the blank is cut centrally between that part of the metal from which the blanks *A* and *B*, Fig. 5, are cut.

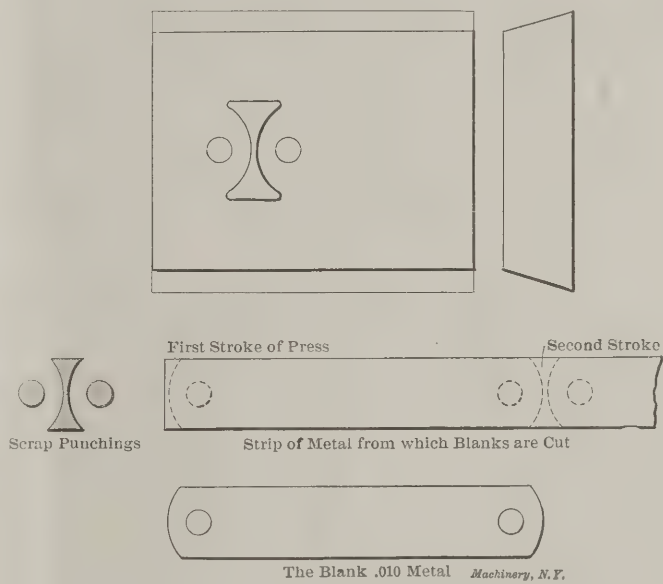

Fig. 10. Blanking Die for Producing Links.

Fig. 6 shows a double die for blanking and piercing brass, producing the shape shown in the sketch at the left; it is laid out so as to save as much of the metal as practically possible without added expense in so far as the operation of blanking and piercing is concerned. By referring to Figs. 7 and 8 it can be seen that the strip of metal from which the blanks are cut is run through a second time for reasons that

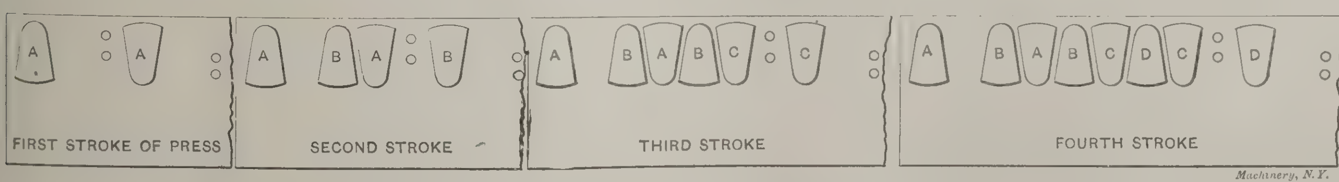

Fig. 9. Appearance of Stock after each successive Stroke of the Press.

right to left until half of the required amount of blanks are cut, after which the piercing punches for the holes are taken out and the metal is run through again and the other half of the required amount of blanks is cut.

In laying out this die which is done after the manner shown in Fig. 11 the line *A* is used as a center line for the piercing

will be given. One reason is that wider metal can be used by doing so which in itself is a saving in so far as the cost of metal is concerned. Wide brass can be bought at a lower price per pound than narrow brass; the other reason is that a strip of metal 1/16 inch wide and as long as the entire length of the strip is saved on every strip that is run through. If

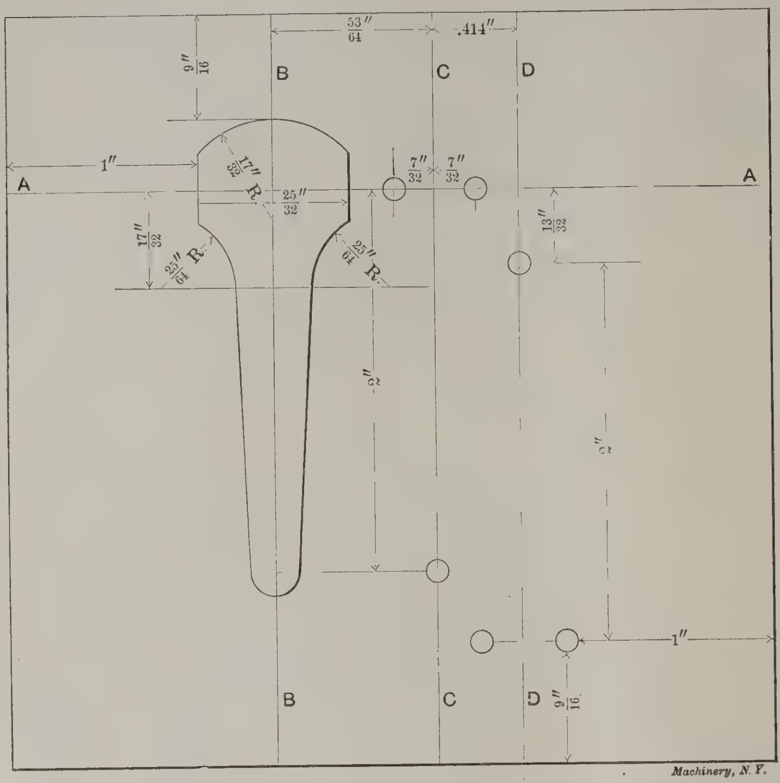

Fig. 11. Layout of Die shown in Fig. 3.

narrow metal were used there would be a waste of ⅛ inch of metal (*i. e.*, 1/16 inch on each side) of every strip run through. But on two strips from which no more blanks can be cut than from the wider strip shown in Fig. 8 there would be a waste of ¼ inch of metal. On the other hand, by using wide metal the waste would be only 3/16 inch, as indicated in the cut. Fig. 12 shows how this die is laid out and should be sufficiently clear to explain itself and thus requires no further words.

To fully understand the manner in which the metal is gradually worked up after each stroke of the press, short sections are shown in Fig. 9. At the first stroke four holes are pierced and two plain blanks—with no holes—*A A* are cut out. At the second stroke there are also four holes pierced and the two blanks *B B* are cut that have the holes pierced at the previous stroke. At the third and fourth strokes the holes begin to match in with each other, as shown so that when the metal is run through it will look like the strip shown in Fig. 7.

It should be borne in mind that four holes are pierced and two blanks are cut at each stroke of the press; also that the

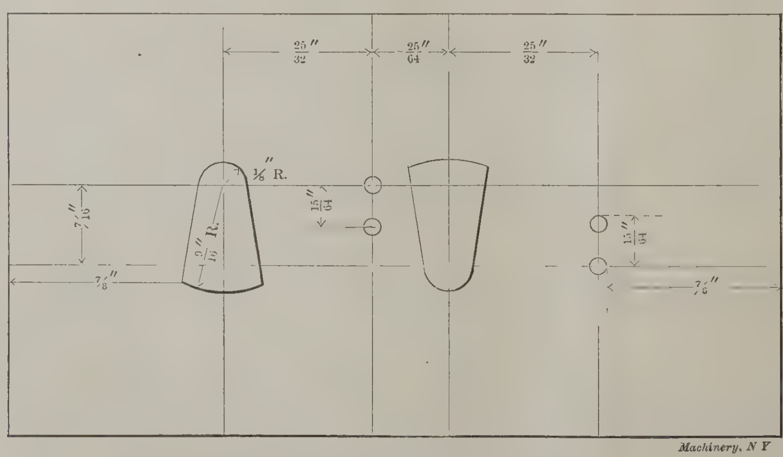

Fig. 12. Layout of Die shown in Fig. 6.

metal is fed after each stroke a distance equal to the distance from the center of *A* to the center of *B*, as indicated in the strip marked "second stroke," Fig. 9, and which is 25/32 inch (see Fig. 12). By way of further explanation it may not be amiss to state that the distances from the center of *A* to *B*, *B* to *C*, *C* to *D*, and *D* to *C*, as shown in the strip marked "fourth stroke" are each 25/64 inch, or half of 25/32 inch.

While the dies shown in Figs. 10 and 13 are commonly known it may not be out of place to say a few words with reference to them as they form an important part in the economical production of sheet metal goods. The first or Fig. 10 shows a die that is used to produce from narrow ribbon a long blank with rounded ends and with a hole pierced in each end. The principal features of this style of die are that there is very little waste of material in the production of the blanks, as will be noted from the sketch of the scrap punchings shown at the left, and the other feature is that by the aid of an adjustable stop, not shown, almost any length of blank can be made without altering or resetting the tools after they have been set up in the press. The working part of the die is laid out a little to the left of the center so as to give sufficient length for the gage plates which are fastened to the die by ¼-inch cap-screws. These gage plates are used to keep the metal in position while it is being fed from right to left as the blanks are cut from the strip.

Fig. 13 is a combination piercing and shearing die and is used for producing the 1-inch square washer shown in the cut. The principal feature of this die is that there is no waste of metal in producing the blank, only, of course, the ¼-inch round punching taken from the center. The strip of metal in

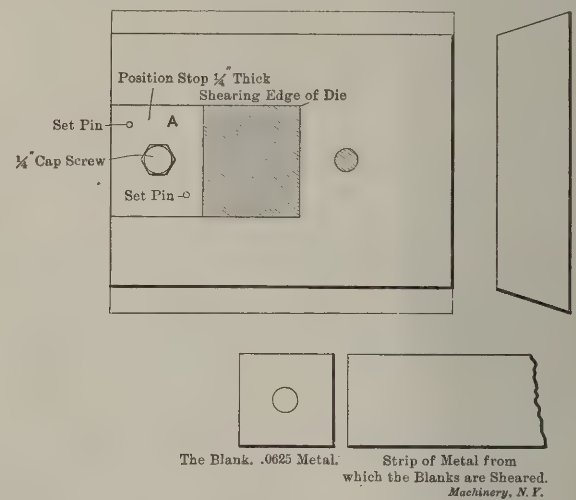

Fig. 13. Blanking Die for Square Washers. Shaded Portions in Die indicate parts punched out from stock

this case can be fed from right to left or front to back as preferred.

* * *

An interesting note in the columns of a contemporary describes a new refrigerator which is "lined with solid white stone mined in the company's own quarries." The statement is made that this stone is almost *ice cold* itself and is therefore specially well qualified to keep the provision chamber at a low temperature and save ice. It is a not uncommon idea that any material which feels cold to the hand must necessarily be a good refrigerating medium. As a matter of fact the colder a piece feels the poorer it is as an insulator, and insulation is largely the secret of refrigerator efficiency, of course. The feeling of cold is due to the conduction of heat away from the hand. The best insulator is that which feels "warm." No simple covering will keep a chunk of ice better than a thick woolen shawl. The shawl has no warmth in itself but is an excellent non-conductor of heat, hence it preserves the ice from melting better than almost any other material so long as it keeps dry.

APPRENTICESHIP EDUCATION.

ENTROPY.

While I have to thank Mr. Strong for his good opinion as expressed in his article (November issue), I thank him more for the opportunity which he seems to give me to sum up the various articles on apprentice education which I have written from time to time under various pen-names. I have tried in the past to present my plan a bit here and a bit there, seeking to interest as many as possible and knowing that the very men whom I wish to reach are the busiest and have the least tendency to begin to read long and learned articles. While the subject is more or less of a hobby with me I am still sufficiently disinterested so that I can take any suggestions in the spirit in which they are sent. My work in this line is not for my personal gain at all, for while I would like to be in at the start of any school or shop organization I do not care to follow it up for a livelihood. With this in mind as well as to persuade Mr. Strong that my plan as a whole covers his point I will put the whole thing as concisely as possible. My plan involves a shop and revolves about the shop as its central idea. The shop must be a commercial shop—absolutely must. Preferably it should make a large enough range of work so that it may train the boy with mechanical ability and incapacity for fine work as well as the boy to whom close measurement is a pleasure.

Then there must be a school in which should be taught those things which are of *direct* use to a machinist, foreman, or master mechanic. No others. This must be religiously adhered to. Otherwise the result will be that some ambitious teacher will make a third-grade engineering school of it. The control of the school must be from the shop to secure its subordination. The division of time should, for commercial reasons, be made such that half the boys are running machine tools all the time. The other half should be divided between school-room work, drafting, and hand work. The length of time which the boys stay in either division should not be over a week.

Pay.

For any man to be content he must feel that he is making a good thing of it. You can pay a man in money or in something which he can reasonably expect to turn into money later. With boys of the class that we must expect to take, money is the best with which to appeal. If they are to be paid in money it must be an equitable payment for what is done. As Mr. Strong hints, when a boy goes into a shop he is enthusiastic and works around lively. As soon as he gets so that he can do something commercially well he finds that he is kept in it as long as he will stand it, without increase of pay. He does not feel that he is being treated right if he does a man's work without a man's pay. His employer tells him that it has cost him good money to teach the apprentice to do this work. If the apprentice has any head for mathematics at all he can figure pretty close to what it has cost the firm to have the foreman stop and make fun of him a few times and show him about once how to do a little job. No wonder he gets listless.

Instead of paying by the hour, pay by the piece. For finished work done acceptably pay a little less than the journeyman's rate to cover increased length of time the apprentice ties up a machine. Charge the boy a certain amount for teaching him each step of his progress. Have him pay cash or work it out by keeping at this one style of job after he has gotten so he can work a commercially acceptable job. If he wants more money to spend or to live on let him work on this same job till he has earned enough to satisfy him. The average boy would stay on the job till he was really pretty expert at it, and I think be very content. The employer would know just how he was coming out at the end of the term of apprenticeship. If a shop is not already on a piecework or premium basis it would mean quite a little work to arrange for the apprentices so that they would get a consistent course and have their piecework or premium rates fair to both sides.

Class of Boys to become Apprentices.

The present and ever present need of the shops is for skilled workmen who can work with judgment. If such boys as now go to technical schools are selected they will become good machinists, but they will not be content to stay machinists long. They will want to and will go higher. It is apart from my purpose to discuss the relative merits of engineers trained in this way and those trained in technical institutions. But this seems sure to me that for an apprentice system to be successful from a manufacturer's point of view its recruits have to be from a stage in life where $15 or $18 a week looks big. To such boys the possibility that if they are diligent they may become leading hands or foremen, or that occasionally one may rise to be a master mechanic, a superintendent, will be enough to attract them. The examination then for admission to such a school should set an upper limit above which a candidate should not pass, as well as a lower limit, which he must equal.

Foremen and Teachers.

To ask the regular shop foreman to take apprentices under his charge and give them the attention they need is an injustice to him. His business is to produce work, not teach. He has to earn his salary if he does his legitimate work. More than that, it is rarely the case that a foreman who is good with the boys is good for much as a foreman. While school-room teaching in addition to the present loose method in the shop would be better than nothing I hope no one will think that I prefer the makeshift which I suggested in the August issue to this main plan. In a shop I would suggest a room partitioned off, as they do in Lynn, from the rest of the shop, but I should keep the boys there full two years of their course in contact only with the best of leading workmen.

These instructors should be men of experience but they should be young enough to have active interest in their work and they should know that their future pay will depend exclusively on results obtained. The instructor in machine work should be a good clean-cut mechanic whose experience and judgment renders him capable of all grades of work, and who can take hold and show the boys. The instructor in the school room should be some young man, say a draftsman with technical education who has been out long enough to have forgotten all his calculus and most of his trigonometry, a man who knows what methods will give solutions of everyday problems with the least mental effort. No teacher of the usual educational type need apply. No one will do who cannot pick up out of his memory a lot of really useful problems.

How a Small Shop can Afford to Start a School.

I should say that a shop with a dozen boys is the lowest number possible. More will be better. With so few boys the shop instructor might do some work himself at the lathe or bench though I mistrust that it would pay to have him right around the boys all the time, even with so small a number. For equipment give them tools already in use in the shop. Not the most antiquated in design but something modern. If badly worn let the best of the boys repair them. Have them keep the tools up in good shape too. The reason for putting the boys all in one room for so long a time is this. Almost all shops have a pacer, or a man who sets the gait at which the rest go. Such a man makes it impossible to get an apprentice to set any faster pace. What is wanted is men who follow no pace but their own. They are wanted badly enough so that they can command their own price and their own hours within reason. If the boys do not know anybody else's pace and are paid piece or premium rates they will, as they grow expert, tend to set a pace which will make them valuable to a point of healthful independence.

Cost.

This is not a philanthropic scheme at all. Unless it pays it neither will be done nor ought to be done. Unless boys can be held by nothing more than their own self-interest they ought not to be held. The old-time apprentice system said to a boy: "Come in and I will teach you a trade. But you must put yourself entirely in my power, be my slave for a term of years." In itself it was an admission that when the boy found out how he was to be treated he would quit if he could. Unless a contract is mutually agreeable it

is a poor contract for either party in the long run. Under my plan we will say to a boy: "Come in and for a certain price we will teach you to do a certain job. We will guarantee you work at fair pay on that job long enough so that you can afford to pay our price. Then if you want to learn another step of the trade we will teach it to you and you shall pay us for doing it. You may leave any time that you think you have learned enough. If you come in you must attend our school and get what you can out of it." Under this plan it is perfectly feasible to so set piece work or premium rates that the proprietor may know pretty closely where he will come out at the end of the year. He ought to come out a trifle ahead. The boy's self interest will keep him working on a job long enough to get some money ahead which will insure his dexterity. His self-interest will make him take up the next job as soon as he can afford it and will make him learn as fast as he can so that he can get to making money. His self-interest will keep him faithful in school for just the same reason that men are faithful to their correspondence school work.

The thing which yet remains to be accomplished before anything can be started is to persuade manufacturers that for their own safety in the future the country needs skilled, intelligent, native workmen; men who can stand on their own bottom and do the work which is needed to keep this country commercially ahead of the world, and men who need hide behind no organization to command the respect of their employers, and men who can and will bring skill and judgment to their work so that they may command compensation beyond the dream of any organization.

WEIGHT OF TIN PLATES.

The accompanying table by Mr. Horace Chrisman, East Pittsburg, Pa., contains some very useful data on tin plates. It includes the different denominations of tin plates and the corresponding number of the United States standard gage; also the nearest Brown & Sharpe gages and the actual thickness in decimals of an inch. The thickness of tin plate varies

WEIGHT OF TIN PLATE PER SQUARE FOOT.

Trade Designation of Gage.	Fraction of a Pound Tin Plate.	Ozs. Tin Plate	U. S. Standard Gage.	Nearest B. & S. Gage.	Thickness in Decimal Parts of an Inch.

according to the coating of tin retained on the surface of the sheet. About two or three numbers of Brown & Sharpe gage should be added to the above columns marked with the asterisk to get the thickness of tinned plates.

* * *

There is a decided difference between a true mathematician and one who is "quick at figures." The true mathematician is a logician; he deducts certain facts and relations by a course of reasoning and proves them by calculation. If the figures do not prove his deduction he is more likely to look for the fault in the calculation than in his course of reasoning, for its very logic denies the possibility of error. The one quick at figures must, of course, be something of a logician but there is the difference that the first uses calculations as the means to prove a logical deduction, while the other always uses concrete quantities to get a definite result, and with, perhaps, only a dim idea of the mathematical principles involved. The use of a general expression to cover all possible cases of a given problem does not appeal to the "figurer" but it is just what the mathematician always seeks.

TEMPERING HOLLOW MILLS AND OTHER TOOLS.

J. F. SALLOWS.

The art of tempering high-class tools is understood by few mechanics; the majority of them know little or nothing whatever about tempering even so common a tool as a cold chisel. They think that standard sized tools bought in large quantities by factories throughout the country, which are stamped "B. & S.," "P. & W.," or some other well-known firm name, must be O. K., and often they would give a great deal to know just how to temper tools as well as these are tempered. This blind faith sometimes is the cause of amusing incidents. I have known a machine shop foreman to send a number of machine steel pieces into the smith to be annealed so they could be drilled. Upon investigation it was found that a new drill was too soft to drill anything except lead or pine, but after hardening, the pieces referred to were easily drilled. The fact of the matter is that the foremen and men under them often take for granted that because a drill is a twist drill and bought from a well-known concern it must, of course, be perfect, but if it were made in the shop where the work was being done and proved faulty they would very likely blame the man who did the tempering—even if it was done as it should be.

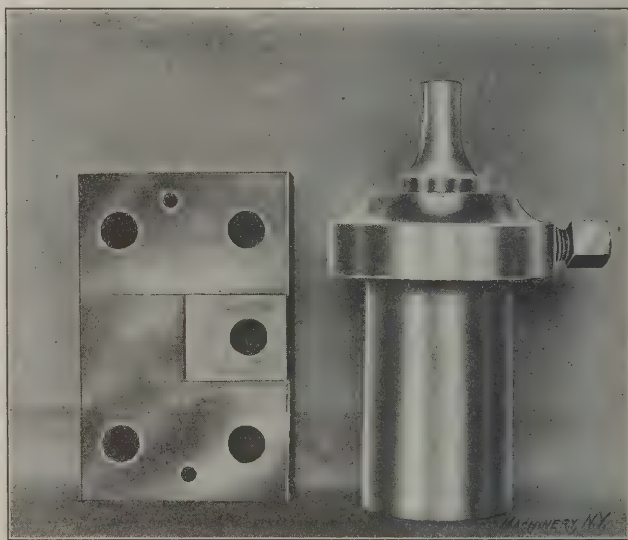

Fig. 1. Punch and Die having a Good Record. Hardened, but not Drawn.

In my experience of twenty-seven years on nearly all kinds of tools I find that each and every kind of tool has to be tempered in a way that suits its individual peculiarities and the class of work which it is intended to do. For example, I would not temper a tool for cutting brass the same as one for cutting machine steel, but nothing is more common than to find a smith tempering all lathe tools alike. This lack of discrimination is the cause of a great deal of trouble in all large plants. The man about to use the tool does not inform the smith who tempers it what the tool is required to do. Therefore, it is impossible to give general satisfaction. The smith who does the tempering blames the steel, and the one using the tool blames the smith and the tempering. As an example of my system I will write at this time about tempering hollow mills and explain what I claim to be the only correct method of tempering them to give satisfaction.

I cannot explain—nor can anyone else satisfactorily—why it is necessary to heat a tool up to a high lemon color and quench it off in cold water, then clean it all over, polish, rub, and perhaps spend ten hours time on what could be done in two hours. This may seem like a radical statement, but it will not appear so when I can prove to you that I can temper a three-inch mill and have it ready for work in twenty minutes. I have seen large tools hardened and put on the bench to be cleaned all over before being drawn to a light or dark straw as the case may require, but I never could find out whether the color was that of pea straw or rye straw (we can, by the way, draw machine steel to a nice straw). I have seen three punches tempered and drawn to the same color;

one was too soft to be of any use and the other two broke similar to cast iron. The difference in action was due to the way in which they were heated. Drawing a tool carefully to color cannot let you out if you do not watch your hardening heat. But, to return to the tools on the bench to be cleaned; when the man was ready to do the cleaning he found instead of having six tools he had eighteen parts of tools. The blame for this catastrophe was laid to the steel when the workman himself was at fault for going at a job he knew nothing about; before he was ready to relieve the so-called

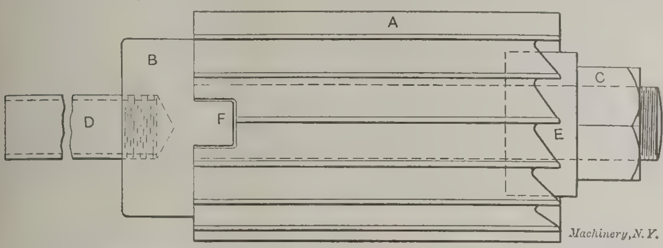

Fig. 2. Mandrel and Handle with Hollow Mill Mounted for Hardening.

internal strains they had relieved themselves, but why have internal strains to relieve? If the tempering smith will temper tools as I am about to explain he will have no internal strains to bother with, and the workman will have a milling cutter that will do more work and give better satisfaction than any internal-strain-relieved straw-colored tool that was ever tempered by any smith in any shop. As an example the accompanying halftone, Fig. 1, shows a 7/16-inch punch and die that has punched 100,000 holes in ¼-inch machine steel, or the equivalent of 25,000 lineal inches. The punch and die are still at work; it is interesting to know that they were never drawn to a straw color and I am sure that neither is troubled with any internal strains.

A smith doing tempering should do no welding and should, when not employed at tool work, be at some kind of work that can always be done at a low heat; then by following the rules laid down here he can become an expert on hollow mills as well as other tools. My equipment and method are as follows:

Fig. 2 shows a hollow mill *A*, mounted on a stud or mandrel *B* which is made of machine steel to fit the mill and

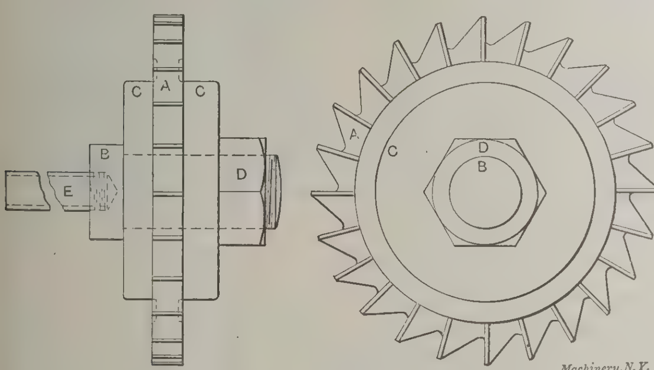

Fig. 3. Rig for Hardening Side Milling Cutters.

provided with a washer *E* and nut *C*. The stud must closely fit in the slot of the hollow mill, as shown at *F*. The end of the stud opposite the threaded end is tapped out with a pipe tap for the pipe handle *D*, which is used for handling the work when heating and hardening, the handle being a half-inch pipe about 24 inches long. This same pipe handle will do for a large variety of different sized studs. Of course if a furnace is provided for heating tools of this kind a pipe handle will not be necessary, but if only an ordinary forge is used for tempering and hardening this scheme is desirable. It is quite necessary to have a good mill file at hand to test the hardness of tools, for sometimes in my experience I have known the toolmakers to send out tools made from machine steel, and insist on having them hardened and tempered. In such cases the file is the only method of showing the toolroom foreman his mistake. I have experienced this trouble more than once and know whereof I speak.

Build a fire in the tempering forge with charcoal lumps about the size of a hen's egg. Place the hollow mill assembled as shown in Fig. 2 on the fire and cover with charcoal; shut off the blast and let the tool heat with the charcoal until it has reached a nice bright heat, then take out, dip into a solution of salt and water in the proportion of about ½ pint of salt to 2 gallons of water. Be sure that the salt is well dissolved. Do not let the milling cutter cool in the water, but when the red is all gone remove from the water, let the tool dry and plunge in a crock of fish-oil. Leave the cutter there until cold enough to handle, then take out, remove the nut and washer, take the cutter off and send it to the toolroom to be put to work. Perhaps the smith will not be successful with the first one hardened and tempered by this method but a few trials will lead to success.

When tempering milling cutters of the type shown in Fig. 3 the smith must have a small, high fire and put on the blast lightly, turning the tool constantly until ready to dip. Then dip in salt water the same as directed for the hollow mill. The result is no warping or cracking and no internal strains in any cutters tempered in this manner, and they will stand more hard work than if tempered in any other way. In explanation of the rig used for tempering the milling cutter shown in Fig. 3, *A* is the cutter, *B* the stud, *C* the washers, *D* the nut, *E* the pipe for handling. The washers protect the body of the cutter from heating and only the teeth are heated to the hardening temperature. The consequence is that there is no necessity for drawing the temper of the body of the cutter inasmuch as it has never been heated to the hardening heat; consequently it is always left soft.

A serious trouble with heating tools to remove internal strains aside from those already mentioned is shown in the case of a solid reamer. Suppose a solid reamer is held over the fire to remove internal strains. The result is that the thin edges which are the cutting parts are heated much quicker than the internal parts, and are softened, so much, perhaps, as to render the tool useless, but by hardening as just directed and taking the reamer out of the water before it is cool and putting it into fish-oil its toughness is preserved and at the same time it does not get any softer than it was when it was removed from the water.

[The method recommended by Mr. Sallows, of course, is radically different from general practice, although strictly analogous to the common practice of hardening and tempering chipping chisels and similar tools. If a milling cutter, hollow mill or any other expensive tool can be successfully hardened on the points of the teeth only we are sure that the practice is one to be recommended for several obvious reasons. If there are serious objections let us hear what they are.—EDITOR.]

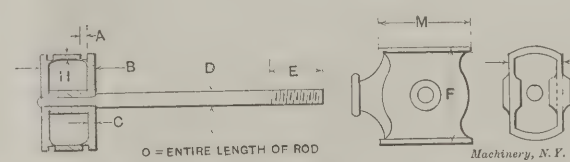
SLIDE VALVE ENGINE PROPORTIONS.

The accompanying tables on plain slide valve engine proportions, including cylinders, connecting-rods, valves, pistons and piston-rods, crossheads, crankshafts, crankpins, crank-disks and eccentrics, were compiled by Mr. C. R. McGahey, while superintendent of Lombard Iron Works, Augusta, Ga.

PISTON, PISTON-ROD AND CROSSHEAD.

O = entire length of piston-rod.

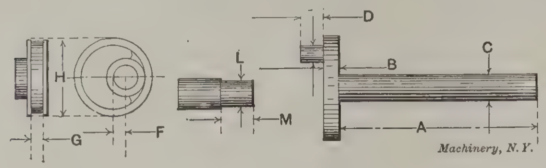


Cylinder.	*A*	*B*	*C*	*D*	*E*	*M*	*N*	*H*	*O*	*F*
7 x 10	⅜	3	⅜	1⅜	3⅝	7¾	4	⅜	23⅝	8
8 x 10	⅜	3	⅜	1⅜	3⅝	7¾	4	⅜	23⅝	8
9 x 12	½	3½	½	1½	5	9½	5	½	28⅝	10
10 x 12	½	3½	½	1½	5	9½	5	½	28⅝	10
11 x 14	⅝	3⅞	½	1¾	5½	10½	5½	½	33	11¼
12 x 14	⅝	3⅞	½	1¾	5½	10½	5½	½	33	11¼

We are assured by Mr. McGahey that the tables of dimensions represent the most advanced and best known practice with this type of steam engine. The tables are of the same order as the dimensions of equal section and concentric piston rings contributed by Mr. McGahey in the February (1906) issue.

ECCENTRIC, CRANKSHAFT AND CRANK-PIN.

I = travel of valve. J = width main bearing. K = width main bearing pillow block.



Cylinder.	A	B	C	D	E	F	G	H	I	J	K	L	M

10 x 12	54	3	$4\frac{3}{8}$	$3\frac{1}{2}$	$2\frac{1}{2}$	$1\frac{1}{4}$	$1\frac{3}{4}$	8	$2\frac{1}{2}$	$8\frac{1}{2}$	10	$2\frac{3}{8}$	$2\frac{7}{8}$
11 x 14	57	$3\frac{3}{8}$	$5\frac{3}{8}$	$3\frac{3}{4}$	$2\frac{11}{16}$	$1\frac{3}{8}$	2	$8\frac{1}{2}$	$2\frac{3}{4}$	10	$12\frac{1}{2}$	$2\frac{9}{16}$	$3\frac{1}{8}$
12 x 14	57	$3\frac{3}{8}$	$5\frac{3}{8}$	$3\frac{3}{4}$	$2\frac{11}{16}$	$1\frac{3}{8}$	2	$8\frac{1}{2}$	$2\frac{3}{4}$	10	$12\frac{1}{2}$	$2\frac{9}{16}$	$3\frac{1}{8}$

the cutting edges, which are further apart to insure that the width of the land would be equal in all cases. That this is impracticable when fluting reamers in any large quantities is easily apprehended, as it would necessitate raising or lowering the milling machine table for each flute being cut. In the *Zeitschrift für Werkzeugmaschinen und Werkzeuge*, a method is shown employed by the large machine tool firm of Ludwig Loewe & Co., Berlin, Germany. The principle of this method is clearly shown in the accompanying cut. A formed cutter, eccentrically relieved, is employed which, instead of forming only the flutes, forms the actual land of the reamer, thus insuring that every land becomes equally wide with the others. The depth of the flute is determined by the depth of the portion of the cutter in front of the cutting edge of the reamer and it is easily seen that all the flutes will be equally deep.

That this method will be more expensive than the one commonly employed, in which the lands are permitted to become wide or narrow according to the amount the flutes are broken up, is evident, but it cannot be disputed that the general appearance of the reamer will be greatly improved. The greater expense in making reamers in this manner will depend on two factors. In the first place, the eccentrically relieved cutter will cost more to produce than the ordinary fluting cutter. In the second place, the cutting speed cannot be as high with a cutter of this description as it could be with an ordinary milling cutter. On the other hand, it is possible not only to gain the advantages mentioned above in regard to width of land and depth of flute, but incidentally there is also gained the possibility of giving to the flute a more correct form to answer the requirements of strength as well as chip room, which are often by necessity overlooked on account of the straight sides forming the flutes which are necessary to adopt when using the ordinary straight-sided fluting cutter, with milling cutter teeth of the common shape. While it cannot be expected that this method will be used to any great extent on account of its drawbacks from a commercial point of view, it is ingenious and well worth attention.

NEW METHOD OF MILLING THE FLUTES OF REAMERS.

In milling the flutes of reamers it is customary to mill them so that the cutting edges will not come an equal distance from one another. This prevents chattering and permits the use of an even number of flutes. The difficulties encountered in milling the flutes on unequal distances, or breaking up the flutes as it is commonly termed in the shop, are that if all the grooves are milled to the same depth the remaining land evidently will be wider in the case where the distance from cutting edge to cutting edge is larger than it will be in the case where this distance is smaller. To overcome this it would, of course, be possible to mill the flutes deeper between

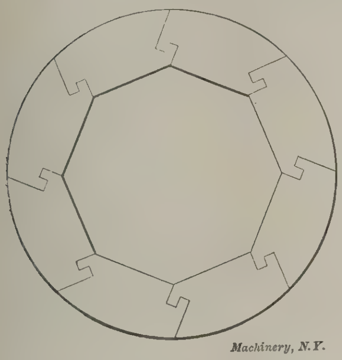
ITEMS OF MECHANICAL INTEREST.

WOODEN LOCK-JOINT COLUMN.

The Woodworker illustrates a method of making column joints which, on account of its ingenious interlocking device, may deserve the attention and interest of others than woodworkers. As seen from the cut, the finished column constitutes a solid, which cannot be disintegrated by any other means than by sliding one of the interlocking parts out in a longitudinal direction. Evidently it cannot be assembled in any other way, either, than by sliding in the last section from the end.



Method of Making a Wooden Lock-joint Column.

PAPER MILK BOTTLE.

Here is an item of mechanical interest for this page quite out of the usual run, but it is nevertheless of much general interest. It is a paper milk bottle designed to replace the glass bottles now generally used. The paper bottle is claimed to have the advantages of less cost, much less weight, greater cleanliness, no expense for washing and return transportation. When it is known that the ordinary glass milk bottle weighs as much as the milk, *i. e.*, two pounds for a quart bottle it at once becomes apparent that the bottles represent half the dead weight when milk is transported in this shape. The dead weight loss is still greater in that the bottles have to be returned. The paper bottle is designed to be used only once and then thrown away, thus saving all cost of returned transportation, and also washing. The bottles are made in three sizes, quarts, pints and half-pints, the material used being three-ply spruce wood fiber paper rolled into a frustrum of a cone. The bottoms are secured by an ingenious lock, and it is claimed that the inverted bottle will support a load of 200 pounds without collapse. The lid is an inverted cup fitted into the lumen of the bottle and having a contact with the sides of ½ inch. Removal is facilitated by four tabs which permit of finger hold. The whole bottle including the bottom and top is covered with a coat of paraffine which more or less completely impregnates the paper. The cone shape facilitates packing, as they may be assembled in "nests," putting one inside another and thus saving much space. An idea of the saving of weight may be gained from the fact that 150,000 paper bottles may be shipped in an ordinary freight car, the weight being only about six or eight ounces each as against about thirty-two ounces with glass.

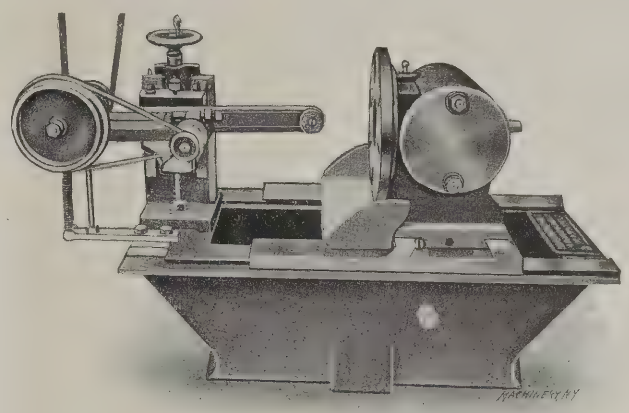
SQUARE HOLE GRINDING MACHINE.

An unusual machine for an unusual operation—the grinding of square holes, as indicated in the title—has been designed and is being put on the market by C. W. Burton, Griffiths & Co., Ludgate Square, Ludgate Hill, London, E. C. The special operation for which the machine is needed is that of finishing square holes in the hardened gears used in automobile speed transmission cases; it is intended to do away with the slow and costly lapping operation which has hitherto been resorted to for truing up these surfaces in getting rid of the distortion resulting from the hardening operation to which they are subjected. It is also applicable to the finishing of dies of various kinds and other hardened parts having internal flat surfaces difficult to reach by ordinary means.

The work is fastened on the faceplate at the right of the machine. This faceplate, which is 12 inches in diameter, is mounted on a spindle having a 4-inch diameter hole to permit gears or pieces with projecting bosses to enter the end of spindle and thus make the clamping more convenient. In the case of the plain machine this faceplate has indexing notches and is provided with a locking lever. A cross slide operated by a screw and hand wheel, graduated to 0.001 inch, gives the necessary adjustments for feeding. This machine is adapted for grinding parallel holes only. The universal machine, in addition to grinding parallel holes, will grind tapered ones, the work carrier having an angular adjustment both above and below the horizontal axis and a circular movement around its base. Where required the machine can be furnished with self-acting travel of the work carriage on the bed at extra cost.

The vital feature of the machine is the method of supporting and driving the emery wheel. This wheel, of small enough diameter to enter the square hole which it is desired to finish, is mounted on a transverse axis at the outer end of the long bar shown. The short spindle which carries the wheel at one end is mounted on ball bearings set as far apart as possible and carries a grooved pulley at the opposite extremity. An endless belt, made from a leather ring rolled until the edges have been rounded, is used to drive this short spindle and the wheel fastened to it. As will be readily understood from the cut, the spindle, emery wheel, belt and bar are all of such proportions that they can enter bodily the hole which is to be finished. In order that the maximum of stiffness may be obtained in the support of the grinding wheel, it is recommended that a separate bar be used for each size of hole, with separate spindle and wheel for each. The price of one bar and its attachments is included with the machine.



Square Hole Grinding Machine.

A small speed multiplying countershaft is used to transmit the motion from the countershaft belt to the wheel. The bar is carried on a vertical slide adjustable by the handwheel shown. The countershaft is supported by a mounted arm with spring tension so as to prevent vibration in the driving belt from affecting the emery wheel bar as it would be liable to do if attached rigidly to it. This precaution, in addition to the use of an endless belt for driving the wheel spindle, assures the freedom from jar and vibration necessary for accurate work. The vertical adjustment of the slide permits the grinding of flat, broad surfaces greater than the diameter of the wheel. The work is ordinarily traversed by means of a rack and pinion operated by a hand wheel.

* * *

Where any apparatus, such, for example, as a small jib crane, has to be operated by hand power and which requires a considerable exertion of a man or a number of men, the location and throw of the crank become important. Apparently, experience has shown that a height of 32 inches above the ground or platform for the crankshaft and a crank length of about 16 inches (32 inches throw) suits the average laborer best. For light exertion the crank length should be made only about one-half this diameter, or, say, 8 inches, and should be elevated so that the crankshaft is, say, about 40 inches above the floor level.

RAILWAY MACHINERY

A SPECIAL EDITION OF MACHINERY FOR THE RAILWAY SHOP, DEVOTED TO LOCOMOTIVE AND CAR EQUIPMENT AND MECHANICS.

Published monthly by

THE INDUSTRIAL PRESS,

66-70 WEST BROADWAY, NEW YORK CITY.

DOMESTIC SUBSCRIPTIONS, $2.00 A YEAR. FOREIGN, $3.00 A YEAR. SINGLE COPIES, TWENTY CENTS.

The receipt of a subscription is acknowledged by sending the current issue. Remittances should be made to THE INDUSTRIAL PRESS, and not to the Editors. Money enclosed in letters is at the risk of the sender. Changes of address must reach us by the 15th to take effect on the following month; give old address as well as new. Domestic trade is supplied by the American News Company or its branches.

We solicit communications from practical men on subjects pertaining to railway machine shop practice, for which the necessary illustrations will be made at our expense. All copy must reach us by the 5th of the month preceding publication.
